

ASM HANDBOOK®

VOLUME
17

**Nondestructive
Evaluation and
Quality Control**

Nondestructive Evaluation and Quality Control was published in 1989 as Volume 17 of the 9th Edition *Metals Handbook*. With the second printing (1992), the series title was changed to *ASM Handbook*. The Volume was prepared under the direction of the ASM Handbook Committee.

Foreword

Volume 17 of *Metals Handbook* is a testament to the growing importance and increased sophistication of methods used to nondestructively test and analyze engineered products and assemblies. For only through a thorough understanding of modern techniques for nondestructive evaluation and statistical analysis can product reliability and quality control be achieved and maintained.

As with its 8th Edition predecessor, the aim of this Volume is to provide detailed technical information that will enable readers to select, use, and interpret nondestructive methods. Coverage, however, has been significantly expanded to encompass advances in established techniques as well as introduce the most recent developments in computed tomography, digital image enhancement, acoustic microscopy, and electromagnetic techniques used for stress analysis. In addition, material on quantitative analysis and statistical methods for design and quality control (subjects covered only briefly in the 8th Edition) has been substantially enlarged to reflect the increasing utility of these disciplines.

Publication of Volume 17 also represents a significant milestone in the history of ASM International. This Volume completes the 9th Edition of *Metals Handbook*, the largest single source of information on the technology of metals that has ever been compiled. The magnitude, respect, and success of this unprecedented reference set calls for a special tribute to its many supporters. Over the past 13 years, the ASM Handbook Committee has been tireless in its efforts, ASM members have been unflagging in their support, and the editorial staff devoted and resourceful. Their efforts, combined with the considerable knowledge and technical expertise of literally thousands of authors, contributors, and reviewers,

have resulted in reference books which are comprehensive in coverage and which set the highest standards for quality. To all these men and women, we extend our most sincere appreciation and gratitude.

Richard K. Pitler

President, ASM International

Edward L. Langer

Managing Director, ASM International

Preface

The subject of nondestructive examination and analysis of materials and manufactured parts and assemblies is not new to *Metals Handbook*. In 1976, Volume 11 of the 8th Edition--*Nondestructive Inspection and Quality Control*--provided what was at that time one of the most thorough overviews of this technology ever published. Yet in the relatively short time span since then, tremendous advances and improvements have occurred in the field--so much so that even the terminology has evolved. For example, in the mid-1970s the examination of an object or material that did not render it unfit for use was termed either nondestructive testing (NDT) or nondestructive inspection (NDI). Both are similar in that they involve looking at (or through) an object to determine either a specific characteristic or whether the object contains discontinuities, or flaws.

The refinement of existing methods, the introduction of new methods, and the development of quantitative analysis have led to the emergence of a third term over the past decade, a term representing a more powerful tool. With nondestructive evaluation (NDE), a discontinuity can be classified by its size, shape, type, and location, allowing the investigator to determine whether or not the flaw is acceptable. The title of the present 9th Edition volume was modified to reflect this new technology.

Volume 17 is divided into five major sections. The first contains four articles that describe equipment and techniques used for qualitative part inspection. Methods for both defect recognition (visual inspection and machine vision systems) and dimensional measurements (laser inspection and coordinate measuring machines) are described.

In the second section, 24 articles describe the principles of a wide variety of nondestructive techniques and their application to quality evaluation of metallic, composite, and electronic components. In addition to detailed coverage of more commonly used methods (such as magnetic particle inspection, radiographic inspection, and ultrasonic inspection), newly developed methods (such as computed tomography, acoustic microscopy, and speckle metrology) are introduced. The latest developments in digital image enhancement are also reviewed. Finally, a special six-page color section illustrates the utility of color-enhanced images.

The third section discusses the application of nondestructive methods to specific product types, such as one-piece products (castings, forgings, and powder metallurgy parts) and assemblies that have been welded, soldered, or joined with adhesives. Of particular interest is a series of reference radiographs presented in the article "Weldments, Brazed Assemblies, and Soldered Joints" that show a wide variety of weld discontinuities and how they appear as radiographic images.

The reliability of discontinuity detection by nondestructive methods, referred to as quantitative NDE, is the subject of the fourth section. Following an introduction to this rapidly maturing discipline, four articles present specific guidelines to help the investigator determine the critical discontinuity size that will cause failure, how long a structure containing a discontinuity can be operated safely in service, how a structure can be designed to prevent catastrophic failure, and what inspections must be performed in order to prevent failure.

The final section provides an extensive review of the statistical methods being used increasingly for design and quality control of manufactured products. The concepts of statistical process control, control charts, and design of experiments are presented in sufficient detail to enable the reader to appreciate the importance of statistical analysis and to organize and put into operation a system for ensuring that quality objectives are met on a consistent basis.

This Volume represents the collective efforts of nearly 200 experts who served as authors, contributors of case histories, or reviewers. To all we extend our heartfelt thanks. We would also like to acknowledge the special efforts of Thomas D.

Cooper (Wright Research & Development Center, Wright-Patterson Air Force Base) and Vicki E. Panhuise (Allied-Signal Aerospace Company, Garrett Engine Division). Mr. Cooper, a former Chairman of the ASM Handbook Committee, was instrumental in the decision to significantly expand the material on quantitative analysis. Dr. Panhuise organized the content and recruited all authors for the section "Quantitative Nondestructive Evaluation." Such foresight and commitment from Handbook contributors over the years has helped make the 9th Edition of *Metals Handbook*--all 17 volumes and 15,000 pages--the most authoritative reference work on metals ever published.

The Editors

General Information

Officers and Trustees of ASM International

Officers

- **Richard K. Pitler** President and Trustee Allegheny Ludlum Corporation (retired)
- **Klaus M. Zwilsky** Vice President and Trustee National Materials Advisory Board National Academy of Sciences

Previous Chairmen of the ASM Handbook Committee

- **R.S. Archer** (1940-1942) (Member, 1937-1942)
- **L.B. Case** (1931-1933) (Member, 1927-1933)
- **T.D. Cooper** (1984-1986) (Member, 1981-1986)
- **E.O. Dixon** (1952-1954) (Member, 1947-1955)
- **R.L. Dowdell** (1938-1939) (Member, 1935-1939)
- **J.P. Gill** (1937) (Member, 1934-1937)
- **J.D. Graham** (1966-1968) (Member, 1961-1970)
- **J.F. Harper** (1923-1926) (Member, 1923-1926)
- **C.H. Herty, Jr.** (1934-1936) (Member, 1930-1936)
- **J.B. Johnson** (1948-1951) (Member, 1944-1951)
- **L.J. Korb** (1983) (Member, 1978-1983)
- **R.W.E. Leiter** (1962-1963) (Member, 1955-1958, 1960-1964)
- **G.V. Luerssen** (1943-1947) (Member, 1942-1947)
- **G.N. Maniar** (1979-1980) (Member, 1974-1980)
- **J.L. McCall** (1982) (Member, 1977-1982)
- **W.J. Merten** (1927-1930) (Member, 1923-1933)
- **N.E. Promisel** (1955-1961) (Member, 1954-1963)
- **G.J. Shubat** (1973-1975) (Member, 1966-1975)
- **W.A. Stadler** (1969-1972) (Member, 1962-1972)
- **R. Ward** (1976-1978) (Member, 1972-1978)
- **M.G.H. Wells** (1981) (Member, 1976-1981)
- **D.J. Wright** (1964-1965) (Member, 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Joseph R. Davis, Manager of Handbook Development; Kathleen M. Mills, Manager of Book Production; Steven R. Lampman, Technical Editor; Theodore B. Zorc, Technical Editor; Heather J. Frissell, Editorial Supervisor; George M. Crankovic, Editorial Coordinator; Alice W. Ronke, Assistant Editor; Jeanne Patitsas, Word Processing Specialist; and Karen Lynn O'Keefe, Word Processing Specialist. Editorial assistance was provided by Lois A. Abel, Wendy L. Jackson, Robert T. Kiepora, Penelope Thomas, and Nikki D. Wheaton. The Volume was prepared under the direction of Robert L. Stedfeld, Director of Reference Publications.

Conversion to Electronic Files

ASM Handbook, Volume 17, *Nondestructive Evaluation and Quality Control* was converted to electronic files in 1998. The conversion was based on the fifth printing (1997). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Marlene Seuffert, Gayle Kalman, Scott Henry, Robert Braddock, Alexandra Hoskins, and Erika Baxter. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Third printing, May 1994

Fourth printing, January 1996

Fifth printing, December 1997

ASM Handbook is a collective effort involving thousands of technical specialists. It brings together in one book a wealth of information from world-wide sources to help scientists, engineers, and technicians solve current and long-range problems.

Great care is taken in the compilation and production of this Volume, but it should be made clear that no warranties, express or implied, are given in connection with the accuracy or completeness of this publication, and no responsibility can be taken for any claims that may arise.

Nothing contained in the ASM Handbook shall be construed as a grant of any right of manufacture, sale, use, or reproduction, in connection with any method, process, apparatus, product, composition, or system, whether or not covered by letters patent, copyright, or trademark, and nothing contained in the ASM Handbook shall be construed as a defense against any alleged infringement of letters patent, copyright, or trademark, or as a defense against any liability for such infringement.

Comments, criticisms, and suggestions are invited, and should be forwarded to ASM International.

Introduction

VISUAL INSPECTION is a nondestructive testing technique that provides a means of detecting and examining a variety of surface flaws, such as corrosion, contamination, surface finish, and surface discontinuities on joints (for example, welds, seals, solder connections, and adhesive bonds). Visual inspection is also the most widely used method for detecting and examining surface cracks, which are particularly important because of their relationship to structural failure mechanisms. Even when other nondestructive techniques are used to detect surface cracks, visual inspection often provides a useful supplement. For example, when the eddy current examination of process tubing is performed, visual inspection is often performed to verify and more closely examine the surface disturbance.

Given the wide variety of surface flaws that may be detectable by visual examination, the use of visual inspection may encompass different techniques, depending on the product and the type of surface flaw being monitored. This article focuses on some equipment used to aid the process of visual inspection. The techniques and applicability of visual inspection for some products are considered in the Selected References in this article and in the Section "Nondestructive Inspection of Specific Products" in this Volume.

The methods of visual inspection involve a wide variety of equipment, ranging from examination with the naked eye to the use of interference microscopes for measuring the depth of scratches in the finish of finely polished or lapped surfaces. Some of the equipment used to aid visual inspection includes:

- Flexible or rigid borescopes for illuminating and observing internal, closed or otherwise inaccessible areas
- Image sensors for remote sensing or for the development of permanent visual records in the form of photographs, videotapes, or computer-enhanced images
- Magnifying systems for evaluating surface finish, surface shapes (profile and contour gaging), and surface microstructures
- Dye and fluorescent penetrants and magnetic particles for enhancing the observation of surface cracks (and sometimes near-surface conditions in the case of magnetic particle inspection)

This article will review the use of the equipment listed above in visual inspection, except for dye penetrants and magnetic particles, which are discussed in the articles "Liquid Penetrant Inspection" and "Magnetic Particle Inspection," respectively, in this Volume.

Acknowledgements

ASM International would like to thank Oliver Darling and Morley Melden of Spectrum Marketing, Inc., for their assistance in preparing the section on borescopes. They provided a draft of a textbook being developed for Olympus Corporation. Thanks are also extended to Virginia Torrey of Welch Allyn, Inc., for the information on videoscopes and to Peter Sigmund of Lindhult and Jones, Inc., for the information on instruments from Lenox, Inc.

Visual Inspection

Borescopes

A borescope (Fig. 1) is a long, tubular optical device that illuminates and allows the inspection of surfaces inside narrow tubes or difficult-to-reach chambers. The tube, which can be rigid or flexible with a wide variety of lengths and diameters, provides the necessary optical connection between the viewing end and an objective lens at the distant, or distal, tip of the borescope. This optical connection can be achieved in one of three different ways:

- By using a rigid tube with a series of relay lenses
- By using a tube (normally flexible but also rigid) with a bundle of optical fibers
- By using a tube (normally flexible) with wiring that carries the image signal from a charge-coupled device (CCD) imaging sensor at the distal tip

These three basic tube designs can have either fixed or adjustable focusing of the objective lens at the distal tip. The distal tip also has prisms and mirrors that define the direction and field of view (see Fig. 2). These views vary according to the type and application of borescope. The design of illumination system also varies with the type of borescope. Generally, a fiber optic light guide and a lamp producing white light is used in the illumination system, although ultraviolet light can be used to inspect surfaces treated with liquid fluorescent penetrants. Light-emitting diodes at the distal tip are sometimes used for illumination in videoscopes with working lengths greater than 15 m (50 ft).

(a)

(b)

(c)

Fig. 1 Three typical designs of borescopes. (a) A rigid borescope with a lamp at the distal end. (b) A flexible fiberscope with a light source. (c) A rigid borescope with a light guide bundle in the shaft

Rigid Borescopes

Rigid borescopes are generally limited to applications with a straight-line path between the observer and the area to be observed. The sizes range in lengths from 0.15 to 30 m (0.5 to 100 ft) and in diameters from 0.9 to 70 mm (0.035 to 2.75 in.). Magnification is usually 3 to 4 \times , but powers up to 50 \times are available. The illumination system is either an incandescent lamp located at the distal tip end (Fig. 1a) or a light guide bundle made from optical fibers (Fig. 1c) that conduct light from an external source.

The choice of viewing heads for rigid borescopes (Fig. 2) varies according to the application, as described in the section "Selection" in this article. Rigid borescopes generally have a 55° field of view, although the fields of view can range from 10 to 90°. Typically, the distal tips are not interchangeable, but some models (such as the extendable borescopes) may have interchangeable viewing heads.

Some rigid borescopes have orbital scan (Fig. 1c), which involves the rotation of the optical shaft for scanning

Fig. 2 Typical directions and field of view with rigid borescopes

purposes. Depending on the borescope model, the amount of rotation can vary from 120 to 370°. Some rigid borescopes also have movable prisms at the tip for scanning.

Rigid borescopes are available in a variety of models having significant variations in the design of the shaft, the distal tip, and the illumination system. Some of these design variations are described below.

Basic Design. The rigid borescope typically has a series of achromatic relay lenses in the optical tube. These lenses preserve the resolution of the image as it travels from the objective lens to the eyepiece. The tube diameter of these borescopes ranges from 4 to 70 mm (0.16 to 2.75 in.). The illumination system can be either a distal lamp or a light guide bundle, and the various features may include orbital scan, various viewing heads, and adjustable focusing of the objective lens.

Miniboreoscopes. Instead of the conventional relay lenses, miniboreoscopes have a single image-relaying rod or quartz fiber in the optical tube. The lengths of miniboreoscopes are 110 and 170 mm (4.3 and 6.7 in.), and the diameters range from 0.9 to 2.7 mm (0.035 to 0.105 in.). High magnification (up to 30 \times) can be reached at minimal focal lengths, and an adjustable focus is not required, because the scope has an infinite depth of field. The larger sizes have forward, side view, and forward-oblique views. The 0.9 mm (0.035 in.) diam size has only a forward view. Miniboreoscopes have an integral light guide bundle.

Hybrid boreoscopes utilize rod lenses combined with convex lenses to relay the image. The rod lenses have fewer glass-air boundaries; this reduces scattering and allows for a more compact optical guide. Consequently, a larger light guide bundle can be employed with an increase in illumination and an image with a higher degree of contrast.

Hybrid boreoscopes have lengths up to 990 mm (39 in.), with diameters ranging from 5.5 to 12 mm (0.216 to 0.47 in.). All hybrid boreoscopes have adjustable focusing of the objective lens and a 370° rotation for orbital scan. The various viewing directions are forward, side, retrospective, and forward-oblique.

Extendable boreoscopes allow the user to construct a longer boreoscopic tube by joining extension tubes. Extendable boreoscopes are available with either a fiber-optic light guide or an incandescent lamp at the distal end. Extendable boreoscopes with an integral lamp have a maximum length of about 30 m (100 ft). Scopes with a light guide bundle have a shorter maximum length (about 8 m, or 26 ft), but do allow smaller tube diameters (as small as 8 mm, or 0.3 in.). Interchangeable viewing heads are also available. Extendable boreoscopes do not have adjustable focusing of the objective lens.

Rigid chamberscopes allow more rapid inspection of larger chambers. Chamberscopes (Fig. 3) have variable magnification (zoom), a lamp at the distal tip, and a scanning mirror that allows the user to observe in different directions. The higher illumination and greater magnification of chamberscopes allow the inspection of surfaces as much as 910 mm (36 in.) away from the distal tip of the scope.

Fig. 3 Typical chamberscope. Courtesy of Lenox Instrument Company

Mirror sheaths can convert a direct-viewing borescope into a side-viewing scope. A mirror sheath is designed to fit over the tip of the scope and thus reflect an image from the side of the scope. However, not all applications are suitable for this device. A side, forward-oblique, or retrospective viewing head provides better resolution and a higher degree of image contrast. A mirror sheath also produces an inverse image and may produce unwanted reflections from the shaft.

Scanning. In addition to the orbital scan feature described earlier, some rigid borescopes have the ability to scan longitudinally along the axis of the shaft. A movable prism with a control at the handle accomplishes this scanning. Typically, the prism can shift the direction of view through an arc of 120°.

Flexible Borescopes

Flexible borescopes are used primarily in applications that do not have a straight passageway to the point of observation. The two types of flexible borescopes are flexible fiberscopes and videoscopes with a CCD image sensor at the distal tip.

Flexible Fiberscopes. A typical fiberscope (Fig. 1b) consists of a light guide bundle, an image guide bundle, an objective lens, interchangeable viewing heads, and remote controls for articulation of the distal tip. Fiberscopes are available in diameters from 1.4 to 13 mm (0.055 to 0.5 in.) and in lengths up to 12 m (40 ft). Special quartz fiberscopes are available in lengths up to 90 m (300 ft).

The fibers used in the light guide bundle are generally 30 μm (0.001 in.) in diameter. The second optical bundle, called the image guide, is used to carry the image formed by the objective lens back to the eyepiece. The fibers in the image guide must be precisely aligned so that they are in an identical relative position to each other at their terminations for proper image resolution.

The diameter of the fibers in the image guide is another factor in obtaining good image resolution. With smaller diameter fibers, a brighter image with better resolution can be obtained by packing more fibers in the image guide. With higher resolution, it is then possible to use an objective lens with a wider field of view and also to magnify the image at the eyepiece. This allows better viewing of objects at the periphery of the image (Fig. 4). Image guide fibers range from 6.5 to 17 μm (255 to 670 $\mu\text{in.}$).

Fig. 4 Two views down a combustor can with the distal tip in the same position. A fiberscope with smaller diameter fibers and 40% more fibers in the image bundle provides better resolution (a) than a fiberscope with larger fibers (b). Courtesy of Olympus Corporation

The interchangeable distal tips provide various directions and fields of view on a single fiberscope. However, because the tip can be articulated for scanning purposes, distal tips with either a forward or side viewing direction are usually sufficient. Fields of view are typically 40 to 60°, although they can range from 10 to 120°. Most fiberscopes provide adjustable focusing of the objective lens.

Videoscopes with CCD probes involve the electronic transmission of color or black and white images to a video monitor. The distal end of electronic videoscopes contains a CCD chip, which consists of thousands of light-sensitive elements arrayed in a pattern of rows and columns. The objective lens focuses the image of an object on the surface of the CCD chip, where the light is converted to electrons that are stored in each picture element, or pixel, of the CCD device. The image of the object is thus stored in the form of electrons on the CCD device. At this point, a voltage proportional to the number of electrons at each pixel is determined electronically for each pixel site. This voltage is then amplified, filtered, and sent to the input of a video monitor.

Videoscopes with CCD probes produce images (Fig. 5) with spatial resolutions of the order of those described in Fig. 6. Like rigid borescopes and flexible fiberscopes, the resolution of videoscopes depends on the object-to-lens distance and the fields of view, because these two factors affect the amount of magnification (see the section "Magnification and Field of View" in this article). Generally, videoscopes produce higher resolution than fiberscopes, although fiberscopes with smaller diameter fibers (Fig. 4a) may be competitive with the resolution of videoscopes.

(a)

(b)

Fig. 6 Typical resolution of CCD videoscopes with a 90° field of view (a), 60° field of view (b), 30° field of view (c). Source: Welch Allyn, Inc.

Another advantage of videoscopes is their longer working length. With a given amount of illumination at the distal tip, videoscopes can return an image over a greater length than fiberscopes. Other features of videoscopes include:

- The display can help reduce eye fatigue (but does not allow the capability of direct viewing through an eyepiece)
- There is no honeycomb pattern or irregular picture distortion as with some fiberscopes (Fig. 7)
- The electronic form of the image signal allows digital image enhancement and the potential for integration with automatic inspection systems.
- The display allows the generation of reticles on the viewing screen for point-to-point measurements.

Special Features

Measuring borescopes and fiberscopes contain a movable cursor that allows measurements during viewing (Fig. 8). When the object under measurement is in focus, the movable cursor provides a reference for dimensional measurements in the optical plane of the object. This capability eliminates the need to know the object-to-lens distance when determining magnification factors.

Fig. 8 View through a measuring fiberscope with reticles for 20° and 40° field-of-view lenses. Courtesy of Olympus Corporation

Working channels are used in borescopes and fiberscopes to pass working devices to the distal tip. Working channels are presently used to pass measuring instruments, retrieval devices, and hooks for aiding the insertion of thin, flexible fiberscopes. Working channels are used in flexible fiberscopes with diameters as small as 2.7 mm (0.106 in.). Working channels are also under consideration for the application and removal of dye penetrants and for the passage of wires and sensors in eddy current measurements.

Selection

Flexible and rigid borescopes are available in a wide variety of standard and customized designs, and several factors can influence the selection of a scope for a particular application. These factors include focusing, illumination, magnification, working length, direction of view, and environment.

Focusing and Resolution. If portions of long objects are at different planes, the scope must have sufficient focus adjustment to achieve an adequate depth of field. If the scope has a fixed focal length, the object will be in focus only at a specific lens-to-object distance.

To allow the observation of surface detail at a desired size, the optical system of a borescope must also provide adequate resolution and image contrast. If resolution is adequate but contrast is lacking, detail cannot be observed.

In general, the optical quality of a rigid borescope improves as the size of the lens increases; consequently, a borescope with the largest possible diameter should be used. For fiberscopes, the resolution is dependent on the accuracy of alignment and the diameter of the fibers in the image bundle. Smaller-diameter fibers provide more resolution and edge contrast (Fig. 4), when combined with good geometrical alignment of the fibers. Typical resolutions of videoscopes are given in Fig. 6.

Illumination. The required intensity of the light source is determined by the reflectivity of the surface, the area of surface to be illuminated, and the transmission losses over the length of the scope. At working lengths greater than 6 m (20 ft), rigid borescopes with a lamp at the distal end provide the greatest amount of illumination over the widest area. However, the heat generated by the light source may deform rubber or plastic materials. Fiber-optic illumination in scopes with working lengths less than 6 m (20 ft) is always brighter and is suitable for heat-sensitive applications because filters can remove infrared frequencies. Because the amount of illumination depends on the diameter of the light guide bundle, it is desirable to use the largest diameter possible.

Magnification and field of view are interrelated; as magnification is increased, the field of view is reduced. The precise relationship between magnification and field of view is specified by the manufacturer.

The degree of magnification in a particular application is determined by the field of view and the distance from the objective lens to the object. Specifically, the magnification increases when either the field of view or the lens-to-object distance decreases.

Working Length. In addition to the obvious need for a scope of sufficient length, the working length can sometimes dictate the use of a particular type of scope. For example, a rigid borescope with a long working length may be limited by the need for additional supports. In general, videoscopes allow a longer working length than fiberscopes.

Direction of View. The selection of a viewing direction is influenced by the location of the access port in relation to the object to be observed. The following sections describe some criteria for choosing the direction of view shown in Fig. 2. Flexible fiberscopes or videoscopes, because of their articulating tip, are often adequate with either a side or forward viewing tip.

Circumferential or panoramic heads are designed for the inspection of tubing or other cylindrical structures. A centrally located mirror permits right-angle viewing of an area just scanned by the panoramic view.

The forward viewing head permits the inspection of the area directly ahead of the viewing head. It is commonly used when examining facing walls or the bottoms of blind holes and cavities.

Forward-oblique heads bend the viewing direction at an angle to the borescope axis, permitting the inspection of corners at the end of a bored hole. The retrospective viewing head bends the cone of view at a retrospective angle to the borescope axis, providing a view of the area just passed by the advancing borescope. It is especially suited to inspecting the inside neck of cylinders and bottles.

Environment. Flexible and rigid borescopes can be manufactured to withstand a variety of environments. Although most scopes can operate at temperatures from -34 to 66 °C (-30 to 150 °F), especially designed scopes can be used at temperatures to 1925 °C (3500 °F). Scopes can also be manufactured for use in liquid media.

Special scopes are required for use in pressures above ambient and in atmospheres exposed to radiation. Radiation can cause the multicomponent lenses and image bundles to turn brown. When a scope is used in atmospheres exposed to radiation, quartz fiberscopes are generally used. Scopes used in a gaseous environment should be made explosionproof to minimize the potential of an accidental explosion.

Applications

Rigid and flexible borescopes are available in different designs suitable for a variety of applications. For example, when inspecting straight process piping for leaks rigid borescopes with a 360° radial view are capable of examining inside diameters of 3 to 600 mm (0.118 to 24 in.). Scopes are also used by building inspectors and contractors to see inside walls, ducts, large tanks, or other dark areas.

The principal use of borescope is in equipment maintenance programs, in which borescopes can reduce or eliminate the need for costly teardowns. Some types of equipment, such as turbines, have access ports that are specifically designed for borescopes. Borescopes provide a means of checking in-service defects in a variety of equipment, such as turbines (Fig. 9), automotive components (Fig. 10), and process piping (Fig. 11).

Fig. 11 Operator viewing a weld 21 m (70 ft) inside piping with a videoscope. Courtesy of Olympus Corporation

Borescopes are also extensively used in a variety of manufacturing industries to ensure the product quality of difficult-to-reach components. Manufacturers of hydraulic cylinders, for example, use borescopes to examine the interiors of bores for pitting, scoring, and tool marks. Aircraft and aerospace manufacturers also use borescopes to verify the proper placement and fit of seals, bonds, gaskets, and subassemblies in difficult-to-reach regions.

Visual Inspection

Optical Sensors

Visible light, which can be detected by the human eye or with optical sensors, has some advantages over inspection methods based on nuclear, microwave, or ultrasound radiation. For example, one of the advantages of visible light is the capability of tightly focusing the probing beam on the inspected surface (Ref 1). High spatial resolution can result from this sharp focusing, which is useful in gaging and profiling applications (Ref 1).

Some different types of image sensors used in visual inspection include:

- Vidicon or plumbicon television tubes
- Secondary electron-coupled (SEC) vidicons
- Image orthicons and image isocons

- Charge-coupled device sensors
- Holographic plates (see the article "Optical Holography" in this Volume)

Television cameras with vidicon tubes are useful at higher light levels (about 0.2 lm/m^2 , or 10^{-2} ftc), while orthicons, isocons, and SEC vidicons are useful at lower light levels. The section "Television Cameras" in the article "Radiographic Inspection" in this Volume describes these cameras in more detail.

Charge-coupled devices are suitable for many different information-processing applications, including image sensing in television-camera technology. Charge-coupled devices offer a clear advantage over vacuum-tube image sensors because of the reliability of their solid-state technology, their operation at low voltage and low power dissipation, extensive dynamic range, visible and near-infrared response, and geometric reproducibility of image location. Image enhancement (or visual feedback into robotic systems) typically involve the use of CCDs as the optical sensor or the use of television signals that are converted into digital form.

Optical sensors are also used in inspection applications that do not involve imaging. The articles "Laser Inspection" and "Speckle Metrology" in this Volume describe the use of optical sensors when laser light is the probing tool. In some applications, however, incoherent light sources are very effective in non-imaging inspection applications utilizing optical sensors.

Example 1: Monitoring Surface Roughness on a Fast-Moving Cable.

A shadow projection configuration that can be used at high extrusion speeds is shown in Fig. 12. A linear-filament lamp is imaged by two spherical lenses of focal length f_1 on a large-area single detector. Two cylindrical lenses are used to project and recollimate a laminar light beam of uniform intensity, nearly 0.5 mm (0.02 in.) wide across the wire situated near their common focal plane. The portion of the light beam that is not intercepted by the wire is collected on the detector, which has an alternating current output that corresponds to the defect-related wire diameter fluctuations. The wire speed is limited only by the detector response time. With a moderate detector bandwidth of 100 kHz, wire extrusion speeds up to 50 m/s (160 ft/s) can be accepted. Moreover, the uniformity of the nearly collimated projected beam obtained with such a configuration makes the detected signal relatively independent of the random wire excursions in the plane of Fig. 12. It should be mentioned that the adoption of either a single He-Ne laser or an array of fiber-pigtailed diode lasers proved to be inadequate in this case because of speckle noise, high-frequency laser amplitude or mode-to-mode interference fluctuations, and line nonuniformity.

Fig. 12 Schematic of line projection method for monitoring the surface roughness on fast-moving cables

An industrial prototype of such a sensor was tested on the production line at extruding speeds reaching 30 m/s (100 ft/s). Figure 13 shows the location of the sensor just after the extruder die. Random noise introduced by vapor turbulence could be almost completely suppressed by high-pass filtering. Figure 14 shows two examples of signals obtained with a wire of acceptable and unacceptable surface quality. As shown, a roughness amplitude resolution of a few micrometers can be

obtained with such a device. Subcritical surface roughness levels can thus be monitored for real time control of the extrusion process.

Visual Inspection

Magnifying Systems

In addition to the use of microscopes in the metallographic examination of microstructures (see the article "Replication Microscopy Techniques for NDE" in this Volume), magnifying systems are also used in visual reference gaging. When tolerances are too tight to judge by eye alone, optical comparators or toolmakers' microscopes are used to achieve magnifications ranging from 5 to 500 \times .

A **toolmakers' microscope** consists of a microscope mounted on a base that carries an adjustable stage, a stage transport mechanism, and supplementary lighting. Micrometer barrels are often incorporated into the stage transport mechanism to permit precisely controlled movements, and digital readouts of stage positioning are becoming increasingly available. Various objective lenses provide magnifications ranging from 10 to 200 \times .

Optical comparators (Fig. 15) are magnifying devices that project the silhouette of small parts onto a large projection screen. The magnified silhouette is then compared against an optical comparator chart, which is a magnified outline drawing of the workpiece being gaged. Optical comparators are available with magnifications ranging from 5 to 500 \times .

Fig. 15 Schematic of an optical comparator

Parts with recessed contours can also be successfully gaged on optical comparators. This is done with the use of a pantograph. One arm of the pantograph is a stylus that traces the recessed contour of the part, and the other arm carries a follower that is visible in the light path. As the stylus moves, the follower projects a contour on the screen.

Laser Inspection

Carl Bixby, Zygo Corporation

Introduction

THE FIRST LASER was invented in 1960, and many useful applications of laser light have since been developed for metrology and industrial inspection systems. Laser-based inspection systems have proved useful because they represent a fast, accurate means of noncontact gaging, sorting, and classifying parts. Lasers have also made interferometers a more convenient tool for the accurate measurement of length, displacement, and alignment.

Lasers are used in inspection and measuring systems because laser light provides a bright, unidirectional, and collimated beam of light with a high degree of temporal (frequency) and spatial coherence. These properties can be useful either singly or together. For example, when lasers are used in interferometry, the brightness, coherence, and collimation of laser light are all important. However, in the scanning, sorting, and triangulation applications described in this article, lasers are used because of the brightness, unidirectionality, and collimated qualities of their light; temporal coherence is not a factor.

The various types of laser-based measurement systems have applications in three main areas:

- Dimensional measurement

- Velocity measurement
- Surface inspection

The use of lasers may be desirable when these applications require high precision, accuracy, or the ability to provide rapid, noncontact gaging of soft, delicate, hot, or moving parts. Photodetectors are generally needed in all the applications, and the light variations or interruptions can be directly converted into electronic form.

Laser Inspection

Carl Bixby, Zygo Corporation

Dimensional Measurements

Lasers can be used in several different ways to measure the dimensions and the position of parts. Some of the techniques include:

- Profile gaging of stationary and moving parts with laser scanning equipment
- Profile gaging of stationary parts by shadow projection on photodiode arrays
- Profile gaging of small gaps, and small-diameter parts from diffraction patterns
- Gaging of surfaces that cannot be seen in profile (such as concave surfaces, gear teeth, or the inside diameters of bores) with laser triangulation sensors
- Measuring length, alignments, and displacements with interferometers
- Sorting of parts
- Three-dimensional gaging of surfaces with holograms
- Measuring length from the velocity of moving, continuous parts (see the section "Velocity Measurements" in this article)

These techniques provide high degrees of precision and accuracy as well as the capability for rapid, noncontact measurement.

Scanning Laser Gage. Noncontact sensors are used in a variety of inspection techniques, such as those involving capacitive gages, eddy-current gages, and air gages. Optical gages, however, have advantages because the distance from the sensor to the workpiece can be large and because many objects can be measured simultaneously. Moreover, the light variations are directly converted into electronic signals, with the response time being limited only by the photodetector and its electronics.

Optical sensors for dimensional gaging employ various techniques, such as shadow projection, diffraction phenomena, and scanning light beams. If the workpiece is small or does not exhibit large or erratic movements, diffraction phenomena or shadow projection on a diode array sensor can work well. However, diffraction techniques become impractical if the object has a dimension of more than a few millimeters or if its movement is large. Shadow projection on a diode array sensor may also be limited if the size or movement of the part is too large.

The scanning laser beam technique, on the other hand, is suited to a broad range of product sizes and movements. The concept of using a scanning light beam for noncontact dimensional gaging predates the laser; the highly directional and collimated nature of laser light, however, greatly improves the precision of this method over techniques that use ordinary light. The sensing of outside diameters of cylindrical parts is probably the most common application of a laser scanning gage.

A scanning laser beam gage consists of a transmitter, a receiver, and processor electronics (Fig. 1). A thin band of scanning laser light is projected from the transmitter to the receiver. When an object is placed in a beam, it casts a time-dependent shadow. Signals from the light entering the receiver are used by the microprocessor to extract the dimension represented by the time difference between the shadow edges. The gages can exhibit accuracies as high as $\pm 0.25 \mu\text{m}$ (± 10

μin.) for diameters of 10 to 50 mm (0.5 to 2 in.) For larger parts (diameters of 200 to 450 mm, or 8 to 18 in.), accuracies are less.

Fig. 1 Schematic of a scanning laser gage

There are two general types of scanning laser gages: separable transmitters and receivers designed for in-process applications, and self-contained bench gages designed for off-line applications. The in-process scanning gage consists of a multitasking electronic processor that controls a number of scanners. The separable transmitters and receivers can be configured for different scanning arrangements. Two or more scanners can also be stacked for large parts, or they can be oriented along different axes for dual-axis inspection. High-speed scanners are also available for the detection of small defects, such as lumps, in moving-part applications.

The bench gage is compact and can measure a variety of part sizes quickly and easily (Fig. 2). As soon as measurements are taken, the digital readout displays the gaged dimension and statistical data. It indicates the total number of measurements taken, the standard deviation, and the maximum, minimum, and mean readings of each batch tested.

Fig. 2 Self-contained laser bench micrometer

Applications. A wide variety of scanning laser gages are available to fit specific applications. Measurement capabilities fall within a range of 0.05 to 450 mm (0.002 to 18 in.), with a repeatability of $0.1\ \mu\text{m}$ ($5\ \mu\text{in.}$) for the smaller diameters. Typical applications include centerless grinding, precision machining, extrusions, razor blades, turbine blades, computer disks, wire lines, and plug gages.

Photodiode Array Imaging. Profile imaging closely duplicates a shadowgraph or contour projector where the ground-glass screen has been replaced by a solid-state diode array image sensor. The measurement system consists of a laser light source, imaging optics, a photodiode array, and signal-processing electronics (Fig. 3). The object casts a shadow, or profile image, of the part on the photodiode array. A scan of the array determines the edge image location and then the location of the part edges from which the dimension of the part can be determined.

Fig. 3 Schematic of profile imaging. The laser beam passing the edge of a cylindrical part is imaged by a lens onto a photodiode array. A scan of the array determines the edge image location and then the location of the part edges from which the dimension of the part can be determined.

Accuracies of $\pm 0.05\ \mu\text{m}$ ($\pm 2\ \mu\text{in.}$) have been achieved with photodiode arrays. For large-diameter parts, two arrays are used—one for each edge. When large or erratic movement of the part is involved, photodiode arrays are not suitable. However, when part rotation is involved, stroboscopic illumination can freeze the image of the part.

Diffraction Pattern Technique. Diffraction pattern metrology systems can be used on-line and off-line to measure small gaps and small diameters of thin wire, needles, and fiber optics. They can also be used to inspect such defects as burrs of hypodermic needles and threads on bolts.

In a typical system, the parallel coherent light in a laser beam is diffracted by a small part, and the resultant pattern is focused by a lens on a linear diode array. One significant characteristic of the diffraction pattern is that the smaller the part is, the more accurate the measurement becomes. Diffraction is not suitable for diameters larger than a few millimeters.

The distance between the alternating light and dark bands in the diffraction pattern bears a precise mathematical relationship to the wire diameter, the wavelength of the laser beam, and the focal length of the lens. Because the laser

beam wavelength and the lens focal length are known constants of the system, the diameter can be calculated directly from the diffraction pattern measurement.

Laser triangulation sensors determine the standoff distance between a surface and a microprocessor-based sensor. Laser triangulation sensors can perform automatic calculations on sheet metal stampings for gap and flushness, hole diameters, and edge locations in a fraction of the time required in the past with manual or ring gage methods.

The principle of single-spot laser triangulation is illustrated in Fig. 4. In this technique, a finely focused laser spot of light is directed at the part surface. As the light strikes the surface, a lens in the sensor images this bright spot onto a solid-state, position-sensitive photodetector. As shown in Fig. 4, the location of the image spot is directly related to the standoff distance from the sensor to the object surface; a change in the standoff distance results in a lateral shift of the spot along the sensor array. The standoff distance is calculated by the sensor processor.

Fig. 4 Schematic of laser triangulation method of measurement. As light strikes the surface, a lens images the point of illumination onto a photosensor. Variations in the surface cause the image dot to move laterally along the photosensor.

Laser triangulation sensors provide quick measurement of deviations due to changes in the surface. With two sensors, the method can be used to measure part thickness or the inside diameters of bores. However, it may not be possible to probe the entire length of the bore. Laser triangulation sensors can also be used as a replacement for touch-trigger probes on coordinate measuring machines. In this application, the sensor determines surface features and surface locations by utilizing an edge-finding device.

The accuracy of laser triangulation sensors varies, depending on such performance requirements as standoff and range. Typically, as range requirements increase, accuracy tends to decrease; therefore, specialized multiple-sensor units are designed to perform within various specific application tolerances.

Interferometers provide precise and accurate measurement of relative and absolute length by utilizing the wave properties of light. They are employed in precision metal finishing, microlithography, and the precision alignment of parts.

The basic operational principles of an interferometer are illustrated in Fig. 5. Monochromatic light is directed at a half-silvered mirror acting as a beam splitter that transmits half the beam to a movable mirror and reflects the other half 90° to a fixed mirror. The reflections from the movable and fixed mirrors are recombined at the beam splitter, where wave interference occurs according to the different path lengths of the two beams.

Fig. 5 Schematic of a basic interferometer

When one of the mirrors is displaced very slowly in a direction parallel to the incident beam without changing its angular alignment, the observer will see the intensity of the recombined beams increasing and decreasing as the light waves from the two paths undergo constructive and destructive interference. The cycle of intensity change from one dark fringe to another represents a half wavelength displacement of movable mirror travel, because the path of light corresponds to two times the displacement of the movable mirror. If the wavelength of the light is known, the displacement of the movable mirror can be determined by counting fringes.

Variations on the basic concepts described above produce interferometers in different forms suited to diverse applications. The two-frequency laser interferometer, for example, provides accurate measurement of displacements (see the following section in this article). Multiple-beam interferometers, such as the Fizeau interferometer, also have useful applications. The Fizeau interferometer has its greatest application in microtopography and is used with a microscope to provide high resolution in three dimensions (see the section "Interference Microscopes" in this article).

Displacement and Alignment Measurements. Laser interferometers provide a high-accuracy length standard (better than 0.5 ppm) when measuring linear positioning, straightness in two planes, pitch, and yaw. The most accurate systems consists of a two-frequency laser head, beam directing and splitting optics, measurement optics, receivers, wavelength compensators, and electronics (Fig. 6).

Fig. 6 Components of a laser interferometer. The components include a laser head, beam directing and measuring optics, receivers, electronic couplers, and a computer system.

The most important element in the system is a two-frequency laser head that produces one frequency with a P polarization and another frequency with an S polarization. The beam is projected from the laser head to a remote interferometer, where the beam is split at the polarizing beam splitter into its two separate frequencies. The frequency with the P polarization becomes the measurement beam, and the frequency with the S polarization becomes the reference beam (Fig. 7).

Fig. 7 Schematic of a two-frequency laser interferometer

The measurement beam is directed through the interferometer to reflect off a moving optical element, which may be a target mirror or retroreflector attached to the item being measured. The reference beam is reflected from a stationary optical element, which is usually a retroreflector. The measurement beam then returns to the interferometer, where it is recombined with the reference beam and directed to the receiver.

Whenever the measurement target mirror or retroreflector moves, the accompanying Doppler effect induces a frequency shift in the returning beam. Because of their orthogonal polarization, the frequencies do not interfere to form fringes until the beam reaches the receiver. Consequently, the receiver can monitor the frequency shift associated with the Doppler effect, which is compared to the reference frequency to yield precise measurement of displacement.

The principal advantage of the two-frequency system is that the distance information is sensed in terms of frequency. Because a change in frequency is used as the basis for measuring displacement, a change in beam intensity cannot be interpreted as motion. This provides greater measurement stability and far less sensitivity to noise (air turbulence, electrical noise, and light noise). Because motion detection information is embedded in the frequency of the measurement signal, only one photodetector per measurement axis is required; this decreases the sensitivity of optical alignment. Another advantage of the two-frequency interferometer is that the laser head need not be mounted on the machine or instrument being tested.

Typical applications include the calibration of length-measuring standards such as glass scales and the characterization of positional, angular, and straightness errors in precision equipment, such as machine tools, coordinate measuring machines, and X-Y stages. The linear resolution of a two-frequency displacement interferometer is 1 nm (0.05 $\mu\text{in.}$), the angular resolution is 0.03 arc seconds, and the straightness resolution is 40 nm (1.6 $\mu\text{in.}$).

The laser interferometric micrometer uses interferometric technology and a laser beam to perform absolute length measurements to a resolution of 0.01 μm (0.4 $\mu\text{in.}$) with an accuracy of $\pm 0.08 \text{ mm}$ ($\pm 0.003 \text{ in.}$). A contact probe interfaces with an internal interferometer that measures changes in distance (Fig. 8). The part to be measured is placed under the probe, and the interference effects are electronically analyzed and displayed in terms of the distance from the probe to the datum (Fig. 8).

Fig. 8 Schematic of a laser interferometric micrometer

Based on user-entered information, the system can automatically compensate for room temperature, humidity, atmospheric pressure, the temperature of the part, and the thermal expansion of the probe. The instrument performs gage comparison, maximum and minimum surface deviation, and total indicator reading measurements. Simple statistical functions include mean and one standard deviation reporting. Actual measurement readings can be compared to user-entered tolerance limits for automatic "go, no-go" testing.

Sorting. Parts can be sorted by dimension, prior to automatic assembly, with an in-process inspection system. A laser beam sorting system can provide accept-or-reject measurements of length, height, diameter, width, thread presence, and count. Each production run of a different part requires a simple setup to accommodate the part to be measured.

In operation, a collimated laser beam is optically processed, focused, and directed onto the part. A photodetector converts the light signals to electrical signals for processing. For length inspection, the laser beam is split into three beams. The center beam is stationary and acts as a reference beam. Both of the other two beams are adjusted independently by micrometer dials to define the distance between an over- or undersize

measurement. The parts can then be gravity fed past the laser quantification system for accept-or-reject measurement. In many applications, parts can be inspected at a rate of 100 to 700 parts per minute. A typical application for a laser-based sorting system is the in-process, accept-or-reject measurement of bolts, nuts, rivets, bearings, tubes, rollers, and stampings.

Holography is an important measurement technique in the three-dimensional contouring of large spatial areas. Holography can determine small deviations (as small as 0.1 μm , or 4 $\mu\text{in.}$) in surface shape over large areas for all types of surface microstructure. This is accomplished by illuminating both the object and the hologram of its original or desired

shape with the original reference wave (see the article "Optical Holography" in this Volume). If the object deviates from its original or desired shape, interference fringes will appear during illumination with the reference wave.

The exactness of the holographic image makes it invaluable for detecting faults in such diverse items as automobile clutch plates, brake drums, gas pipelines, and high-pressure tanks. The holographic image also depicts the vibration pattern of mechanical components and structures such as turbine blades.

Laser Inspection

Velocity Measurements

Velocity measurements from the Doppler effect on laser light have become a useful tool for measuring gas, liquid, and solid-surface velocities. Many systems are intended for laboratory applications. However, instruments have also been introduced for industrial process control. One application is in the primary metals industries and consists of measuring length in a unidirectional flow process.

The laser Doppler velocity gage is a non-contact instrument that uses laser beams and microprocessors to measure the speed and length of a moving surface. It can measure almost any type of continuously produced material without coming into contact with it, whether it is hot, cold, soft, or delicate. It outputs various types of measurements, such as current speed, average speed, current lengths, and total length.

The instrument consists of a sensor, the controller, and a computer. The sensor emits two laser beams that converge on the surface of the product being measured. The light reflected from the product surface exhibits Doppler shifts because of the movement. The frequency of the beam pointing toward the source of the product is shifted up, and the beam pointing toward the destination is shifted down. The processor measures the frequency shift and uses this information to calculate the speed and length of the product.

Laser Inspection

Carl Bixby, Zygo Corporation

Surface Inspection

Surface inspection includes the in-process detection of surface flaws and the measurement of surface defects and roughness. Lasers are used in both of these functions.

One technique of in-process flaw detection is illustrated in Fig. 9. A rotating polygonal mirror scans the laser light across the moving sheet, and a stationary photo-multiplier detects the scattered light. If there is a defect on the surface, the intensity of the scattered light increases; if the defect is a crack, the intensity decreases. Similar arrangements can estimate surface roughness by analyzing the envelope of scattered light.

Fig. 9 System for the high-speed scanning of steel sheets for surface defects. In one system, the scanner acquired 10^4 data points per millisecond on a 3 mm^2 (0.005 in.^2) sheet.

Interference microscopes are used to measure the microtopography of surfaces. The interference microscope divides the light from a single point source into two or more waves. In multiple-beam interference microscopes, this is done by placing a partially transmitting and partially reflecting reference mirror near the surface of the specimen (Fig. 10).

The multiple beams illustrated in Fig. 10 are superimposed after traveling different lengths. This produces interference patterns, which are magnified by the microscope. The interference fringes having a perfectly flat surface appear as straight, parallel lines of equal width and spacing. Height variations cause the fringes to appear curved or jagged, depending on the unit used. With multiple-beam interferometers, height differences as small as $\lambda/200$ can be measured, where λ is the wavelength of the light source.

Fig. 10 General principle of a multiple-beam interferometer

Lasers can provide a monochromatic light source, which is required in interference microscopes. One such system is shown in Fig. 11. This system involves

the use of photodetectors with displays of isometric plots, contour plots, and up to five qualitative parameters, such as surface roughness, camber, crown, radius of curvature, cylindrical sag, and spherical sag.

Fig. 11 Laser interference microscope with displays. Fizeau and Mirau interferometers are mounted in the turret.

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

Introduction

THE COORDINATE MEASURING MACHINE (CMM) fulfills current demands on manufacturing facilities to provide extremely accurate as well as flexible three-dimensional inspection of both in-process and finished parts on the assembly line. Manufacturers are under tremendous financial pressure to increase production and to minimize waste. Part tolerances once quoted in fractional figures are now quoted in thousandths of a millimeter, and manufacturers are under ever-increasing pressure to meet ever more demanding specifications on a regular basis.

The CMM, which first appeared some 25 years ago, has developed rapidly in recent years as the state-of-the-art measuring tool available to manufacturers. The capabilities, accuracy, and versatility of the CMM, as well as the roles it will play in manufacturing, continue to increase and evolve almost daily.

Coordinate measuring machines are an object of intense interest and aggressive development because they offer potentially viable solutions to a number of challenges facing manufacturers:

- The need to integrate quality management more closely into the manufacturing process
- The need to improve productivity and to reduce waste by eliminating the manufacture of out-of-tolerance parts faster
- The realization that the measurement process itself needs to be monitored and verified
- The objective to eliminate fixtures and fixed gages (and their inherent rebuild costs due to evolving products), thus providing increased gaging flexibility
- The potential to incorporate existing technology into new and more efficient hybrid systems

Historically, traditional measuring devices and CMMs have been largely used to collect inspection data on which to make the decision to accept or reject parts. Although CMMs continue to play this role, manufacturers are placing new emphasis on using CMMs to capture data from many sources and bring them together centrally where they can be used to control the manufacturing process more effectively and to prevent defective components from being produced. In addition, CMMs are also being used in entirely new applications--for example, reverse engineering and computer-aided design and manufacture (CAD/CAM) applications as well as innovative approaches to manufacturing, such as the flexible manufacturing systems, manufacturing cells, machining centers, and flexible transfer lines.

Before purchasing a CMM, the user needs to understand and evaluate modern CMMs and the various roles they play in manufacturing operations today and in the future. This article will:

- Define what a CMM is
- Examine various types of machines available
- Outline CMM capabilities
- Examine major CMM components and systems
- Examine various applications in which CMMs can be employed
- Provide guidelines for use in specifying and installing CMMs

Terminology germane to CMMs includes:

- *Ball bar*: A gage consisting of two highly spherical tooling balls of the same diameter connected by a rigid bar
- *Gage*: A mechanical artifact of high precision used either for checking a part or for checking the accuracy of a machine; a measuring device with a proportional range and some form of indicator, either analog or digital
- *Pitch*: The angular motion of a carriage, designed for linear motion, about an axis that is perpendicular to the motion direction and perpendicular to the yaw axis
- *Pixel*: The smallest element into which an image is divided, such as the dots on a television screen
- *Plane*: A surface of a part that is defined by three points
- *Repeatability*: A measure of the ability of an instrument to produce the same indication (or measured value) when sequentially sensing the same quantity under similar conditions
- *Roll*: The angular motion of a carriage, designed for linear motion, about the linear motion axis
- *Yaw*: The angular motion of a carriage, designed for linear motion, about a specified axis perpendicular to the motion direction. In the case of a carriage with horizontal motion, the specified axis should be vertical unless explicitly specified. For a carriage that does not have horizontal motion, the axis must be explicitly specified

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

CMM Operating Principles

Technically speaking, a CMM is a multi-axial device with two to six axes of travel or reference axes, each of which provides a measurement output of position or displacement. Coordinate measuring machines are primarily characterized by their flexibility, being able to make many measurements without adding or changing tools. As products evolve, the same CMM can generally be used (depending on size and accuracy limitations) simply by altering software instead of altering equipment mechanics or electronics.

Practically speaking, CMMs consist of the machine itself and its probes and moving arms for providing measurement input, a computer for making rapid calculations and comparisons (to blueprint specifications, for example) based on the measurement input, and the computer software that controls the entire system. In addition, the CMM has some means of providing output to the user (printer, plotter CRT, and so on) and/or to other machines in a complete manufacturing system. Coordinate measuring machines linked together in an overall inspection or manufacturing system are referred to as coordinate measuring systems.

When CMMs were first introduced in the late 1950s, they were called universal measuring machines. Today, they are sometimes referred to as flexible inspection systems or flexible gages. The most important feature of the CMM is that it can rapidly and accurately measure objects of widely varying size and geometric configuration--for example, a particular part and the tooling for that part. Coordinate measuring machines can also readily measure the many different features of a part, such as holes, slots, studs, and weldnuts, without needing other tools. Therefore, CMMs can replace the numerous hand tools used for measurement as well as the open-plate and surface-plate inspection tools and hard gages traditionally used for part measurement and inspection.

Coordinate measuring machines do not always achieve the rates of throughput or levels of accuracy possible with fixed automation-type measuring systems. However, if any changes must be made in a fixed system for any reason--for example, a different measurement of the same part or measurement of a different part--making the change will be costly and time consuming. This is not the case with a CMM. Changes in the measurement or inspection routine of a CMM are made quickly and easily by simply editing the computer program that controls the machine. The greater or more frequent the changes required, the greater the advantage of the CMM over traditional measuring devices. This flexibility, as well as the resulting versatility, is the principal advantage of the CMM.

CMM Measurement Techniques

A CMM takes measurements of an object within its work envelope by moving a sensing device called a probe along the various axes of travel until the probe contacts the object. The precise position of the contact is recorded and made available as a measurement output of position or displacement (Fig. 1). The CMM is used to make numerous contacts, or hits, with the probe; using all axes of travel, until an adequate data base of the surfaces of the object has been constructed. Various features of an object require different quantities of hits to be accurately recorded. For example, a plane, surface, or circular hole can be recorded with a minimum of three hits.

Fig. 1 Elements of a CMM showing typical digital position readout. The probe is positioned by brackets slid along two arms. Coordinate distances from one point to another are measured in effect by counting electronically the lines in gratings ruled along each arm. Any point in each direction can be set to zero, and the count is made in a plus or minus direction from there.

Once repeated hits or readings have been made and stored, they can be used in a variety of ways through the computer and geometric measurement software of the CMM. The data can be used to create a master program, for example, of the precise specifications for a part; they can also be compared (via the software) to stored part specification data or used to inspect production parts for compliance with specifications. A variety of other sophisticated applications are also possible using the same captured measurement data—for example, the reverse engineering of broken parts or the development of part specifications from handmade models.

Coordinate Systems. The CMM registers the various measurements (or hits) it takes of an object by a system of coordinates used to calibrate the axes of travel. There are several coordinate systems in use. The most commonly used system is Cartesian, a three-dimensional, rectangular coordinate system the same as that found on a machine tool. In this system, all axes of travel are square to one another. The system locates a position by assigning it values along the x , y , and z axes of travel.

Another system used is the polar coordinate system. This system locates a point in space by its distance or radius from a fixed origin point and the angle this radius makes with a fixed origin line. It is analogous to the coordinate system used on a radial-arm saw or radial-arm drill.

Types of Measurements. As stated earlier, fundamentally, CMMs measure the size and shape of an object and its contours by gathering raw data through sensors or probes. The data are then combined and organized through computer software programs to form a coherent mathematical representation of the object being measured, after which a variety of inspection reports can be generated. There are three general types of measurements for which CMMs are commonly used, as follows.

Geometric measurement deals with the elements commonly encountered every day—points, lines, planes, circles, cylinders, cones, and spheres. In practical terms, these two-dimensional and three-dimensional elements and their numerous combinations translate into the size and shape of various features of the part being inspected.

A CMM can combine the measurements of these various elements into a coherent view of the part and can evaluate the measurements. It can, for example, gage the straightness of a line, the flatness of a plane surface, the degree of parallelism

between two lines or two planes, the concentricity of a circle, the distance separating two features on a part, and so on. Geometric measurement clearly has broad application to many parts and to a variety of industries.

Contour measurement deals with artistic, irregular, or computed shapes, such as automobile fenders or aircraft wings. The measurements taken by a CMM can be easily plotted with an exaggerated display of deviation to simplify evaluation. Although contour measurements are generally not as detailed as geometric measurements, presenting as they do only the profile of an object with its vector deviation from the nominal or perfect shape, they too have broad application.

Specialized surface measurement deals with particular, recurring shapes, such as those found on gear teeth or turbine blades. In general, these shapes are highly complex, containing many contours and forms, and the part must be manufactured very precisely. Tight tolerances are absolutely critical. Because manufacturing accuracy is critical, measurement is also highly critical, and a specialty in measuring these forms has evolved. By its nature, specialized surface measurement is applied to far fewer applications than the other two types.

CMM Capabilities

Coordinate measuring machines have the fundamental ability to collect a variety of different types of very precise measurements and to do so quickly, with high levels of repeatability and great flexibility. In addition, they offer other important capabilities based on computational functions.

Automatic Calculation of Measurement Data. The inclusion of a computer in the CMM allows the automatic calculation of such workpiece features as hole size, boss size, the distance between points, incremental distances, feature angles, and intersections. Prior to this stage of CMM development, an inspector had to write down the measurements he obtained and manually compare them to the blueprint. Not only is such a process subject to error, but it is relatively time consuming. While waiting for the results of the inspection, production decisions are delayed and parts (possibly not being produced to specifications) are being manufactured.

Compensation for Misaligned Parts. Coordinate measuring machines no longer require that the parts being measured be manually aligned to the coordinate system of the machine. The operator cannot casually place the part within the CMM work envelope. Once the location of the appropriate reference surface or line has been determined through a series of hits on the datum features of the part, the machine automatically references that position as its zero-zero starting point, creates an x , y , z part coordinate system, and makes all subsequent measurements relative to that point. In addition, the part does not have to be leveled within the work envelope. Just as the CMM will mathematically compensate if the part is rotationally misaligned, it will also compensate for any tilt in the part.

Multiple Frames of Reference. The CMM can also create and store multiple frames of reference or coordinate systems; this allows features to be measured on all surfaces of an object quickly and efficiently. The CMM automatically switches to the appropriate new alignment system and zero point (origin) for each plane (face) of the part. The CMM can also provide axis and plane rotation automatically.

Probe Calibration. The CMM automatically calibrates for the size and location of the probe tip (contact element) being used. It also automatically calibrates each tip of a multiple-tip probe.

Part Program and Data Storage. The CMM stores the program for a given part so that the program and the machine are ready to perform whenever this part comes up for inspection. The CMM can also store the results of all prior inspections of a given part or parts so that a complete history of its production can be reconstructed. This same capability also provides the groundwork for all statistical process control applications.

Part programs can also be easily edited, rather than completely rewritten, to account for design changes. When a dimension or a feature of a part is changed, only that portion of the program involving the workpiece revision must be edited to conform to part geometry.

Interface and Output. As mentioned earlier, CMMs can be linked together in an overall system or can be integrated with other devices in a complete manufacturing system. The CMM can provide the operator with a series of prompts that tell him what to do next and guide him through the complete measurement routine.

Output is equally flexible. The user can choose the type and format of the report to be generated. Data can be displayed in a wide variety of charts and graphs. Inspection comments can be included in the hard copy report and/or stored in memory for analysis of production runs.

CMM Applications

Coordinate measuring machines are most frequently used in two major roles: quality control and process control. In the area of quality control, CMMs can generally perform traditional final part inspection more accurately, more rapidly, and with greater repeatability than traditional surface-plate methods.

With regard to process control, CMMs are providing new capabilities. Because of the on-line, real-time analytical capability of many CMM software packages, CMMs are increasingly used to monitor and identify evolving trends in production before scrap or out-of-spec parts are fabricated in the first place. Thus, the emphasis has shifted from inspecting parts and subsequently rejecting scrap parts at selected points along the production line to eliminating the manufacture of scrap parts altogether and producing in-tolerance parts 100% of the time.

In addition to these uses, there is a trend toward integrating CMMs into systems for more complete and precise control of production. Some shop-hardened CMMs, also known as process control robots, are being increasingly used in sophisticated flexible manufacturing systems in the role of flexible gages.

Coordinate measuring machines can also be used as part of a CAD/CAM system. The CMM can measure a part, for example, and feed that information to the CAD/CAM program, which can then create an electronic model of the part. Going in the other direction, the model of the desired part in the CAD/CAM system can be used to create the part program automatically.

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

Types of CMMs

The ANSI/ASME B89 standard formally classifies CMMs into ten different types based on design. All ten types employ three axes of measurement along mutually perpendicular guideways. They differ in the arrangement of the three movable components, the direction in which they move, and which one of them carries the probe, as well as where the workpiece is attached or mounted. However, among the many different designs of CMMs, each with its own strengths, weaknesses, and applications, there are only two fundamental types: vertical and horizontal. They are classified as such by the axis on which the probe is mounted and moves. The ANSI/ASME B89 Performance Standard classifies coordinate measuring machines as:

Vertical	Horizontal
Fixed-table cantilever	Moving ram, horizontal arm
Moving-table cantilever	Moving table, horizontal arm
Moving bridge	Fixed table, horizontal arm

Fixed bridge	
L-shaped bridge	
Column	
Gantry	

In addition, the two types of machine can be characterized to some degree by the levels of accuracy they each achieve (although there is a considerable degree of overlap based on the design of an individual machine), by the size of part they can handle, and by application. The prospective buyer/user of a CMM cannot make an intelligent choice of the type of machine that will best meet his needs, let alone the specific make and model of CMM, until he thoroughly evaluates and plans both the specific intended application of the CMM and the overall manufacturing and quality context in which it will operate. Table 1 provides a general comparison of CMM types, applications, and levels of measurement accuracy a CMM user can expect.

Table 1 Typical CMM specifications

Application	CMM type	Bearing type	Minimum measurement	
			mm	in.
Laboratory quality ^(a)				
Laboratory grade	Vertical, moving bridge	Air bearings	<0.003	<0.0001
Clean room	Vertical, moving bridge	Air bearings	<0.003	<0.0001
Production machines				
Open shop	Vertical, moving bridge	Air bearings	<0.013-0.025	<0.0005-0.001
Sheet metal	Horizontal (with fixed x-y axis)	Recirculating bearing packs	<0.025-0.050	<0.001-0.002
Clean room and shop	Vertical, moving bridge; all horizontal	Air/roller bearings	<0.050	<0.002

(a) These CMMs have specific environments into which they must be installed to maintain their rated accuracies.

Experience clearly shows that the user who simply buys a CMM and places it in use without considering the impact of the unit on the manufacturing process will almost invariably fail. On the other hand, the user who determines the results desired from the CMM, the resources required to achieve those results, and the effect of the CMM on the overall manufacturing process will likely realize the maximum benefits a CMM can provide.

Evaluation and planning are further discussed in the section "CMM Implementation" in this article.

Vertical CMMs

Vertical CMMs, which have the probe or sensor mounted on the vertical z -axis, have the potential to be the most accurate type. Vertical CMMs in general can be more massive and can be built with fewer moving parts than their horizontal counterparts. They are therefore more rigid and more stable. Their limitation, however, is the size of part they can conveniently handle, because the part to be measured must fit under the structural member from which the probe descends.

In an attempt to overcome this limitation, various designs have been produced. As a result, within the overall category of vertical CMM, there are designs utilizing moving or fixed bridges, cantilevers, gantries, and so on. Each design approach is of course a compromise, because as the size of the work envelope of the machine and the travel distance along the axes increase, so also do the problems of maintaining rigidity and accuracy. A gantry design has proved to be an effective solution to the problem of increasing the capacity of a CMM while maintaining a high level of accuracy. A cantilever design, on the other hand, presents some inherent problems associated with isolating the CMM from floor vibrations and maintaining high precision due to the overhanging unsupported arm.

Cantilever-type CMMs employ three movable components moving along mutually perpendicular guideways. The probe is attached to the first component, which moves vertically (z -direction) relative to the second. The second component moves horizontally (y -direction) relative to the third. The third component is supported at one end only, cantilever fashion, and moves horizontally (x -direction) relative to the machine base. The workpiece is supported on the worktable. A typical machine of this configuration is shown in Fig. 2(a). A modification of the fixed-table cantilever configuration is the moving-table cantilever CMM shown in Fig. 2(b).

Fig. 2 Motion of components in cantilever-type CMMs. (a) Fixed table. (b) Moving table

The cantilever design provides openness and accessibility from three sides, making it popular for small, manual CMMs. Its cantilevered y -axis places a size limitation on this configuration. Because of the small y - z assembly, this configuration is lightweight and provides fast measuring speeds in direct computer control (DCC) applications.

Bridge-type CMMs employ three movable components moving along mutually perpendicular guideways. The probe is attached to the first component, which moves vertically (z -direction) relative to the second. The second component moves horizontally (y -direction) relative to the third. The third component is supported on two legs that reach down to opposite sides of the machine base, and it moves horizontally (x -direction) relative to the base. The workpiece is supported on the base.

Moving Bridge. A typical moving-bridge CMM is shown schematically in Fig. 3(a). This configuration accounts for 90% of all CMM sales.

Fig. 3 Motion of components in bridge-type CMMs. (a) Moving bridge. (b) Fixed bridge. (c) L-shaped bridge

The moving-bridge design overcomes the size limitations inherent in the cantilever design by providing a second leg, which allows for an extended y -axis. The second leg does, however, reduce access to the unit. The limitations of this configuration usually occur because of walking problems associated with retaining drive through just one leg. Higher speeds, achieved by increasing dynamic forces and reducing machine setting time, accentuate the problem. Vertical moving-bridge CMMs can be controlled manually (Fig. 4) and with DCC hardware (Fig. 5).

Fig. 4 Vertical moving-bridge CMM inspecting a case-hardened cast steel automotive crank-shaft using a touch-trigger probe. This manually operated unit has a granite table.

Fig. 5 Vertical moving-bridge CMM, which incorporates a granite base, inspecting a cast aluminum alloy four-wheel-drive transaxle gear case. The DCC motor drive that controls all of the axial movements is equipped with a remote joystick controller.

The fixed-bridge configuration (Fig. 3b) provides a very rigid structure and allows a relatively light moving x - z structure that can achieve fast x - z moves. The moving table in larger machines can become massive, with decreased throughput capability. The influence of part weight on accuracy becomes a consideration for large parts.

L-Shaped Bridge. Another modification of the bridge configuration has two bridge-shaped components (Fig. 3c). One of these bridges is fixed at each end to the machine base. The other bridge, which is an inverted L-shape, moves horizontally (x -direction) on guideways in the fixed bridge and machine base.

The column CMM goes one step further than the fixed bridge in providing a very rigid z -axis configuration, and a two-axis saddle that allows movement in the horizontal (x - y) directions (Fig. 6). High accuracy can be achieved with this design. As in the fixed-bridge configuration, however, part mass and table considerations can restrict measuring volume and speed.

Fig. 6 Schematic of column CMM illustrating movement of probe, column, and table components

Column CMMs are often referred to as universal measuring machines rather than CMMs by manufacturers. Column units are considered gage-room instruments rather than production-floor machines.

Gantry CMMs employ three movable components moving along mutually perpendicular guideways (Fig. 7). The probe is attached to the probe quill, which moves vertically (z -direction) relative to a crossbeam. The probe quill is mounted in a carriage that moves horizontally (y -direction) along the crossbeam. The crossbeam is supported and moves in the x -direction along two elevated rails, which are supported by columns attached to the floor.

Fig. 7 Schematic of gantry CMM illustrating movement of probe, crossbeam, and elevated rails

The gantry design has relatively restricted part access unless utilized in very large machines. The machine is physically large with respect to the size of the part. Large axis travels can be obtained, and heavy parts are not a problem, because the weight of the part can be decoupled from the measurement system by proper design of the machine base (foundation in a large machine). This is not as practical in smaller CMMs, and this configuration is most popular for large machines.

The gantry configuration was initially introduced in the early 1960s to inspect large parts, such as airplane fuselages, automobile bodies, ship propellers, and diesel engine blocks. The open design permits the operator to remain close to the part being inspected while minimizing the inertia of the moving machine parts and maintaining structural stiffness.

Horizontal CMMs

Horizontal CMMs, which have the probe mounted on the horizontal y-axis, are generally used in applications in which large parts must be measured—for example, automobile bodies or airplane wings. Horizontal CMMs require no bridge over the part because the part is approached from the side. Therefore, there is substantially less restriction on the sizes of the parts that can be measured.

Most horizontal CMMs, however, do not measure to state-of-the-art levels of accuracy, because of the high cost of achieving such accuracy in machines capable of handling large parts. In general, it is more cost effective to accept accuracy in the 0.050 mm (0.002 in.) range when gaining the part-handling capabilities of large horizontal machines and to use vertical designs when finer measurement is demanded.

In any CMM design, fewer moving parts and joints will result in higher potential levels of accuracy. This principle has been applied to a class of horizontal CMM called process control robots. In these units, fixed members that move together provide the flexibility and capacity of a horizontal CMM, along with the higher accuracy of a vertical design. The horizontal direction of attack makes these CMMs the logical design for production applications in which horizontal machine tools are used.

In choosing a CMM, the buyer must take into consideration not only the degree of accuracy required but also the location of the unit and the measurements to be taken. In general, when dealing with smaller parts where measurements of very high accuracy are required, the potential user is likely to be best served by a machine located in a clean room environment. When on-line process control is desired, the appropriate shop-hardened CMM that can be located in the shop itself is the best solution.

Horizontal-Arm CMMs. Several different types of horizontal-arm CMMs are available. As with all CMMs, the horizontal-arm configuration employs three movable components moving along mutually perpendicular guideways.

Horizontal-arm CMMs are used to inspect the dimensional and geometric accuracy of a broad spectrum of machined or fabricated workpieces. Utilizing an electronic probe, these machines check parts in a mode similar to the way they are machined on horizontal machine tools. They are especially suited for measuring large gearcases and engine blocks, for which high-precision bore alignment and geometry measurements are required. Four-axis capability can be obtained by incorporating a rotary table.

Horizontal arms for large machines have a lower profile than vertical arms. For some applications, horizontal access is desirable. For others, it is restrictive and a rotary table is usually required, thus increasing the cost.

Moving-Ram Type. In this design, the probe is attached to the horizontal arm, which moves in a horizontal y -direction (Fig. 8a). The ram is encased in a carriage that moves in a vertical (z) direction and is supported on a column that moves horizontally (x -direction) relative to the base.

Fig. 8 Schematic illustrating three types of horizontal-arm CMMs. (a) Moving ram. (b) Moving table. (c) Fixed table. Length of table/base is usually two to three times the width. Units with bases capable of accommodating two to three interstate buses situated end-to-end have been built for major automotive manufacturers.

Moving-Table Type. In this configuration, the probe is attached to the horizontal arm, which is permanently attached at one end only to a carriage that moves in a vertical (z) direction (Fig. 8b) on the column. The arm support and table move horizontally (x - and y -directions) relative to the machine base. The moving-table horizontal-arm CMM unit shown in Fig. 9 is even more versatile because of the introduction of a rotary moving table.

Fig. 9 Horizontal-arm moving-table CMM equipped for operation in hostile environments is shown inspecting a cast iron automotive engine block. The unit incorporates a rotary table, a motorized programmable probe, and an environmentally protected automatic probe changer. With its process control robot, this CMM is designed for easy integration and installation in manufacturing cells.

Fixed-Table Type. In the fixed-table version, the probe is attached to the horizontal arm, which is supported cantilever style at the arm support and moves in a vertical (z) direction (Fig. 8c). The arm support moves horizontally (x - and y -directions) relative to the machine base. Parts to be inspected are mounted on the machine base. The versatility of the fixed-table horizontal-arm design is readily illustrated by its ability to inspect a relatively plane surface such as a door (Fig. 10) as well as an array of cylindrical surfaces encountered in a valve assembly (Fig. 11).

Fig. 10 Horizontal-arm fixed-table CMM using a metal scribing tool to inspect a steel sheet metal automotive door taken from the production line. This manually operated unit has a cast iron table.

Fig. 11 Horizontal-arm fixed-table CMM using an edge-finder probe to inspect a precision cast aluminum alloy valve body. This manually operated unit incorporates a cast iron table.

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

Key CMM Components

As stated earlier, it is virtually impossible for the CMM buyer to select the appropriate unit without carefully evaluating which functions are needed, where the unit will operate, under what conditions, who will operate it, and so on. Every CMM offers trade-offs and its own cost-to-benefits ratio. The CMM that provides state-of-the-art measurement, for example, may not be the best choice if the user cannot provide the correct operating environment. The best CMM is the one that matches the application in terms of design, capacity, accuracy, protection, and so on. Once these factors have been considered, the CMM buyer should assess the characteristics and capabilities of the following major components of the CMM.

Base/Bed Construction. The first major component to examine is the overall construction of the machine. The CMM must be rigidly built to minimize errors introduced by unintended movement between the machine members and in their movement along the axes of travel. Some designs (such as the cantilever) require a more massive structure to provide the same degree of rigidity than do others (such as the gantry type) that have more inherent rigidity. If the CMM is to operate in the shop, the user should select a design having the same toughness and shielding as a machine tool. If the CMM will be used in a laboratory, a less protected model can be selected.

Traditionally, all measuring machines had cast iron bases or beds, but today granite is also frequently used because of its mass and thermal stability. In the past, it was essential that the bed of the measuring machine be perfectly flat, but with the advent of computer-based error compensation, this characteristic has become far less vital.

Coordinate measuring machines designed for use in the laboratory or clean room are usually built with granite beds. Horizontal-arm CMMs and any CMM intended for use on the factory floor are still built with a cast iron base because of their larger size and the levels of accuracy required in these applications. Steel is also far easier than granite to fabricate and use in integrated systems involving automated materials handling and similar functions.

Key elements of the structure (such as bearing ways and scales) may be of stainless steel, granite, aluminum, or more exotic materials, such as ceramic. One principal factor, however, is that all these critical components must be of the same material. This reduces the effects of expansion and contraction due to temperature changes. The buyer wants a machine that is thermally stable, and the manufacturer can achieve this stability in several ways. A CMM whose key components are of ceramic will be thermally stable because ceramic reacts very slowly to temperature changes. By the same token, a CMM with aluminum components will provide thermal stability because these components react very quickly to temperature changes. In both cases, the user knows with a high degree of certainty the thermal condition of the CMM.

Bearing Construction. Bearings have a direct impact on the accuracy of all CMMs because of their effect on every motion of the machine along its axes. Bearing assemblies can be of the air or roller type or can consist of recirculating bearing packs.

Air Bearings. For CMMs that will be used in a laboratory or clean room, where there is a minimum of dirt or dust, air bearings are the best choice because they move without friction and are therefore the most accurate. Air bearings are not suitable on CMMs located on the shop floor, because the bearings need constant cleaning and require costly air-activated vibration isolation systems, which slow the measuring speed and decrease the accuracy of the CMM. The isolation system also increases the potential for failure because of its complexity and generally fragile design.

Roller Bearings. For many shop applications, such as those for sheet metal grade CMMs, roller bearings are a good choice. Although they provide somewhat lower levels of potential accuracy than air bearings, roller bearings are sturdier and can function in an atmosphere containing some dirt and dust. They are not suitable for CMMs in hostile environments.

Recirculating Bearing Packs. The durability of roller bearings and accuracy approaching that of air bearings are available from recirculating bearing packs such as those typically used on grinding machines. Because these bearing packs are completely sealed, they permit operation in harsh factory environments, and they can handle the weight of larger, more rigid machines. Their inherent stiffness provides volumetric accuracies and repeatabilities equal to those of air bearings at significantly higher accelerations, which shorten measurement cycle times.

Scales and Encoders. The scales of a CMM show where the probe is located on the x , y , and z axes within the work envelope of the machine. Because CMMs measure to such a high degree of resolution, the scales used are machine readable and cannot be read by the naked eye. The CMM encoder reads the scales and inputs this measurement data into the computer for computation. A machine readout amplifies the same measurement data so that they are accessible to the operator by the naked eye. The buyer should make sure that the readout on any CMM is both visible and decipherable.

There are many different kinds of scales--for example, rotary, wire, magnetic, linear metal, and glass. The most accurate scales are glass because this material permits finer etching of measurement lines than steel or other commonly used materials. The resolution of the finest scales is to the submicron level. The buyer should make sure that the scales of any machine intended for shop use are thoroughly sealed and protected from the outside environment.

Sensors and Probes. Sensors and probes are the devices through which CMMs collect their measurement input. A broad variety of probes are currently available, each with its own application, permitting users to obtain very accurate measurements of virtually any type of part feature, contour, surface, and so on.

Hard or fixed probes have been in use since the mid-1970s. They were the original type used on CMMs. The CMM operator manually brings a hard probe into contact with the object being measured and reads (via the machine) the coordinates of the measurement from the machine scales. Hard probes are available in a variety of configurations (ball, tapered plug, and edge) and continue to have broad application and utility, primarily on manual machines.

Of the various types of hard probes, ball probes are used to measure the distance from one point to another. Tapered-plug probes are used for such measurements as the distance between the centerline of two holes. Edge probes are used to locate edge points.

The shortcoming of all hard or fixed probes is that they depend on a subjective element in the performance of the machine operator. Every operator has his own touch, a light or heavy hand in moving and bringing the probe in contact with the part. Just as one operator will use more force than another to close a micrometer on a part and thus obtain a variation in measurement, the CMM operator can unknowingly influence measurements taken with a hard probe.

Touch-trigger or electronic touch-trigger probes are the second major category of probe currently used. Touch-trigger probes operate like an electronic switch that closes when the probe comes in contact with the workpiece measured. The development of touch-trigger probes was a major break-through for CMM technology.

Not only do touch-trigger probes remove a major source of operator error, they greatly increase the flexibility of measurements and facilitate direct computer-controlled CMMs. Because of their considerable advantages, touch-trigger probes are replacing hard probes in many applications. Touch-trigger probes are also available in many configurations and types, that is, with extensions, special mounts, multiaxis motorized heads, and so on.

Noncontact trigger probes are used in a similar manner to the contact touch-trigger probes described above. However, with noncontact probes, a beam of light (generally a diode) is used (operating as an optical switch) to probe the workpiece rather than the physical contact of a probe tip. The probe is permanently set to a specific stand-off distance at which the laser beam is triggered and measurements are taken. Because the probe never comes in contact with the part, the likelihood of damage to the probe or part is greatly reduced, and the measurement speed is greatly improved with only slight reduction in accuracy.

Touch Scanners. This type of probe, which produces analog readings instead of the digital measurements produced by the probes mentioned above, is used for taking contour measurements. These probes remain in contact with the workpiece as they move along its surface.

Laser probes primarily provide measurements of contoured surfaces, but do so without coming in contact with the surface. Laser probes project a beam of laser light, called a footprint, onto the surface of the part, the position of which is then read by triangulation through the lens in the probe receptor. This triangulation (much like surveying) in turn provides the actual position and so on, of the feature on the part being measured.

Vision Probes. This type of sensor is the most recent and sophisticated addition to the sensor systems currently in use. Vision is another form of noncontact sensing and is especially useful where very high speed inspection or measurement is required. In this system, the part is not measured directly. Instead, an electronic representation of it is measured and evaluated. The various features of this image of the workpiece (size, shape, location, and so on) are measured in comparison to various electronic models of expected results by counting the pixels of the electronic image. From this, the true nature of the part being inspected can be inferred and reported.

Probe Changers. Probe changers store alternative and/or backup probes, permitting the exchange or replacement of various probes automatically. The measurement routine of a given part may call for the use of different probes or sensors to measure particular features of the part. A deep bore may require the use of a probe with an elongated tip, for example, while other features may require different specialized probes. The type of probe to be used for the measurement of every feature of a part is written into the parts program (the software program that controls that particular CMM operation). By utilizing a probe changer, which attaches to the CMM, the entire measurement routine can be carried out without stopping for probe changes and without operator intervention.

Computer Hardware. The computer is the heart of the CMM system, giving it the capabilities and versatility that are rapidly making CMMs essential to efficient manufacturing. The computer receives that measurement data gathered by the CMM and, taking guidance from the software program, manipulates it into the forms required by the user. The computer also performs the essential function of automatically aligning parts for measurement and automatically compensating for errors within the structure of the machine. In DCC applications, the computer also operates the CMM.

Because of the vital role of the computer, there are several points the CMM buyer must be aware of. Primarily, the buyer will want to be sure that the operating system is designed to run without assistance or information from the user. The CMM user does not want to become involved in computer programming. The user needs a fast, efficient computer that supports a state-of-the-art operating system (and peripherals, that is, printer, plotter, and so on) and has good, widespread service support. The state-of-the-art permits the user to plug in the CMM and, after proper installation, testing, and qualification, insert the software needed (available as off-the-shelf items) and then immediately begin measuring parts.

The user can communicate with and give instructions to the computer (via the software) in a number of convenient ways--for example, with keyboards, function keys, light pens, touch-sensitive video screens, or a mouse. Most of these devices are excellent for a laboratory or office, but in the shop, the simplest methods requiring the fewest parts, such as touch-sensitive screens, tend to work best. No matter what method is used, however, the CMM operator does not need, nor necessarily will he benefit from, specialized computer training.

Computer Software. Although the computer is the heart of the CMM, it is the software that enables the system to fulfill its potential. Not many years ago, obtaining the appropriate application software to run measurement routines necessitated writing a program in Fortran or Basic, but the situation has very nearly completely reversed itself today. Software for the CMM has been refined to the extent that no computer programming knowledge or experience is needed to run even the most sophisticated measurement programs available.

Virtually all CMM software consists of off-the-shelf, menu-driven (that is, the program asks the operator what he wants to do and even prompts the most likely choice) programs that are very user-friendly, with comprehensive, solid help

screens available. The result is that the software (combined with the formidable power of the personal computer) for any particular routine is very easy and flexible to use and can be customized to fit individual applications using plain English rather than a specific programming language tied to a complicated operating system.

The range of available software is very wide. For example, programs are available for statistical process analysis and control. Programs for sheet metal applications facilitate the location and measurement of parts containing bolts, weldnuts, and similar features. Other contour programs permit the rapid and accurate alignment of complex, nongeometric shapes without straight edges. There is also a family of software that allows the transfer of data between CMMs and CAD systems, and other programs are available that facilitate the communication of data between CAD systems made by different manufacturers. Development in this area has been so dynamic that standards for data formats have already been developed and accepted by the industry, such as Dimensional Measurement Interface Specification for communication from CMMs to CAD systems, and Initial Graphics Exchange Specification for CAD-to-CAD data exchange. Such integration makes possible the use of CMMs in a variety of new applications, such as for reverse engineering, in which specifications are derived from the measurement of a model or a broken part, and for the development of part programs (measurement routines) directly from CAD data.

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

Factors Affecting CMM Performance

Because CMMs are highly sophisticated, precision machines, their performance and accuracy are affected by many environmental, design, and operating factors. Most errors in CMMs are systematic (that is, stemming from machine setup and operating conditions) rather than random. Therefore, to obtain a high level of performance, a user must first choose the appropriate machine for the application. The CMM must then be located in a suitable environment, which can range from the laboratory to the shop floor, and it must be installed with all the appropriate safeguards for proper, error-free operation. This section of the article will outline the factors that affect performance and will provide suggestions for ensuring the satisfactory performance of the CMM.

Volumetric Accuracy. Historically, measuring machines were evaluated in terms of linear scale accuracy but as they began to be used to measure more complex parts, it soon became apparent that the linear accuracy of the machine was insufficient to guarantee the level of measurement performance required. It became important, therefore, to evaluate performance on the basis of the accuracy of the CMM at any point within its three-dimensional work envelope, that is, volumetric accuracy.

Until quite recently, there was no recognized standard for gaging and evaluating the volumetric accuracy of a CMM. Under the auspices of the American Society of Mechanical Engineers and the U.S. Bureau of Standards, CMM manufacturers and users developed testing criteria and methods using laser, step gage, and ball bar tests that verify the volumetric and linear accuracy of the CMM. In 1985, those tests were published as part of ANSI National Standard B89.1.12.

There are 21 degrees of freedom or geometric inaccuracy (all of which can be sources of measurement error in a three-axis CMM): roll, pitch, yaw, scale error, repeatability, two straightness error per axis, plus three squareness errors. To ensure volumetric accuracy, every one of these 21 degrees of freedom must be tested. When testing, the supplier must test the complete CMM system (the mechanics and electronics of the machine plus probe holder, probe, and its measurement software) because it will be used to measure parts to ensure that the results will be accurate predictors of measurement performance.

Historically, errors inherent in machine components were mechanically refined. A cast iron bed was planed, for example, to eliminate irregularities, and granite components were lapped. Today, however, mechanical errors in the CMM are refined with the CMM computer, which automatically compensates for geometric errors with powerful software algorithms in real time as measurements are taken.

Probe Compensation. Every probe must be qualified to locate its position in relation to the x , y , and z axes of the CMM and to compensate for any geometric error introduced into measurement by the difference between the actual

diameter of the probe (or footprint) and its diameter as perceived by the CMM in a given position within the work envelope. This compensation must be made for every probe (probe holder, tip, or combination thereof, and so on) in every position required during a measurement routine. When a probe is replaced because of wear, breakage, or substitution, the new probe must again be qualified in every position in which it will be used. The results of this calibration are then entered into the program guiding the CMM, and the inherent error is factored out in the final measurement data.

Environmental factors are critical to the satisfactory performance of any CMM. The user who fails to provide a suitable environment will almost certainly be disappointed with the performance of the machine. Manufacturers will provide potential buyers with environmental guidelines for the operation of the unit, and these guidelines may vary somewhat from manufacturer to manufacturer. In no case will the manufacturer guarantee the performance of the CMM unless the environmental criteria are met. According to the ANSI/ASME B89.1.12 standard for performance evaluation of CMMs, the user has the clear responsibility of providing a suitable performance test environment (on which to base acceptance of the machine from the supplier), either by meeting the guidelines of the supplier or by accepting reduced performance. Among the environmental factors that can alter CMM performance are vibration, airborne particulates, and temperature.

Vibration can greatly affect the measurement accuracy of any CMM. Motion from other machines, compressors and similar equipment, lift trucks, and so on, can be transferred to the CMM through the floor, foundation, or support system on which it stands. This motion, whether continuous vibration, intermittent shock, or combinations of both, will degrade the accuracy and repeatability of measurements taken by the machine because of the relative motion among the probe, the machine parts, and the workpiece. Extremes of motion may even damage the machine itself.

Therefore, the CMM user must use caution and good judgement in selecting a location for the unit. The area must be examined and analyzed for sources of potential vibration and shock, and an appropriate support or isolation system must be used to isolate the machine from the effects of vibration. The manufacturer will supply a statement of acceptable vibration levels as part of the machine specification so that the user can make intelligent judgements about these requirements before the purchase.

Air bearing equipped CMMs, because of their low, damped natural frequency, will require an air-activated vibration isolation system. However, with CMMs that use roller bearing packs, a typical machine tool-like isolated foundation is all that is required.

Airborne Particulates. Although there is no formal standard for acceptable levels of dirt and dust in the operating environment of a CMM, dirt can be very damaging to the performance of any CMM, most especially to any machine that has not been specifically designed and hardened for operation in a hostile environment. Therefore, the CMM user must give careful consideration to dirt and dust in the environment when selecting a CMM, determining its location in the facility, and estimating the resources required to install and operate it.

A CMM equipped with air bearings can operate without adverse effects on its performance in an environment containing dry dust because the bearings themselves will expel air and eject the containment. Wet dirt, however, will tend to stick and clog the machine and will probably introduce a source of significant error and possible damage to the machine.

A CMM operating in a clean room or laboratory must be dusted on a daily basis, paying particular attention to the bearing ways, scales, encoder, and so on. Any CMM operating in a harsh or hostile environment must be massive and sturdy to withstand the rigors of its environment, with the vital components mentioned above shielded from dirt, oil, grease, chips, and so on. The performance of any CMM will benefit from a conscientious program of periodic and thorough preventive maintenance.

Temperature exerts a significant influence on the accuracy of the measurements taken by a CMM. The temperature of the various components of the machine and the workpiece should be as uniform and constant as is reasonably possible within the working environment. Although specific operating temperature standards have not been established, various factors that affect operating temperatures, changes in temperature, and CMM accuracy have been identified and must be considered when choosing the location of a CMM unit and establishing the environment in which it will operate.

A CMM should not be exposed to direct sunlight or other powerful sources of radiant energy, such as fluorescent lighting. The rate and speed of air flow around the machine should be limited, as should the amount and rate of temperature change in the surrounding room.

As in the case of vibration and shock, the manufacturer will supply guidelines for an acceptable thermal environment for operation of the CMM. Although adherence to these guidelines will not ensure accuracy, it will shift responsibility for unsatisfactory performance of the machine from the user to the manufacturer.

Coordinate Measuring Machines

David H. Genest, Brown & Sharpe Manufacturing Company

CMM Implementation

Successful implementation of one or many CMMs depends on thorough, detailed planning and complete integration of the unit into the manufacturing system as a whole. Selection of a CMM should be based on detailed knowledge of the capabilities, strengths, and weakness of the manufacturing process. Knowledge of the statistical performance of the process is very helpful and, if available, can be utilized to address many of the key questions that must be answered for successful implementation. However, absolutely essential is a clear recognition of the prevailing philosophy of measurement and a full understanding of the implications of that philosophy.

Quality Plan Objectives. Before any decisions or evaluation can be made regarding CMMs, the buyer will be best served by developing a quality plan that outlines every aspect of the implementation of the CMM, its use, and the role it will play in the manufacturing process. The buyer should consider the following questions and as many more as can be formulated concerning the impact of the CMM on the overall manufacturing process:

- What is desired, and what must be accomplished relative to gaging?
- How will the CMM be integrated into the manufacturing process as a whole?
- What will be the relationship of the CMM to the process as a whole?

A laboratory-grade, vertical CMM can be used off-line, for example, as a master arbiter of part specifications, or a shop-hardened, horizontal CMM can be used on-line for continuing workpiece measurement and real-time statistical process control. Either approach, as well as many others, can be perfectly valid, but any approach must fit smoothly within the overall system. Based on manufacturing capacity and historical records, the buyer must consider such questions as:

- To what degree of accuracy will parts be gaged?
- What parts are critical to manufacturing?
- What are the roles of the critical parts in the final product?
- Which of these parts will be measured?
- How frequently will they be measured?

The answers to such questions will begin to narrow the field of potential CMMs. If a manufacturing process requires accuracy to less than 0.010 mm (0.0004 in.), for example, then production-grade, horizontal machines are eliminated. The buyer knows that the machine must be housed in a clean room environment. The buyer should also be aware that a particular measurement could be far removed from the production line, thus affecting the ability to react quickly to parts that fall below specification.

The buyer must also identify the resources that will be needed for implementation and must realistically evaluate where the resources will be obtained and at what expense. Relevant questions include the following:

- Where will the CMMs be located?
- How much space is required?
- Will the CMMs require a separate room or enclosure, or will they operate on the shop floor?
- Will they require isolation pads or special air bearings?

- Are compressed air, electrical service, and so on, of sufficient quality and readily available?

Environmental concerns must also be carefully analyzed. The following factors must be considered:

- What environment will best suit the CMM?
- Where are the sources of thermal energy that may interfere with CMM operation?
- What sources of vibration are present, and how can the CMM be shielded from them?
- Are dirt, oil, grit, and so on, present in the atmosphere, and how will the CMM be shielded from them?

Ongoing Operations. Answers to the above questions will provide insight and guidance regarding the obstacles that must be overcome for successful implementation as well as the factors that will affect ongoing operations. For example, a hostile environment may lead the user to consider enclosing the CMM in a separate room. However, this will also slow the measuring process compared to a CMM located on the shop floor, because parts will have to soak until they reach thermal equilibrium with the CMM.

In writing the parts programs that guide the measurement routines, the user must determine the information needed and the best way to obtain it. The following questions are relevant:

- What features of the part are critical?
- How many measurements must be taken?
- What probes will be required?

Training of CMM Personnel. Another essential area often overlooked at great expense to the success of CMM utilization is training. This aspect of CMM implementation involves the following considerations:

- What personnel will be utilized to operate CMMs?
- How many will be trained?
- For how long?
- How, when, and where will they be trained?

Experience has shown that personnel with inspection backgrounds tend to make the best CMM operators. If they happen to have an interest in computers, so much the better. It is often more difficult to teach inspection principles to individuals with a computer background than vice versa. Regardless of the personnel selected, it is essential that operator training be given full attention and made an integral part of the implementation plan.

Machine Vision and Robotic Inspection Systems

John D. Meyer, Tech Tran Consultants, Inc.

Introduction

MACHINE VISION emerged as an important new technique for industrial inspection and quality control in the early 1980s. When properly applied, machine vision can provide accurate and inexpensive 100% inspection of workpieces, thus dramatically increasing product quality. Machine vision is also increasing in use as an in-process gaging tool for controlling the process and correcting trends that could lead to the production of defective parts. Consequently, manufacturers in a variety of industries have investigated this important new technology, regardless of the products being manufactured. As shown in Fig. 1, the automotive and electronics industries combined have purchased nearly 60% of the 2500 machine vision systems installed in 1984.

Fig. 1 Breakdown of machine vision systems market by industry in 1984. Based on annual sales at 2500 units. Source: Ref 1 (Tech Tran Consultants, Inc.)

Machine vision, sometimes referred to as computer vision or intelligent vision, is a means of simulating the image recognition and analysis capabilities of the human eye/brain system with electronic and electromechanical techniques. A machine vision system senses information about an image and analyzes this information to make a useful decision about its content; in much the same way, the eye acts as the body's image sensor, with the brain analyzing this information and taking action based on the analysis.

Therefore, a machine vision system includes both visual-sensing and interpretive capabilities. An image-sensing device, such as a vidicon camera or a charge-coupled device (CCD) image sensor, is nothing more than a visual sensor that receives light through its lens and converts this light into electrical signals. When a data-processing device, such as a microcomputer, is used, these electrical signals can be refined and analyzed to provide an interpretation of the scene that generated the signals. This information can then be used as a basis for taking an appropriate course of action. The entire process of image formation, analysis, and decision making is referred to as machine vision.

This ability to acquire an image, analyze it, and then make an appropriate decision is extremely useful in inspection and quality control applications. It enables machine vision to be used for a variety of functions, including:

- Identification of shapes
- Measurement of distances and ranges
- Gaging of sizes and dimensions
- Determining orientation of parts
- Quantifying motion
- Detecting surface shading

These functional capabilities, in turn, allow users to employ machine vision systems for cost-effective and reliable 100% inspection of workpieces.

The analogy of human eye/brain system is helpful in understanding machine vision, but the human eye/brain system is extremely complex and operates in ways and at data rates much different from those of commercial machine vision systems. Humans are more flexible and often faster than machine vision systems. On the other hand, machine vision systems provide capabilities not achievable by humans, particularly with respect to consistency and reliability. Table 1 compares human and machine vision capabilities, and Table 2 evaluates the performance of each. In addition, machine vision systems can detect wavelengths in the ultraviolet and infrared ranges, while the human eye is limited to wavelengths in the visible range (Fig. 2).

Table 1 Comparison of machine and human vision capabilities

Capabilities	Machine vision	Human vision
Distance	Limited capabilities	Good qualitative capabilities
Orientation	Good for two dimensions	Good qualitative capabilities
Motion	Limited; sensitive to image blurring	Good qualitative capabilities
Edges/regions	High-contrast image required	Highly developed
Image shapes	Good quantitative measurements	Qualitative only
Image organization	Special software needed; limited capability	Highly developed
Surface shading	Limited capability with gray scale	Highly developed
Two-dimensional interpretation	Excellent for well-defined features	Highly developed
Three-dimensional interpretation	Very limited capabilities	Highly developed
Overall	Best for quantitative measurement of structured scene	Best for qualitative interpretation of complex, unstructured scene

Source: Ref 1 (Tech Tran Consultants, Inc.)

Table 2 Evaluation of machine and human vision capabilities

Performance criteria	Machine vision	Human vision
Resolution	Limited by pixel array size	High resolution capability
Processing speed	Fraction of a second per image	Real-time processing
Discrimination	Limited to high-contrast images	Very sensitive discrimination
Accuracy	Accurate for part discrimination based on quantitative differences; accuracy remains consistent at high production volume.	Accurate at distinguishing qualitative differences; may decrease at high volume
Operating cost	High for low volume; lower than human vision at high volume	Lower than machine at low volume
Overall	Best at high production volume	Best at low or moderate production volume

Source: Ref 1 (Tech Tran Consultants, Inc.)

Fig. 2 Spectral response of the human eye, vidicon camera, and CCD image sensor. Source: Ref 2

As indicated in Tables 1 and 2, neither machine vision nor human vision is clearly superior in all applications. Human vision is better for the low-speed, qualitative interpretation of complex, unstructured scenes. An example in which human vision is superior to machine vision is the inspection of automobile body surfaces for paint quality. Human vision can easily and quickly detect major flaws, such as paint sagging, scratches, or unpainted areas, but this same task would be much more difficult and time consuming with machine vision techniques.

Machine vision, on the other hand, is better suited to the high-speed measurement of quantitative attributes in a structured environment. Thus, machine vision is very good at inspecting the masks used in the production of microelectronic devices and at measuring basic dimensions for machined workpieces, for example. Machine vision can not only perform these types of inspection better than humans but can do so reliably, without the fatigue and the errors that confront humans doing these types of repeated inspection tasks.

Machine vision also has several additional important characteristics. First, it is a noncontacting measurement technique. This is particularly important if the workpiece is fragile or distorts during contact or if the workpiece would be contaminated or damaged if it were touched. Second, machine vision can be very accurate. Although accuracy is a function of many variables, including camera resolution, lens quality, field of view, and workpiece size, machine vision systems are often used to make measurements with an accuracy of $\pm 3 \mu\text{m}$ ($\pm 120 \mu\text{in.}$) or better. Third, machine vision can perform these functions at relatively large standoff distances--up to 1 m (3 ft) or more in some applications. Finally, these capabilities can be provided at relatively low cost. The price of a machine vision system may range from \$5000 to \$500,000, depending on the specific application and the capabilities of the system, but the typical price is less than \$50,000. Collectively, these characteristics of machine vision provide the user with a capability that, for many applications, cannot be matched by human vision or other sensor or inspection technologies.

Machine Vision and Robotic Inspection Systems

John D. Meyer, Tech Tran Consultants, Inc.

Machine Vision Process

To understand the capabilities and limitations of machine vision, it is useful to examine how a machine vision system operates. Figure 3(a) shows the key components of a machine vision system, and Fig. 3(b) illustrates the process.

Fig. 3(a) Schematic illustrating the key components of a machine vision system.

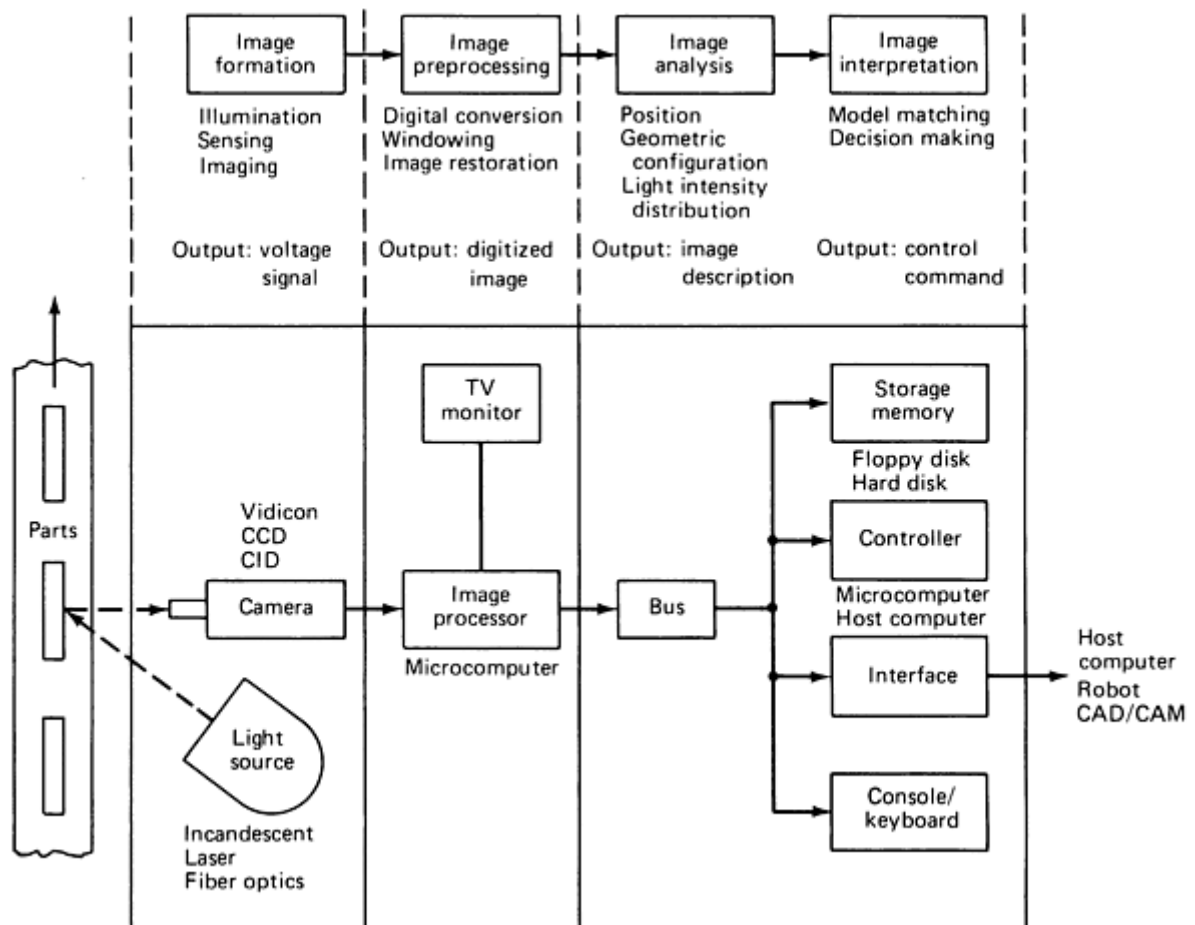

Fig. 3(b) Overview of the machine vision process. CID, charge-injected device. Source: Ref 1 (Tech Tran Consultants, Inc.)

The machine vision process consists of four basic steps:

- An image of the scene is formed
- The image is processed to prepare it in a form suitable for computer analysis
- The characteristics of the image are defined and analyzed
- The image is interpreted, conclusions are drawn, and a decision is made or action taken, such as accepting or rejecting a workpiece

Image Formation

The machine vision process begins with the formation of an image, typically of a workpiece being inspected or operated on. Image formation is accomplished by using an appropriate sensor, such as a vidicon camera, to collect information about the light being generated by the workpiece.

The light being generated by the surface of a workpiece is determined by a number of factors, including the orientation of the workpiece, its surface finish, and the type and location of lighting being employed. Typical light sources include incandescent lights, fluorescent tubes, fiber-optic bundles, arc lamps, and strobe lights. Laser beams are also used in some special applications, such as triangulation systems for measuring distances. Polarized or ultraviolet light can also be used to reduce glare or to increase contrast.

Proper Illumination. Correct placement of the light source is extremely important because it has a major effect on the contrast of the image. Several commonly used illumination techniques are illustrated in Fig. 4. When a simple silhouette image is all that is required, backlighting of the workpiece can be used for maximum image contrast. If certain key features on the surface of the workpiece must be inspected, frontlighting would be used. If a three-dimensional feature is being inspected, sidelighting or structured lighting may be required. In addition to proper illumination, fixturing of the workpiece may also be required to orient the part properly and to simplify the rest of the machine vision process.

Fig. 4 Schematics of commonly used illumination techniques for machine vision systems. Source: Ref 1 (Tech Tran Consultants, Inc.)

Once the workpiece or scene has been properly arranged and illuminated, an image sensor is used to generate the electronic signal representing the image. The image sensor collects light from the scene (typically through a lens) and then converts the light into electrical energy by using a photosensitive target. The output is an electrical signal corresponding to the input light.

Most image sensors used in industrial machine vision systems generate signals representing two-dimensional arrays or scans of the entire image, such as those formed by conventional television cameras. Some image sensors, however, generate signals using one-dimensional or linear arrays that must be scanned numerous times in order to view the entire scene.

Vidicon Camera. The most common image sensor in the early machine vision systems was the vidicon camera, which was extensively used in closed-circuit television systems and consumer video recorders. An image is formed by focusing the incoming light through a series of lenses onto the photoconductive faceplate of the vidicon tube. An electron beam within the tube scans the photoconductive surface and produces an analog output voltage proportional to the variations in light intensity for each scan line of the original scene. Normally, the output signal conforms to commercial television standards--525 scan lines interlaced into 2 fields of 262.5 lines and repeated 30 times per second.

The vidicon camera has the advantage of providing a great deal of information about a scene at very fast speeds and at relatively low cost. Vidicon cameras do have several disadvantages, however. They tend to distort the image due to their construction and are subject to image burn-in on the photoconductive surface. Vidicon cameras also have limited service lives and are susceptible to damage from shock and vibration.

Solid-State Cameras. Most state-of-the-art machine vision systems used solid-state cameras, which employ charge-coupled (Fig. 5) or charge-injected device image sensors. These sensors are fabricated on silicon chips using integrated circuit technology. They contain matrix or linear arrays of small, accurately spaced photosensitive elements. When light passing through the camera lens strikes the array, each detector converts the light falling on it into a corresponding analog electrical signal. The entire image is thus broken down into an array of individual picture elements known as pixels. The magnitude of the analog voltage for each pixel is directly proportional to the intensity of light in that portion of the image. This voltage represents an average of the light intensity variation of the area of the individual pixel. Charge-coupled and charge-injected device arrays differ primarily in how the voltages are extracted from the sensors.

Fig. 5 Typical CCD image sensor. Courtesy of Sierra Scientific Corporation

Typical matrix array solid-state cameras have 256×256 detector elements per array, although a number of other configurations are also popular. The output from these solid-state matrix array cameras may or may not be compatible with commercial television standards. Linear array cameras typically have 256 to 1024 or more elements. The use of a linear array necessitates some type of mechanical scanning device (such as a rotating mirror) or workpiece motion (such as a workpiece traveling on a conveyor) to generate a two-dimensional representation of an image.

Selection of a solid-state camera for a particular application will depend on a number of factors, including the resolution required, the lenses employed, and the constraints imposed by lighting cost, and so on. Solid-state cameras offer several important advantages over vidicon cameras. In addition to being smaller than vidicon cameras, solid-state cameras are also more rugged. The photosensitive surfaces in solid-state sensors do not wear out with use as they do in vidicon

cameras. Because of the accurate placement of the photo detectors, solid-state cameras also exhibit less image distortion. On the other hand, solid-states cameras are usually more expensive than vidicon cameras, but this cost difference is narrowing.

Although most industrial machine vision systems use image sensors of the types described above, some systems use special-purpose sensors for unique applications. This would include, for example, specialty sensors for weld seam tracking and other sensor types, such as ultrasonic sensors.

Image Preprocessing

The initial sensing operation performed by the camera results in a series of voltage levels that represent light intensities over the area of the image. This preliminary image must then be processed so that it is presented to the microcomputer in a format suitable for analysis. A camera typically forms an image 30 to 60 times per second, or once every 33 to 17 ms. At each time interval, the image is captured, or frozen, for processing by an image processor. The image processor, which is typically a microcomputer, transforms the analog voltage values for the image into corresponding digital values by means of an analog-to-digital converter. The result is an array of digital numbers that represent a light intensity distribution over the image area. This digital pixel array is then stored in memory until it is analyzed and interpreted.

Vision System Classifications. Depending on the number of possible digital values that can be assigned to each pixel, vision systems can be classified as either binary or gray-scale systems.

Binary System. The voltage level for each pixel is assigned a digital value of 0 or 1, depending on whether the magnitude of the signal is less than or greater than some predetermined threshold level. The light intensity for each pixel is therefore considered to be either white or black, depending on how light or dark the image is.

Gray-Scale System. Like the binary system, the gray-scale vision system assigns digital values to pixels, depending on whether or not certain voltage levels are exceeded. The difference is that a binary system allows two possible values to be assigned, while a gray-scale system typically allows up to 256 different values. In addition to white or black, many different shades of gray can be distinguished. This greatly increased refinement capability enables gray-scale systems to compare objects on the basis of such surface characteristics as texture, color, or surface orientation, all of which produce subtle variations in light intensity distributions. Gray-scale systems are less sensitive to the placement of illumination than binary systems, in which threshold values can be affected by lighting.

Binary Versus Gray-Scale Vision Systems. Most commercial vision systems are binary. For simple inspection tasks, silhouette images are adequate (for example, to determine if a part is missing or broken). However, gray-scale systems are used in many applications that require a higher degree of image refinement. Figure 6 shows the effects of gray-scale digitization on the surface of an integrated circuit module.

Fig. 6 Gray scale digitization of an IC module on a printed circuit board. (a) Binary. (b) 8-level. (c) 64-level. Courtesy of Cognex Corporation

One of the most fundamental challenges to the widespread use of true gray-scale systems is the greatly increased computer processing requirements relative to those of binary systems. A 256×256 pixel image array with up to 256 different values per pixel will require over 65,000 8-bit storage locations for analysis. At a speed of 30 images per second, the data-processing requirement becomes very large, which means that the time required to process large amounts of data

can be significant. Ideally, a vision system should be capable of the real-time processing and interpretation of an image, particularly when the system is used for on-line inspection or the guidance and control of equipment such as robots.

Windowing. One approach to reducing the amount of data to be processed, and therefore the time, is technique know as windowing, which can substantially reduce processing time. This process creates an electronic mask around a small area of an image to be studied. Only the pixels that are not blocked out will be analyzed by the computer. This technique is especially useful for such simple inspection application as determining whether or not a certain part has been attached to another part. Rather than process the entire image, a window can be created over the area where the attached part is expected to be located. By simply counting the number of pixels of a certain intensity within the window, a quick determination can made as to whether or not the part is present. A window can be virtually any size, from one pixel up to a major portion of the image.

Image Restoration. Another way in which the image can be prepared in a more suitable form during the preprocessing step is through the techniques of image restoration. Very often an image suffers various forms of degradation, such as blurring of lines or boundaries, poor contrast between image regions, or the presence of background noise. There are several possible causes of image degradation, including:

- Motion of the camera or object during image formation
- Poor illumination or improper placement of illumination
- Variations in sensor response
- Defects or poor contrast on the surface of the subject, such as deformed letters on labels or overlapping parts with similar light intensities

Techniques for improving the quality of an image include constant brightness addition, contrast stretching, and Fourier-domain processing.

Constant brightness addition involves simply adding a constant amount of brightness to each pixel. This improves the contrast in the image.

Contrast stretching increases the relative contrast between high- and low-intensity elements by making light pixels lighter and dark pixels darker.

Fourier-domain processing is a powerful technique based on the principle that changes in brightness in an image can be represented as a series of sine and cosine waves. These waves can be described by specifying amplitudes and frequencies in a series of equations. By breaking the image down into its sinusoidal components, each component image wave can be acted upon separately. Changing the magnitude of certain component waves will produce a sharper image that results in a less blurred image, better defined edges or lines, greater contrast between regions, or reduced background noise.

Additional Data Reduction Processing Techniques. Some machine vision systems perform additional operations as part of the preprocessing function to facilitate image analysis or to reduce memory storage requirements. These operations, which significantly affect the design, performance, and cost of vision systems, differ according to the specific system and are largely dependent on the analysis technique employed in later stages of the process. Two commonly used preprocessing operations--edge detection and run length encoding--are discussed below.

Edge Detection. An edge is a boundary within an image where there is a dramatic change in light intensity between adjacent pixels. These boundaries usually correspond to the real edges on the workpiece being examined by the vision system and are therefore very important for such applications as the inspection of part dimensions. Edges are usually determined by using one of a number of different gradient operators, which mathematically calculate the presence of an edge point by weighting the intensity value of pixels surrounding the point. The resulting edges represent a skeleton of the outline of the parts contained in the original image.

Some vision systems include thinning, gap filling, and curve smoothing to ensure that the detected edges are only one pixel wide, continuous, and appropriately shaped. Rather than storing the entire image in memory, the vision system stores only the edges or some symbolic representation of the edges, thus dramatically reducing the amount of memory required.

Run length encoding is another preprocessing operation used in some vision systems. This operation is similar to edge detection in binary images. In run length encoding, each line of the image is scanned, and transition points from black-to-white or white-to-black are noted, along with the number of pixels between transitions. These data are then stored in memory instead of the original image, and serve as the starting point for the image analysis. One of the earliest and most widely used vision techniques, originally developed by Stanford Research Institute and known as the SRI algorithms, uses run length encoded imaged data.

Image Analysis

The third general step in the vision-sensing process consists of analyzing the digital image that has been formed so that conclusions can be drawn and decisions made. This is normally performed in the central processing unit of the system. The image is analyzed by describing and measuring the properties of several image features. These features may belong to the image as a whole or to regions of the image. In general, machine vision systems begin the process of image interpretation by analyzing the simplest features and then adding more complicated features until the image is clearly identified. A large number of different techniques are either used or being developed for use in commercial vision systems to analyze the image features describing the position of the object, its geometric configuration, and the distribution of light intensity over its visible surface.

Determining the position of a part with a known orientation and distance from the camera is one of the simpler tasks a machine vision system can perform. For example, consider the case of locating a round washer lying on a table so that it can be grasped by a robot. A stationary camera is used to obtain an image of the washer. The position of the washer is then determined by the vision system through an analysis of the pattern of the black and white pixels in the image. This position information is transmitted to the robot controller, which calculates an appropriate trajectory for the robot arm. However, in many cases, neither the distance between the part and the camera nor the part orientation is known, and the task of the machine vision system is much more difficult.

Object-Camera Distance Determination. The distance, or range, of an object from a vision system camera can be determined by stadimetry, triangulation, and stereo vision.

Stadimetry. Also known as direct imaging, this is a technique for measuring distance based on the apparent size of an object in the field of view of the camera (Fig. 7a). The farther away the object, the smaller will be its apparent image. This approach requires an accurate focusing of the image.

Fig. 7 Techniques for measuring the distance of an object from a vision system camera. (a) Stadimetry. (b) Triangulation. (c) Stereo vision. Source: Ref 1 (Tech Tran Consultants, Inc.)

Triangulation is based on the measurement of the baseline of a right triangle formed by the light path to the object, the reflected light path to the camera, and a line from the camera to the light source (Fig. 7b). A typical light source for this technique is an LED or a laser, both of which form a well-defined spot of light (see the section "Laser Triangulation Sensors" in the article "Laser Inspection" in this Volume). Because the angle between the two light paths is preset, the standoff distance is readily calculated. Typical accuracies of $1\text{ }\mu\text{m}$ ($40\text{ }\mu\text{in.}$) can be achieved.

Stereo vision, also known as binocular vision, is a method that uses the principle of parallax to measure distance (Fig. 7c). Parallax is the change in the relative perspective of a scene as the observer (or camera) moves. Human eyesight provides the best example of stereo vision. The right eye views an object as if the object were rotated slightly from the

position observed by the left eye. Also, an object in front of another object seems to move relative to the other object when seen from one eye and then from the other. The closer the objects, the greater the parallax. A practical stereo vision system is not yet available, primarily because of the difficulty in matching the two different images that are formed by two different views of the same object.

Object orientation is important in manufacturing operations such as material handling or assembly to determine where a robot may need to position itself relative to a part to grasp the part and then transfer it to another location. Among the methods used for determining object orientation are the equivalent ellipse, the connecting of three points, light intensity distribution, and structured light.

Equivalent Ellipse. For an image of an object in a two-dimensional plane, an ellipse can be calculated that has the same area as the image. The major axis of the ellipse will define the orientation of the object. Another similar measure is the axis that yields the minimum moment of inertia of the object.

Connecting of Three Points. If the relative positions of three noncolinear points in a surface are known, the orientation of the surface in space can be determined by measuring the apparent relative position of the points in the image.

Light Intensity Distribution. A surface will appear darker if it is oriented at an angle other than normal to the light source. Determining orientation based on relative light intensity requires knowledge of the source of illumination as well as the surface characteristics of the object.

Structured light involves the use of a light pattern rather than a diffused light source. The workpiece is illuminated by the structured light, and the way in which the pattern is distorted by the part can be used to determine both the three-dimensional shape and the orientation of the part.

Object Position Defined by Relative Motion. Certain operations, such as tracking or part insertion, may require the vision system to follow the motion of an object. This is a difficult task that requires a series of image frames to be compared for relative changes in position during specified time intervals. Motion in one dimension, as in the case of a moving conveyor of parts, is the least complicated motion to detect. In two dimensions, motion may consist of both a rotational and a translational component. In three dimensions, a total of six motion components (three rotational axes and three translational axes) may need to be defined.

Feature Extraction. One of the useful approaches to image interpretation is analysis of the fundamental geometric properties of two-dimensional images. Parts tend to have distinct shapes that can be recognized on the basis of elementary features. These distinguishing features are often simple enough to allow identification independent of the orientation of the part. For example, if surface area (number of pixels) is the only feature needed for differentiating the parts, then orientation of the part is not important. For more complex three-dimensional objects, additional geometric properties may need to be determined, including descriptions of various image segments. The process of defining these elementary properties of the image is often referred to as feature extraction. The first step is to determine boundary locations and to segment the image into distinct regions. Next, certain geometric properties of these regions are determined. Finally, these image regions are organized in a structure describing their relationship.

Light Intensity Variations. One of the most sophisticated and potentially useful approaches to machine vision is the interpretation of an image based on the difference intensity of light in different regions. Many of the features described above are used in vision systems to create two-dimensional interpretations of images. However, analysis of subtle changes in shadings over the image can add a great deal of information about the three-dimensional nature of the object. The problem is that most machine vision techniques are not capable of dealing with the complex patterns formed by varying conditions of illuminations, surface texture and color, and surface orientation.

Another, more fundamental difficulty is that image intensities can change drastically with relatively modest variations in illumination or surface condition. Systems that attempt to match the gray-level values of each pixel to a stored model can easily suffer a deterioration in performance in real-world manufacturing environments. The use of such geometric features such as edges or boundaries is therefore likely to remain the preferred approach. Even better approaches are likely to result from research being performed on various techniques for determining surface shapes from relative intensity levels. One approach, for example, assumes that the light intensity at a given point on the surface of an object can be precisely determined by an equation describing the nature and location of the light source, the orientation of the surface at the point, and the reflectivity of the surface.

Image Interpretation

When the system has completed the process of analyzing image features, some conclusions must be drawn with regard to the findings, such as the verification that a part is or is not present, the identification of an object based on recognition of its image, or the determination that certain parameters of the object fall within acceptable limits. Based on these conclusions, certain decisions can then be made regarding the object or the production process. These conclusions are formed by comparing the results of the analysis with a prestored set of standard criteria. These standard criteria described the expected characteristics of the image and are developed either through a programmed model of the image or by building an average profile of previously examined objects.

Statistical Approach. In the simplest case of a binary system, the process of comparing an image with standard criteria, may simply require that all white and black pixels within a certain area be counted. Once the image is segmented (windowed), all groups of black pixels within each segment that are connected (called blobs) are identified and counted. The same process is followed for groups of white pixels (called holes).

The blobs, holes, and pixels are counted and the total quantity is compared with expected numbers to determine how closely the real image matches the standard image. If the numbers are within a certain percentage of each other, it can be assumed that there is a match.

An example of the statistical approach to image interpretation is the identification of a part on the basis of a known outline, such as the center hole of a washer. As illustrated in Fig. 8, a sample 3×3 pixel window can be used to locate the hole of the washer and to distinguish the washer from other distinctly different washers. The dark pixels shown in Fig. 8(a) represent the rough shape of the washer. When the window is centered on the shape, all nine pixels are assigned a value of 0 (white). In Fig. 8(b), a defective washer appears, with the hole skewed to the right. Because the window counts only six white pixels, it can be assumed that the hole is incorrectly formed. In Fig. 8(c), a second washer category is introduced, one with a smaller hole. In this case, only five white pixels are counted, which is enough information to identify the washer as a different type. In Fig. 8(d), a third washer is inspected, one that is larger than the first. The window counts nine white pixels, as in Fig. 8(a). In this case, some ambiguity remains, and so additional information would be required, such as the use of a 5×5 window. Another approach is to count all the black pixels rather than the white ones.

Fig. 8 Examples of the binary interpretation of washers using windowing. (a) Standard washer (9 pixels in window). (b) Washer with off-center hole (6 pixels in window). (c) Washer with small hole (5 white pixels in window). (d) Large washer (9 white pixels in window; need larger window). Source: Ref 1 (Tech Tran Consultants, Inc.)

Such simple methods are finding useful applications in manufacturing because of the controlled, structured nature of most manufacturing environments. The extent of the analysis required for part recognition depends on both the complexity of the image and the goal of the analysis. In a manufacturing situation, the complexity of the image is often greatly reduced by controlling such factors as illumination, part location, and part orientation. The goal of the analysis is simplified when parts have easily identifiable features, as in the example of the washer.

Much more sophisticated image analysis techniques will be required for machine vision systems to achieve widespread usage. A major reason for using a vision system is to eliminate the need for elaborate jigs and fixtures. A sophisticated vision system can offer a great deal of flexibility by reducing the amount of structure required in presenting parts for inspection, but as structure is reduced, the relative complexity of the image increases (that is, the degree of ambiguity increases). This includes such additional complexities as overlapping parts, randomly aligned parts, and parts that are distinguishable only on the basis of differences in surface features.

Gray-Scale Image Interpretation Versus Algorithms. There are two general ways in which image interpretation capabilities are being improved in vision systems. The first is gray-scale image interpretation, and the second is the use of various algorithms for the complex analysis of image data. The use of gray-scale image analysis greatly increases the quality of the data available for interpreting an image. The use of advanced data analysis algorithms (see Table 3) improves the way in which the data are interpreted. Both of these approaches allow the interpretation of much more complex images than the simple washer inspection example described above. However, even gray-scale image analysis and sophisticated data analysis algorithms do not provide absolute interpretation of images.

Table 3 Typical software library of object location and recognition algorithms available from one machine vision system supplier

Tool	Function	Applications
Search	Locates complex objects and features	Fine alignment, inspection, gaging, guidance
Auto-train	Automatically selects alignment targets	Wafer and PCB alignment without operator involvement
Scene angle finder	Measures angle of dominant linear patterns	Coarse object alignment, measuring code angle for reading
Polar coordinate vision	Measures angle; handles circular images	Locating unoriented parts, inspecting and reading circular parts
Inspect	Performs Stanford Research Institute (SRI) feature extraction (blob analysis)	Locating unoriented parts, defect analysis, sorting, inspection
Histograms	Calculates intensity profile	Presence/absence detection, simple inspection
Projection tools	Collapses 2-dimensional images into 1-dimensional images	Simple gaging and object finding
Character recognition	Reads and verifies alphanumeric codes	Part tracking, date/lot code verification
Image processing library	Filters and transforms images	Image enhancement, rotation, background filtering
V compiler	Compiles C language functions incrementally	All
Programming utilities	Handles errors, aids debugging	All
System utilities	Acquires images, outputs results, draws graphics	All
C library	Performs mathematics, creates reports and menus	All

Source: Cognex Corporation

Machine vision deals in probabilities, and the goal is to achieve a probability of correct interpretation as close to 100% as possible. In complex situations, human vision is vastly superior to machine systems. However, in many simple manufacturing operations, where inspection is performed over long periods of time, the overall percentage of correct conclusions can be higher for machines than for humans, who are subject to fatigue.

The two most commonly used methods of interpreting images are feature weighting and template matching. These methods are described and compared below.

Feature Weighting. In cases in which several image features must be measured to interpret an image, a simple factor weighting method can be used to consider the relative contribution of each feature to the analysis. For example, the image area alone may not be sufficient to ensure the positive identification of a particular valve stem in a group of valve stems of various sizes. The measurement of height and the determination of the centroid of the image may add some additional information. Each feature would be compared with a standard for a goodness-of-fit measurement. Features that are known to be the most likely indicators of a match would be weighted more than others. A weighted total goodness-of-fit score could then be determined to indicate the likelihood that the object has been correctly identified.

Template Matching. In this method, a mask is electronically generated to match a standard image of an object. When the system inspects other objects in an attempt to recognize them, it aligns the image of each object with that of the standard object. In the case of a perfect match, all pixels would align perfectly. If the objects are not precisely the same, some pixels will fall outside of the standard image. The percentage of pixels in two images that match is a measure of the goodness-of-fit. A threshold value can then be assigned to test for pass (positive match) or reject (no match) mode. A probability factor, which presents the degree of confidence with which a correct interpretation has been made, is normally calculated, along with the go/no-go conclusions.

Variations on these two approaches are used in most commercially available vision systems. Although conceptually simple, they can yield powerful results in a variety of manufacturing applications requiring the identification of two-dimensional parts with well-defined silhouettes.

With either method, a preliminary session is usually held before the machine is put into use. During this session, several sample known parts are presented to the machine for analysis. The part features are stored and updated as each part is presented, until the machine is familiar with the part. Then, the actual production parts are studied by comparison with this stored model of a standard part.

Mathematical Modeling. Although model building, or programming, is generally accomplished by presenting a known sample object to the machine for analysis, it is also possible to create a mathematical model describing the expected image. This is generally applicable for objects that have well-defined shapes, such as rectangles or circles, especially if the descriptive data already exist in an off-line data base for computer-aided design and manufacture (CAD/CAM). For example, the geometry of a rectangular machined part with several circular holes of known diameters and locations can be readily programmed. Because more complex shapes may be difficult to describe mathematically, it may be easier to teach the machine by allowing it to analyze a sample part. Most commercial systems include standard image-processing software for calculating basic image features and comparing with models. However, custom programming for model generation can be designed either by the purchaser or by the vision system supplier. Off-line programming is likely to become increasingly popular as CAD/CAM interface methods improve.

Although the techniques described above apply to many, if not most, of the machine vision systems that are commercially available, there are still other approaches being used by some suppliers, particularly for special-purpose systems for such applications as printed circuit board (PCB) inspection, weld seam tracking, robot guidance and control, and inspection of microelectronic devices and tooling. These special-purpose systems often incorporate unique image analysis and interpretation techniques that exploit the constraints inherent in the applications.

For example, some PCB inspection systems employ image analysis algorithms based on design rules rather than feature weighting or template matching. In the design rule approach, the inspection process is based on known characteristics of a good product. For PCBs, this would include minimum conductor width and spacing between conductors. Also, each conductor should end with a solder pad if the board is correct. If these rules are not complied with, then the product is rejected.

Interfacing

A machine vision system will rarely be used without some form of interaction with other factory equipment, such as CAD/CAM devices, robots, or host computers. This interaction is the final element of the machine vision process, in which conclusions about the image are translated into actions. In some cases, the final action may take the form of cumulative storage of information in a host computer, such as counting the number of parts in various categories for inventory control. In other situations, a final action may be a specific motion, such as the transfer of parts into different conveyors, depending on their characteristics. Vision systems are being increasingly used for control purposes through the combination of vision systems and robots. In this case, the vision system greatly expands the flexibility of the robot.

For most applications, interfacing a machine vision system with other equipment is a straightforward task. Most systems are equipped with a number of input and output ports, including a standard RS232C interface. Connecting a vision system to a robot, however, is much more complicated because of timing constraints, data formats, and the inability of most robot controllers to handle vision system inputs. To overcome this problem, several robot and vision system manufacturers have developed integrated system capabilities.

Machine Vision Applications

Machine vision systems can be considered for use in most manufacturing applications in which human vision is currently required. Human vision is required for applications in which noncontact feedback is used to provide information about a production process or a part. For example, a human welder or machinist uses visual feedback to ensure that the correct relationship is maintained between the tool and the workpiece. Human assemblers visually analyze the position of parts so that other parts can be correctly aligned for insertion or some other form of mating. Quality control inspectors visually check products or parts to ensure that there are no defects, such as missing parts, damage, or incorrect location of various features.

As discussed previously, the primary strength of human vision is its ability to analyze qualitative aspects of an object or a scene. However, humans are not particularly adept at measuring quantitative data. For example, although human vision uses a sophisticated approach for depth perception that allows it to correctly determine the relative distances of objects, it is not able to measure a specific distance to an object other than as a very rough estimate. In addition, human vision can measure dimensions only approximately. Humans must rely on some standard frame of reference for judging an object. A standard retained in the memory does not provide a very good frame of reference from which to make quantitative measurements. It is not absolute, and it will vary from individual to individual. Because humans are also subject to fatigue, the interpretation of a standard may change over time.

Machine vision systems are ideally suited to a number of applications in which their ability to interpret images consistently over long periods of time makes them perform better than humans. Machine vision systems are also beginning to be used in many new and unique applications that simply did not exist previously. This includes, for example, on-line inspections that were not economically feasible before and the use of machine vision to increase manufacturing flexibility and reduce dependence on expensive hard tooling. The net result is both improved product quality and lower production costs.

In deciding whether or not machine vision will be effective in a particular application, the user must consider the capabilities of machine vision versus the requirements of the application. Although many applications are suitable for automated vision sensing, there are several complex applications in which the sophisticated recognition capability of human vision is better, such as the inspection of certain complex three-dimensional objects.

In general, machine vision systems are suitable for use in three categories of manufacturing applications:

- Visual inspection of a variety of parts, subassemblies, and finished products to ensure that certain standards are met
- Identification of parts by sorting them into groups
- Guidance and control applications, such as controlling the motion of a robot manipulator

Examples of each of these three areas are listed in Table 4. Figure 9 shows the percentage breakdown of each of these three categories, as well as miscellaneous applications, on the basis of the number of machine vision units purchased in 1984.

Table 4 Typical applications of machine vision systems

Area	Applications
Visual inspection	Measurement of length, width, and area
	Measurement of hole diameter and position
	Inspection of part profile and contour
	Crack detection
	On-line inspection of assemblies
	Verification of part features
	Inspection of surface finish
Part identification	Optical character recognition
	Identification of parts for spray painting
	Conveyor belt part sorting
	Bin picking
	Keyboard and display verification
Guidance and control	Vision-assisted robot assembly
	Vision-assisted robot material handling
	Weld seam tracking
	Part orientation and alignment systems
	Determining part position and orientation
	Monitoring high-speed packaging equipment

Visual Inspection

The ability of an automated vision system to recognize well-defined patterns and to determine if these patterns match those stored in the memory of the system makes it ideal for the inspection of parts, assemblies, containers, and labels. Two types of inspection can be performed by vision systems: quantitative and qualitative. Quantitative inspection is the verification that measurable quantities, such as dimensional measurements or numbers of holes, fall within desired ranges of tolerance. Qualitative inspection is the verification that certain components or properties, such as defects, missing parts, extraneous components, or misaligned parts, are present and located in a certain position. The output from a machine vision inspection task is normally a pass/reject evaluation for the object being inspected, although actual measurement data may also be an output for statistical process control and record-keeping purposes.

Visual inspection represents one of the last manufacturing areas in which automation techniques have been employed. Most visual inspection is performed manually, either by simple observation or by using a measurement tool, such as an optical comparator. One major advantage of using machine vision systems in place of human inspectors is that machine vision systems can perform 100% on-line inspection of parts at high speeds, possibly in working environments that are

unpleasant for humans. Human workers are susceptible to fatigue and boredom and require periodic rest periods, while machine vision systems can operate with consistent results over prolonged periods of time. As a result, while human inspectors can anticipate only an 85 to 90% rate of accuracy in many situations, machine vision systems can achieve close to a 100% accuracy rate.

The objects for which vision systems are being used or considered for use in inspection applications include raw materials, machined parts (Fig. 10), assemblies, finished products, containers, labels, and markings. Vision systems have been considered for use with parts or products that have very simple geometries as well as those with very complex geometries, such as aerospace body frames or engine castings.

Fig. 10 Machine vision inspection of an automotive fuel sender tube with a cycle time of 2 s per part. (d) Screen display of dimension C-C. Courtesy of Industrial Systems Division, Ball Corporation.

One technique applicable to the inspection of simple geometries is polar coordinate vision (Fig. 11). This technique can be used to read codes, inspect components, and measure angles in both circular and rectangular-shaped workpieces (Fig. 12). A polar coordinate vision system, can, for example, verify the existence and location of components such as rollers in a bearing assembly in less than $\frac{1}{8}$ s as described in Fig. 13.

Fig. 11 Steps involved in a polar coordinate transformation. (a) Original system positioned in a Cartesian coordinate system. (b) Same image in a polar coordinate system. (c) A polar transformed image, cut at 0° and unwrapped. Courtesy of Cognex Corporation

Fig. 12 Typical applications of polar coordinate vision. (a) Reading codes printed around an arc. (b) Inspecting circular objects like ball bearing assemblies. (c) Measuring the angle of complex objects such as semiconductor dies. Courtesy of Cognex Corporation

Fig. 13 Polar coordinate vision used to inspect roller bearing assemblies by verification of roller placement. (a) Actual machine vision monitor image of two bearing assemblies on a conveyor belt. (b) First step, requiring <70 ms, is to locate bearing within the image as indicated by the crosshair and square that show x-y position of each assembly. (c) Polar coordinate transformation, requiring <50 ms, of the annulus containing the roller yields the rectangular image shown at the top of the display to aid in the interpretation of the components. (d) System displays complete inspection results by indicating the location of the missing rollers (enclosed in black squares) as well as those rollers correctly positioned (enclosed in white squares) and also specifies which assemblies have passed or failed inspection. Total processing time, which includes part location, image transformation, and roller counting, is <125 ms. Courtesy of Cognex Corporation

Polar coordinate vision can be used in a variety of applications in which the features of interest are arranged radially, such as ball bearings held in a circular assembly (Fig. 12 and 13). Polar coordinate vision consists of two major modules. The first module transforms the Cartesian images described in (x,y) coordinates into polar images, that is, it expresses the same information in (r,ϕ) coordinates. When a transformed image is subsequently analyzed by other vision tools, these tools treat the pixel data just as if it were expressed in (x,y) coordinates. The effect of treating a polar image as if it were a Cartesian image can be visualized as cutting a ring and unwrapping it into a bar. The second module measures the angle of the complex scene and searches for this polar model within the polar image to obtain the ϕ position that provides the best model/image match and then reports this ϕ value as the object's angle.

Machine vision systems are also being used by almost every manufacturing industry inspecting a wide variety of parts and assemblies, including glass containers and textiles, machine parts, microelectronics and PCBs, stampings (Fig. 14) and forgings, fasteners and gears, and pharmaceuticals and food products.

Fig. 14 Robot-based noncontact measuring system shown gaging a sheet metal automotive fender held in a fixture. Fit (gap and flushness) are measured by means of optical triangulation. Courtesy of Diffracto Limited

The advantage of using machine vision for low-volume, complex parts is that it is generally both faster and less error prone than human inspection. A complex part may require hundreds of measurements, which must be performed in a logical sequence to avoid missing any steps. The same qualities that make machine vision suitable for high-volume production applications also make it suitable for parts with a large number of features to be inspected.

Inspection tasks are generally more concerned with verifying the presence of or measuring a workpiece than with the actual recognition of objects. Therefore, the most useful vision system capabilities for inspection applications include the ability to segment images by forming edges and the ability to measure the geometric features of these images and segments. Two-dimensional images are generally used to perform these functions. Of the three performance criteria considered here, the most important for visual inspection is the ability to perform the task at high speed.

Visual inspection of all types, including quantitative and qualitative inspection, has been estimated to account for about 10% of the total labor cost of all manufactured durable goods. This excessively high percentage can be significantly reduced when machine vision is employed. Along with lower cost, the quality of the final product can also be increased.

Part Identification

The most fundamental use for a machine vision system is the recognition of an object from its image. Inspection deals with the examination of object characteristics without necessarily requiring that the objects be identified. In part recognition, however, it is necessary to make a positive identification of an object and then to make a decision based on that knowledge. Generally, the decision involves some form of a categorization of the object into one of several groups. This categorization can be in the form of information, such as categories of inventories to be monitored (Fig. 15, 16, and

17), or it can be in a physical form, as in the placement of parts on different conveyor belts, depending on their characteristics.

Fig. 15 Monitor screen of a machine vision inspection system verifying the expiration date and lot code on a pharmaceutical bottle. Courtesy of Cognex Corporation

Fig. 16 Machine vision system reading box labels for sortation in a shipping facility. Courtesy of Cognex Corporation

Fig. 17 Machine vision used to read part numbers engraved on semiconductor wafers in order to expedite work

tracking of components. Courtesy of Cognex Corporation

The process of part identification generally requires strong geometric feature interpretation capabilities because most manufacturing applications allow part differentiation on the basis of differences in silhouette shapes (Fig. 18). As in the inspection applications, processing speed is generally more important than resolution or discrimination ability. Recognition applications often require an interface capability with some form of part-handling equipment, such as an industrial robot.

Fig. 18 Machine vision system that controls a multiple-programmed cam grinder being used to identify each specific automotive camshaft to determine machine settings. Courtesy of Industrial Automation Systems, Gould, Inc.

Guidance and Control

One of the basic limitations of industrial robots in such applications as assembly, machining, welding, or other process-oriented operations is that feedback capabilities are limited. In these applications, parts must be continuously monitored and positioned relative to other parts with a high degree of precision. In some applications, such as bolt tightening, a force feedback capability may be required to determine when the operation should cease. In many other applications, a vision system can be a powerful tool for controlling production operations when combined with other forms of automated equipment.

These guidance and control applications tend to require advanced machine vision system capabilities. Because of the need to determine spatial relationships among objects, the ability to measure distance is often important (Fig. 19), along with the ability to measure the orientation and geometric shape of an object (Fig. 20). In addition, an ideal vision system would allow three-dimensional interpretation of images. Finally, the precise positioning requirements of these tasks means that a high degree of image resolution is desirable.

Fig. 19 Adaptive robotic arc welding of automotive bodies using a three-dimensional vision system for seam tracking and measurement of seam width depth. Additional Applications

As machine vision technology evolves and becomes more widely used within industry, additional applications are beginning to emerge. Many of these applications represent special-purpose equipment that has been designed to satisfy a particular need, while others combine two or more of the previously mentioned functions (visual inspection, part identification, and guidance and control). For example, the system shown in Fig. 21 can inspect as well as sort various fasteners and similar multiple-diameter parts. Still other applications reflect machine vision systems that are incorporated into other equipment.

Fig. 21 Noncontact digital computer-vision-based fastener inspection system used to gage and then sort parts. Unit measures 11 parameters for up to 24 different fasteners that are stored in a memory and is capable of sorting up to 180 parts per minute or over 10,000 parts per hour. Courtesy of Diffracto Limited

Special-Purpose Systems. In the future, special-purpose systems are likely to represent a large, if not the largest, use of machine vision technology. One of the best examples of this type of system is equipment for inspecting PCBs. A number of companies have either developed or are in the process of developing such systems, which are expected to be widely used by the end of the decade. Similar special-purpose equipment is entering the market for the inspection of thick-film substrates and circuits, surface-mounted devices, and photolithographic artwork.

Embedded Technology. In the embedded technology are, one of the major uses of machine vision is mask alignment for the production of microelectronic devices. Similarly, vision technology is also becoming widely used for controlling other microelectronic fabrication equipment, such as the automation of wire-bonding machines for connecting integrated circuits to their case. In the future, these two thrusts--special-purpose systems and embedded vision technology--should result in numerous applications unheard of today.

Machine Vision and Robotic Inspection Systems

John D. Meyer, Tech Tran Consultants, Inc.

Future Outlook

The potential for using machine vision in manufacturing applications is enormous. Many inspection operations that are now performed manually could be automated by machine vision, resulting in both reduced costs and improved product quality. However, before machine vision can reach its full potential, several basic improvements in the technology must be made.

Limitations of Current Systems

At the present time, there are six key issues that must be addressed by vision system developers. Many organizations are attempting to resolve these issues through such developments as improved computer hardware or improved software algorithms, but much work remains to be done to develop effective vision systems that are available at a reasonable cost. The following issues represent basic limitations of commercial vision systems:

- Limited 3-D interpretation
- Limited interpretation of surfaces
- Need for structured environment
- Long processing time
- High cost
- Excessive applications engineering

Limited 3-D Interpretation. Most commercial vision systems are two dimensional; that is, they make conclusions about objects from data that are essentially two-dimensional in nature. In many manufacturing situations, an outline of the shape of an object is sufficient to identify it or to determine whether an inspection standard has been achieved. However, in many other operations, such as the inspection of castings, this information is not sufficient. Many more sophisticated operations could be performed with vision systems if the three-dimensional shape of an object could be inferred from an image or a series of images. To accomplish this, vision system suppliers will need to incorporate more sophisticated data interpretation algorithms along with improved system performance (resolution, speed, and discrimination).

Limited Interpretation of Surfaces. Complex surface configurations on objects, such as textures, shadows, and overlapping parts, are difficult for vision systems to interpret. Improved gray-scale image formation capabilities have helped somewhat, but vision systems are extremely limited in their ability to analyze the large amounts of data provided by gray-scale image formation. The ability to accurately interpret light intensity variations over the surface of an object, which is so fundamental to human vision, must be refined if vision systems are to be used for such applications as object recognition or inspection from surface characteristics.

Need for Structured Environment. Although vision systems, being a form of flexible automation, should be able to eliminate the need for elaborate jigs and fixtures, they still require a relatively orderly environment in most current applications. Vision systems have difficulty dealing with overlapping or touching parts; therefore, workpieces must be presented one at a time to the system. Ideally, a vision system should be able to examine parts as humans do--by studying key features no matter how the part is oriented and even if some portions of the parts are obstructed by other overlapping parts.

Long Processing Time. There are constraints on the speed of the manufacturing operation in which a vision system can be used. Only a limited number of real-time (30 images per second) systems have begun to appear on the market. However, most real-time systems are used for simple applications rather than more complex tasks. There is generally a trade-off between the processing time required and the degree of complexity of a processing cycle. An ideal vision system would be capable of performing complex three-dimensional analyses of objects, including surface features, in real time.

High Cost. Although payback periods for vision systems are generally good (1 year or less for some applications), the basic purchase price of many systems is still prohibitively high to promote widespread use of this technology within the manufacturing industry.

Extensive Applications Engineering. It is still nearly impossible to purchase an off-the-shelf vision system and apply it without considerable assistance from a vendor, consultant, or in-house engineering staff. This is partly due to the complexity of real-world applications. Other factors include the limitations of current equipment and the lack of trained personnel within user organizations. Application engineering cost and risk and a shortage of trained technical personnel are major barriers to widespread use of industrial vision systems.

Future Developments

Many developmental programs are underway, both in private industry as well as in universities and other research organizations, to develop advanced vision systems that are not subject to the limitations discussed previously.

The solution to these problems is likely to emerge from several important developments expected to occur during the next decade; these developments are discussed in the following sections. However even if no further improvements are made in machine vision systems, the number of systems in use would continue to grow rapidly. Machine vision systems are beginning to be introduced into applications for which they previously would have not even been considered, because of the complexity of the manufacturing process.

Improved Camera Resolution. As solid-state cameras with arrays of 512×512 or even 1024×1024 pixels are used, image resolution will improve. As a result, the ability of vision systems to sense small features on the surfaces of objects should also improve.

Ability to Sense Color. A few developmental vision systems are already available that sense color. The addition of this capability to commercial vision systems would allow the measurement of one more feature in identifying objects. It would also provide a greater degree of discrimination in analyzing surfaces.

Effective Range Sensing. This is a prerequisite for three-dimensional interpretation and for certain types of robot vision. Based on research such as that being performed on binocular vision, it is likely that a range-sensing capability will become a standard feature of commercial vision systems within a few years.

Ability to Detect Overlap. This capability will approve the ability of vision systems to interpret surfaces and three-dimensional objects. It will also provide a greater degree of flexibility for vision systems. There will no longer be a need to ensure that moving parts on a conveyor are not touching or overlapping, and this will reduce the amount of structure required.

Improved Gray-Scale Algorithms. As vision system hardware becomes capable of forming more complex images, the software algorithms for interpreting these images will improve, including the ability to infer shape from changes in light intensity over an image.

Robot Wrist-Mounted Vision System. Based on work being performed at a number of organizations, it is likely that an effective wrist-mounted vision system will be available within the next few years. Mounting the camera on the robot's wrist provides the advantage of greatly reducing the degree of structure required during such operations as robot-controlled welding, assembly, or processing.

Motion-Sensing Capability. There are two elements being developed in this area. First is the ability of a vision system to create and analyze an image of a moving object. This requires the ability to freeze each frame without blurring for analysis by the computer. Second is the more complex problem of determining the direction of motion of an object and even the magnitude of the velocity. This capability will be valuable in such applications as collision avoidance or tracking moving parts.

Parallel Processing of Whole Image. One of the most promising methods of approaching a real-time processing capability is the use of a parallel processing architecture. Several systems currently on the market offer this type of architecture. This approach is likely to be used more extensively in the future.

Standardized Software Algorithms. Although some standard vision system application algorithms are available, most programs for current manufacturing applications are custom designed. It is likely that standard programs will become increasingly available for standard application. In addition, programming languages will continue to become more user oriented.

Computers Developed Specifically for Vision Systems. Most vision systems today use standard off-the-shelf computers, which tends to limit the data analysis capabilities of the vision system. In the future, especially as sales volumes increase, it is likely that computers will be designed specifically for dedicated use with a vision system. This will reduce processing times and help to reduce system prices. Several systems have been developed with this type of custom computer architecture.

Hard-Wired Vision Systems. To overcome the problem of processing speed, some researchers have suggested the use of hard-wired circuitry rather than microprocessor-based systems. This would significantly speed up image processing times, but may result in less system flexibility and limited capabilities.

Special-Purpose Systems. As discussed previously, there is a growing trend toward special-purpose, rather than general-purpose, vision systems. This permits the system developer to take advantage of prior knowledge concerning the application and to provide only the features and capabilities required, resulting in more cost-effective systems. A number of vendors have already begun to offer special-purpose systems for such applications as weld seam tracking, robot vision, and PCB inspection.

Integration with Other Systems. One of the major problems with the current vision systems is the difficulty in interfacing them with other types of equipment and systems. A number of companies and research organizations are attacking this problem, particularly with respect to special-purpose vision systems.

Optical Computing. It is possible to perform image processing using purely optical techniques, as opposed to the traditional approach of converting an image into an electrical signal and analyzing this symbolic representation of the image. In the optical domain, processing steps such as the computation of Fourier transforms take place almost instantaneously. Although optical computing techniques offer considerable promise, it will take a number of years before they become a practical reality.

Custom Microelectronic Devices. As the sales volume for vision systems continues to grow, it will become increasingly feasible to implement portions of the system design in custom microelectronic circuits. This will be particularly true for low-level image-processing functions, such as histogram calculations, convolutions, and edge detectors. Such chips should be available within the next few years.

Innovative Sensor Configurations. A number of researchers are working on unique vision sensors to improve overall performance. This includes novel sensor configurations, such as annular arrangements of detector elements, as well as other camera concepts, such as multiple spectral detectors that sense energy in more than one portion of the electromagnetic spectrum.

Visual Servoing. Several researchers are studying the use of vision systems as an integral feedback component in a motion control system, such as a robot vision system for positioning the manipulator arm. Although vision systems are currently used for robot guidance and control, this is usually accomplished outside the control loop. In visual servoing, on the other hand, the vision system would serve as a position-sensing device or error measurement component on a real-time basis.

Introduction

NONDESTRUCTIVE EVALUATION (NDE) comprises many terms used to describe various activities within the field. Some of these terms are nondestructive testing (NDT), nondestructive inspection (NDI), and nondestructive examination (which has been called NDE, but should probably be called NDEx). These activities include testing, inspection, and examination, which are similar in that they primarily involve looking at (or through) or measuring something about an object to determine some characteristic of the object or to determine whether the object contains irregularities, discontinuities, or flaws.

The terms irregularity, discontinuity, and flaw can be used interchangeably to mean something that is questionable in the part or assembly, but specifications, codes, and local usage can result in different definitions for these terms. Because these terms all describe what is being sought through testing, inspection, or examination, the term NDE (nondestructive evaluation) has come to include all the activities of NDT, NDI, and NDEx used to find, locate, size, or determine something about the object or flaws and allow the investigator to decide whether or not the object or flaws are acceptable. A flaw that has been evaluated as rejectable is usually termed a defect.

Guide to Nondestructive Evaluation Techniques

Selection of NDE Methods

The selection of a useful NDE method or a combination of NDE methods first necessitates a clear understanding of the problem to be solved. It is then necessary to single out from the various possibilities those NDE methods that are suitable for further consideration; this is done by reviewing the articles in this Volume and in the technical literature.

Several different ways of comparing the selected NDE methods are presented in this article, but there is no completely acceptable system of comparison, because the results are highly dependent on the application. Therefore, it is recommended that a comparison be developed specifically for each NDE area and application. The final validation of any NDE protocol will depend on acceptance tests conducted using appropriate calibration standards.

Nondestructive evaluation can be conveniently divided into nine distinct areas:

- Flaw detection and evaluation
- Leak detection and evaluation
- Metrology (measurement of dimension) and evaluation
- Location determination and evaluation
- Structure or microstructure characterization
- Estimation of mechanical and physical properties
- Stress (strain) and dynamic response determination
- Signature analysis
- Chemical composition determination

Because two of these areas--signature analysis and chemical composition determination--are usually not considered when NDE applications are discussed and are therefore not covered in this Volume, they will not be discussed further. Information on these subjects can, however, be found in *Materials Characterization*, Volume 10 of *ASM Handbook*,

formerly 9th Edition *Metals Handbook*. The remaining seven areas are vastly different and therefore will be covered separately, along with a discussion of the selection of specific NDE methods* for each.

Note cited in this section

- * Throughout this article the term method is used to describe the various nondestructive testing disciplines (for example, ultrasonic testing) within which various test techniques may exist (for example, immersion or contact ultrasonic testing).

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Flaw Detection and Evaluation

Flaw detection is usually considered the most important aspect of NDE. There are many conceivable approaches to selecting NDE methods. One approach is to consider that there are only six primary factors involved in selecting an NDE method(s):

- The reason(s) for performing the NDE
- The type(s) of flaws of interest in the object
- The size and orientation of flaw that is rejectable
- The anticipated location of the flaws of interest in the object
- The size and shape of the object
- The characteristics of the material to be evaluated

The most important question to be answered before an NDE method can be selected is, What is the reason(s) for choosing an NDE procedure? There are a number of possible reasons, such as:

- Determining whether an object is acceptable after each fabrication step; this can be called in-process NDE or in-process inspection
- Determining whether an object is acceptable for final use; this can be called final NDE or final inspection
- Determining whether an existing object already in use is acceptable for continued use; this can be called in-service NDE or in-service inspection

After the reasons for selecting NDE have been established, one must specify which types of flaws are rejectable, the size and orientation of flaws that are rejectable, and the locations of flaws that can cause the object to become rejectable. The type, size, orientation, and location of flaws that will cause a rejection must be determined if possible, using stress analysis and/or fracture mechanics calculations. If definitive calculations are not economically feasible, the type, size, and orientation of flaw that will cause the object to be rejected must be estimated with an appropriate safety factor.

The type, size, orientation, and location of the rejectable flaw are often dictated by a code, standard, or requirement, such as the American Society of Mechanical Engineers Pressure Vessel Code, a Nuclear Regulatory Commission requirement, or the American Welding Society Structural Welding Code. If one of these applies to the object under consideration, the information needed will be available in the appropriate document.

Volumetric and Planar Flaws. Once the size and orientation of the rejectable flaw have been established, it is necessary to determine which types of flaws are rejectable. In general, there are two types of flaws: volumetric and planar. Volumetric flaws can be described by three dimensions or a volume. Table 1 lists some of the various types of

volumetric flaws, along with useful NDE detection methods. Planar flaws are thin in one dimension but larger in the other two dimensions. Table 2 lists some of the various types of planar flaws, along with appropriate NDE detection methods.

Table 1 Volumetric flaw classification and NDE detection methods

Volumetric flaws	
Flaw type	Porosity
	Inclusions
	Slag
	Tungsten Other
NDE method	Shrinkage
	Holes and voids
	Corrosion thinning
	Corrosion pitting
NDE detection methods	
NDE method	Visual (surface)

NDE method	Visual
	Replication microscopy
	Magnetic particle
	Magnetic field

- Eddy current
- Microwave
- Electric current perturbation
- Magabsorption
- Ultrasonic
- Acoustic emission
- Thermography

Flaw Location, Shape, and Size. In addition to classifying flaws as volumetric or planar, it is necessary to consider the locations of the flaws in the object. Flaws can be conveniently classified as surface flaws or as interior flaws that do not intercept the surface. Table 3 lists NDE methods used to detect surface and interior flaws.

Table 3 NDE methods for the detection of surface and interior flaws

Surface

- Visual
- Replica
- Liquid penetrant
- Magnetic particle
- Magnetic field
- Electric current
- Magabsorption
- Eddy current

Interior

- Magnetic particle (limited use)
- Magnetic field
- Electric current perturbation
- Magabsorption
- Eddy current
- Microwave
- Ultrasonic
- Acoustic emission
- Radiography
- X-ray computed tomography
- Neutron radiography
- Thermography (possible)
- Optical holography (possible)
- Acoustic holography (possible)

Two additional factors that affect NDE method selection are the shape and size of the object to be evaluated. Tables 4 and 5 compare NDE techniques for varying size (thickness) and shape.

Table 4 Comparison of NDE methods based on size of object to be evaluated

The thickness or dimension limitation is only approximate because the exact value depends on the specific physical properties of the material being evaluated.

Surface only but independent of size

Visual
Replica
Digital enhancement
Liquid penetrant

Shallow depth or thin object (thickness $\lesssim 1$ mm, or 0.04 in.)

Magnetic particle
Magnetic field
Magabsorption
Eddy current

Increased thickness (thickness $\lesssim 3$ mm, or 0.12 in.)

Microwave
Optical holography
Speckle metrology
Acoustic holography
Acoustic microscopy

Increased thickness (thickness $\lesssim 100$ mm, or 4 in.)

X-ray computed tomography

Increased thickness (thickness $\lesssim 250$ mm, or 10 in.)

Neutron radiography^(a)
X-ray radiography

Thickest (dimension $\lesssim 10$ m, or 33 ft)

Ultrasonic

(a) All NDE methods suitable for thick objects can be used on thin objects, except neutron radiography, which is not useful for most thin objects.

Thermography
Microwave
Eddy current
Magnetic particle
Magnetic field
Magabsorption
Neutron radiography
X-ray radiography
Ultrasonic
Liquid penetrant

Digital enhancement
Replica
Visual
X-ray computed tomography
Most complex shape

The characteristics of the material that may affect NDE method selection are highly dependent on the specific NDE method under consideration. Table 6 lists a number of NDE methods and the characteristic of critical importance for each.

Table 6 NDE methods and their important material characteristics

Method	Characteristic
Liquid penetrant	Flaw must intercept surface.
Magnetic particle	Material must be magnetic.
Eddy current	Material must be electrically conductive or magnetic.
Microwave	Microwave transmission
Radiography and x-ray computed tomography	Changes in thickness, density, and/or elemental composition
Neutron radiography	Changes in thickness, density, and/or elemental composition
Optical holography	Surface optical properties

The specific NDE method can be selected by applying all the previously discussed factors. Because each NDE method has a specific behavior, it is often desirable to select several NDE methods having complementary detection capabilities. For example, ultrasonic and radiographic methods can be used together to ensure the detection of both planar flaws (such as cracks) and volumetric flaws (such as porosity).

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Leak Detection and Evaluation

Because many objects must withstand pressure, the nondestructive determination of leakage is extremely important. The NDE area known as leak detection utilizes many techniques, as described in the article "Leak Testing" in this Volume. Each technique has a specific range of applications, and a particular leak detection technique should be selected only after careful consideration of the factors discussed in the article "Leak Testing".

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Metrology and Evaluation

The measurement of dimensions, referred to as metrology, is one of the most widely used NDE activities, although it is often not considered with other conventional NDE activities, such as flaw detection. Although conventional metrology is not specifically discussed in this Volume, modern high-technology metrology is covered in the articles "Laser Inspection," "Coordinate Measuring Machines," and "Machine Vision and Robotic Evaluation."

The selection of a metrology system is highly dependent on the specific requirements of a given application. Standard reference works on the topic should be consulted for conventional metrology, and the articles "Laser Inspection," "Coordinate Measuring Machines," and "Machine Vision and Robotic Evaluation." should be studied for selecting new technology. In addition, other NDE methods, such as eddy current, ultrasonic, optical holography, and speckle metrology, often find application in the field of metrology. Selection of these methods for metrology application can be assisted by the information in the articles "Eddy Current Inspection," "Ultrasonic Inspection," "Optical Holography," and "Speckle Metrology" in this Volume.

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Location Determination and Evaluation

An occasional problem is whether an assembled unit (one that contains several parts) actually contains the necessary components. This type of inspection has resulted in an NDE activity that can be termed location determination. The most commonly employed NDE techniques for location determination are x-ray radiography, x-ray computed tomography, and neutron radiography. These techniques and their selection are discussed in separate articles in this Volume.

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Structure or Microstructure Characterization

Another interesting area of NDE is microstructural characterization, which can be done *in situ* without damaging the object by using replication microscopy (discussed in the article "Replication Microscopy Techniques for NDE" in this Volume) or by using conventional optical microscopy techniques with portable equipment, including polishing, etching, and microscopic equipment. In addition, it is possible to characterize the microstructure through the correlation with some type of NDE information. For example, the transmission of ultrasonic energy has been correlated with the microstructure of gray cast iron.

Microstructure can often be characterized by determining physical or mechanical properties with NDE techniques because there is usually a correlation among microstructure, properties, and NDE response. Characterizing microstructure from NDE responses is a relatively recent area of NDE application, and new developments are occurring frequently.

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Estimation of Mechanical and Physical Properties

As discussed previously, the prediction of mechanical and physical properties with NDE techniques is a relatively new application of NDE. Eddy current, ultrasonic, x-ray and neutron radiography, computed tomography, thermography, and acoustic microscopy phenomena are affected by microstructure, which can be related to some mechanical or physical properties. In addition, microwave NDE can be related to the properties of plastic materials. Several technical meetings are held each year to discuss advances in NDE, and these meetings often feature session on characterizing microstructure and mechanical and physical properties with NDE techniques. Some of the meetings are listed below:

- Annual Review (every spring), Center for Nondestructive Evaluation, The Johns Hopkins University
- Annual Review of Progress in Quantitative NDE (every summer), The Center for NDE, Iowa State University
- Symposium on Nondestructive Evaluation (every other spring), Nondestructive Testing Information Center, Southwest Research Institute
- Spring and Fall Meetings, American Society for Nondestructive Testing

Guide to Nondestructive Evaluation Techniques

John D. Wood, Lehigh University

Stress/Strain and Dynamic Response Determination

The local strain at a specific location in an object under a specific set of loading conditions can be determined by using strain sensing methods such as photoelastic coatings, brittle coatings, or strain gages. These methods are discussed in the article "Strain Measurement for Stress Analysis" in this Volume. If the stress-strain behavior of the material is known, these strain values can be converted into stress values.

A number of methods have also been developed for measuring residual stresses in materials. These include x-ray diffraction, ultrasonics, and electromagnetics. Surface residual stresses can be measured by x-rays as described in the article "X-Ray Diffraction Residual Stress Techniques" in *Materials Characterization*, Volume 10 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Practical application of ultrasonic techniques for characterizing residual stresses have not yet materialized. A number of electromagnetic techniques have, however, been successfully used as described in the articles "Electromagnetic Techniques for Residual Stress Measurements" and "Magnetic Absorption NDE" in this Volume.

Dynamic behavior of an object can be evaluated during real or simulated service by employing strain sensing technology while the object is being dynamically loaded. In addition, accelerometers and acoustic transducers can be used to determine the dynamic response of a structure while it is being loaded. This dynamic response is called a signature and evaluation of this signature is called signature analysis. The nature of this signature can be correlated with many causes, such as machine noise, vibrations, and structural instability (buckling or cracking).

Replication Microscopy Techniques for NDE

Introduction

SURFACE REPLICATION is a well-developed electron microscopy sample preparation technique that can be used to conduct *in situ* measurements of the microstructure of components. The *in situ* determination of microstructural deterioration and damage of materials subjected to various environments is an objective of any nondestructive evaluation

(NDE) of structural components. The need to assess the condition of power plant and petrochemical metallic components on a large scale recently led to the application of surface replication to the problem of determining remaining life. The usual method of metallographic investigation, which may involve cutting large pieces from the component so that laboratory preparation and examination can be performed, usually renders the component unfit for service or necessitates a costly repair. As a result, metallographic investigations are avoided, and important microstructural information is not available for evaluating the component for satisfactory performance. Therefore, an *in situ* or field microscopy examination is needed to aid in the proper determination of component life.

The replica technique for the examination of surfaces has been extensively used for studying the structure of polished-and-etched specimens and for electron fractographic examination (see the article "Transmission Electron Microscopy" in *Fractography*, Volume 12 of *ASM Handbook*, formerly 9th Edition *Metals Handbook* for a discussion of replication techniques in fractography). Surface replication was the predominant technique in electron microscopy prior to being supplemented by thin-foil transmission and scanning electron microscopy. Recently, the replication microscopy technique has become an important NDE method for microstructural analysis, and an American Society for Testing and Materials specification has been written for its implementation (Ref 1).

Specimen Preparation

Mechanical Polishing Methods. Components in service usually have a well-developed corrosion or oxidation product or a decarburized layer on the surface that must be removed before replication. Coarse-grinding equipment can be used as long as the proper precautions are taken to prevent the introduction of artifacts into the structure due to overheating or plastic deformation. Sandblasting, wire wheels, flap wheels, and abrasive disks have all been used. After the initial preparation steps are completed, standard mechanical polishing techniques can be used. Field equipment is commercially available to help the metallographer reproduce the preparation steps normally followed in the laboratory. Depending on the material, various silicon carbide abrasive disks of different grit size, together with polishing cloth disks with diamond paste or alumina of varying grit size, can be used to prepare for the etching step. Finally, any appropriate etchant for the material being examined can be applied to develop the microstructure. For the proper identification of such microstructural features as creep cavities, a maximum double or triple etch-polish-etch procedure should be used (Ref 2). The etchants used for the various materials investigated by the replication technique are described in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook* and in Ref 3.

Electrolytic Preparation Technique. Although electrolytic polishing and etching techniques have often been employed as the final mechanical polish step in sample preparation, inherent problems still exist in this process. The electropolishing technique uses an electrolytic reaction to remove material to produce a scratch-free surface. This is done by making the specimen the anode in an electrolytic cell. The cathode is connected to the anode through the electrolyte in the cell. Specimens can be either polished or etched, depending on the applied voltage and current density, as seen in the fundamental electropolishing curve in Fig. 1. However, the pitting region must be avoided so that artifacts are not introduced into the microstructure. It is virtually impossible to prevent pitting without precise control of the polishing variables, and pits can often be mistakenly identified as creep voids.

Fig. 1 Current density-voltage curve for electropolishing

Several portable electropolishing units are commercially available. The most important variables (time, bath temperature, electrolyte composition, and the current density-voltage relationship) have been investigated for a selected group of electrolytes (Ref 4). A direct comparison of electropolishing units and the precautions necessary for handling certain electrolytes are given in Ref 5.

It should be noted that there are areas in both fossil and nuclear plants in which neither acid etches nor electropolishing methods and materials are allowed because of the potential for intergranular stress-corrosion cracking. Stainless steel piping in nuclear plants can be replicated to determine defects by manual polishing without etchants. Generator retaining rings have been replicated by manual polishing to resolve NDE indications, because they are extremely sensitive to stress-corrosion cracking and no acids or caustics are allowed to be used (Ref 6).

Replication Techniques

Replication techniques can be classified as either surface replication or extraction replication. Surface replicas provided an image of the surface topography of a specimen, while extraction replicas lift particles from the specimen. The advantages and disadvantages of some typical replication techniques are given in Table 1.

Table 1 Comparison of replica techniques

Type	Advantages	Disadvantages
Surface replicas		
Acetate	Excellent resolution	Coating required
Acrylic	Direct viewing	Adhesion
Rubber	Easy removal	Resolution
Extraction replicas		
Direct stripped plastic	Easy preparation	Particle retention
Positive carbon	Excellent particle retention with two-stage etching	Coating required
Direct carbon	Excellent resolution	Not applicable to <i>in situ</i> studies

Surface Replicas. Replication of a surface can involve either direct or indirect methods. In the direct, or single-stage, method, a replica is made of the specimen surface and subsequently examined in the microscope, while in the indirect method, the final replica is taken from an earlier primary replica of the specimen surface. Only the direct method will be considered in this article because it lends itself more favorably to on-site preparation. The most extensively used direct methods involve plastic, carbon, or oxide replica material. All direct methods except plastic methods are destructive and therefore require further preparation of the specimen before making additional replicas.

Plastic replicas lend themselves to in-plant nondestructive examination because of their relative simplicity and short preparation time. Plastic replicas can be examined with the light optical microscope, the scanning electron microscope, and the transmission electron microscope, depending on the resolution required. As illustrated in Fig. 2, the plastic replica technique involves softening a plastic film in a solvent, applying it to the surface, and then allowing it to harden as the solvent evaporates. After careful removal from the surface, the plastic film contains a negative image, or replica, of the microstructure that can be directly examined in the light microscope or, after some preparation, in the electron microscope. Double-faced tape is used to bond the replica to the glass slide in order to obtain large, flat, undistorted replica surfaces.

Fig. 2 Schematic of the plastic replica technique

There are some significant advantages of the replica technique over the use of portable microscopes in the field (Ref 5):

- A permanent record of the specimen is obtained
- Better resolution and higher magnification can be used
- Contamination of the polished surface is minimized
- Time spent in an unpleasant or hazardous environment is minimized
- Scanning electron microscopy can be utilized

Several materials, including acetate, acrylic resin, and rubber, can be used in the surface replica technique (Ref 5). The choice of material depends on the geometry of the component and the microstructural features to be examined.

In the acetate method, an acetate tape is wetted with acetone and applied to the surface; other less volatile solvents, such as methyl acetate, can be used when large areas are replicated. For improved resolution, the back side of the replica can be painted with any fast-drying black paint or ink prior to removal, or for the same effect, evaporated coatings of carbon, aluminum, or gold can be applied at a shadow angle of 45° to the front side of the replica after removal.

In the acrylic casting resin method, dams are required because a powder is mixed with a liquid on the surface to be replicated. After hardening, the replica can be examined directly in an optical microscope without further processing. If adhesion is a problem, a composite replica can be made of an initial layer of Parlodian lacquer before the acrylic layer is applied.

In the dental impression rubber method, uncured liquid rubber material (for example, GE RTV60 silicon rubber compound) is poured onto the surface to be replicated and is contained by a dam. After removal, the replica can be examined directly or can be coated for better resolution.

Extraction Replicas. Several different extraction replica techniques can be used to characterize small particles that are embedded in a matrix, such as small second-phase particles in a steel (see the article "Analytical Transmission Electron Microscopy" in *Materials Characterization*, Volume 10 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). More detailed descriptions of the various extraction replica techniques can be found in Ref 7 and 8.

After careful preparation of the surface using normal polishing methods, the first step in producing an extraction replica is to etch the alloy heavily to leave the particles of interest in relief. In the positive carbon extraction replica, as shown in Fig. 3, a piece of solvent-softened polymeric film (cellulose acetate tape) is pressed onto the surface exposed by this first etch (Ref 5). Once the solvent has evaporated, one of two steps can be taken. The tape can be carefully pulled from the specimen to produce a negative of the surface, or the specimen can undergo a second etch to free the particles exposed by the first etch (Fig. 3). In the second etch, the specimen can be etched through the plastic; most plastics are quite permeable to etching solutions, and the specimen etches almost as rapidly as without the plastic film (Ref 9). Carbon is then evaporated in a vacuum onto the plastic replica. The carbon and plastic containing the particles now make up the positive replica. The cellulose acetate is then dissolved, and the positive carbon replica is allowed to dry. It should be noted that for the negative carbon extraction replica technique, vacuum deposition of carbon onto the surface of the specimen is required, and therefore this replica method is not applicable to NDE.

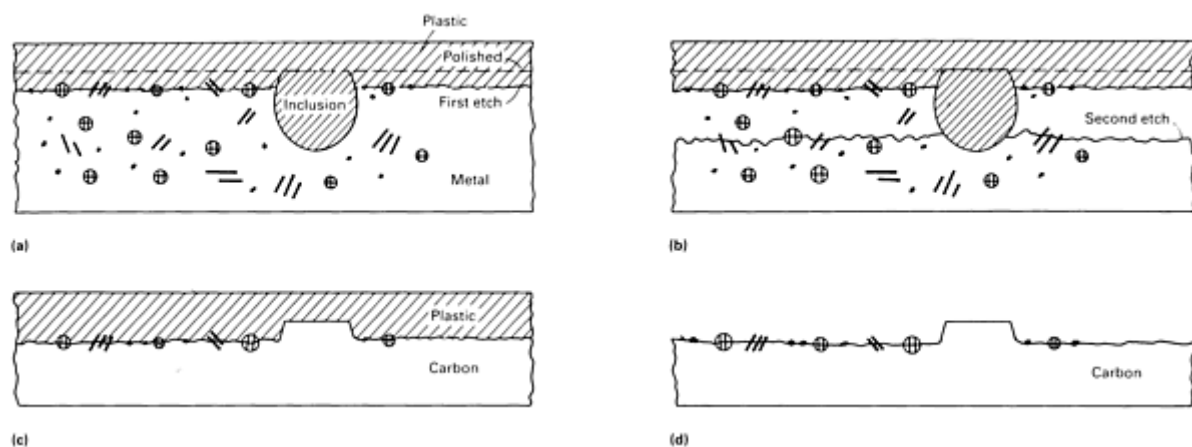

Fig. 3 Positive carbon extraction replication steps. (a) Placement of plastic after the first etch. (b) After the second etch. (c) After the deposition of carbon. (d) The positive replica after the plastic is dissolved

Microstructural Analysis

Crack determination is important to help establish the root cause of a potential failure in a component. After a preliminary evaluation of the crack to assess crack shape and length by using magnetic flux or dye penetrant, the replica

method is then used on unetched specimens to assist in the crack evaluation. Figure 4 schematically shows the propagation of different types of cracks in a steel structure (Ref 10). Each crack has its own characteristics, and it is often possible to make a correct determination of crack type. It is important to determine whether the crack is the original defect or has been caused by service conditions or damage. Once the crack type is identified, the proper corrective action, such as eliminating a corrosive environment or reducing stress levels, can be attempted. Figure 5 shows the replication of surface cracks in a boiler tube.

Fig. 4 Propagation of different crack types. (a) Creep. (b) Fatigue. (c) Stress corrosion. (d) Intergranular corrosion

Fig. 5 Surface crack in a boiler tube. Comparison of the (a) actual microstructure and (b) the replica of the crack

Creep Damage. Creep defects cause the majority of failures in power plant components operating under stress and thermal load, and the replica method is especially suitable for the detection of these defects. Therefore, the replica method has become an especially important tool in the determination of remaining life in such components as boiler tubes, steam piping, and turbine components. The replica method reveals defects due to creep at a much earlier stage than other NDE techniques. Creep defects begin as small holes or cavities at grain boundaries or second phases. With time and stress, these holes or cavities can link up and form cracks that eventually lead to failure of the component (Fig. 6). Creep cracks are usually very localized, and they form in welds, bends, or other highly stressed regions. Determining the remaining life of components normally depends on assessments of regular inspections, as indicated in Table 2. Figure 7 shows a comparison of creep voids in a surface replica and the corresponding bulk microstructure.

Table 2 Creep damage classification

Class	Nature	Action
1	No creep defects	None
2	A few cavities	Reinspection after 20,000 h of service
3	Coalescent cavities	Reinspection after 15,000 h of service
4	Microscopic creep cracks	Reinspection after 10,000 h of service

5	Macroscopic creep cracks	Management must be informed immediately
---	--------------------------	---

Fig. 6 Schematic of creep crack formation. Small cavities (a) link up over time (b) and form intergranular cracks (c) and eventually macrocracks (d)

Fig. 7 Comparison of creep voids in (a) a replica and (b) the actual microstructure

Precipitate Analysis. The detection of various deleterious precipitates in components subjected to high temperature and stress can lead to improved life assessment analysis of these components. The extraction replication technique is an excellent nondestructive method of detecting these precipitates.

Sigma phase is a deleterious FeCr compound that can form in some stainless steels, and its presence can severely limit remaining life. Extraction replicas have been used to determine the amount of σ phase in the microstructure (Ref 12), and

the amount of σ phase has been directly related to the creep rate (Ref 13). Figure 8 shows an example of σ phase in an extraction replica.

Fig. 8 Comparison of σ -phase formation as seen in (a) a replica and (b) the actual microstructure

The composition of carbides, and their stability with time and temperature of exposure, can indicate the remaining life of a component. Extraction replicas have been used to evaluate carbides, and it has been suggested that changes in morphology and chemistry can be used to assist the estimation of effective exposure temperature for use in determining the remaining life of components (Ref 14). Figure 9 shows an example of precipitates extracted from a 200,000-h exposed sample, together with the accompanying chemical analysis.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Introduction

LEAK TESTING is the branch of nondestructive testing that concerns the escape or entry of liquids or gases from pressurized or into evacuated components or systems intended to hold these liquids. Leaking fluids (liquid or gas) can penetrate from inside a component or assembly to the outside, or vice versa, as a result of a pressure differential between the two regions or as a result of permeation through a somewhat extended barrier. Leak testing encompasses procedures for one or a combination of the following:

- Locating (detecting and pinpointing) leaks
- Determining the rate of leakage from one leak or from a system
- Monitoring for leakage

Leak testing is increasing in importance because of the rising value of, and warranties on, manufactured products and because of the constantly increasing sensitivity of components and systems to external contaminants. Environmental concerns are causing additional emphasis on leak testing and its conduct.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Leak Testing Objectives

Like other forms of nondestructive testing, leak testing has a great impact on the safety and performance of a product. Reliable leak testing decreases costs by reducing the number of reworked products, warranty repairs, and liability claims. The most common reasons for performing a leak test are:

- To prevent the loss of costly materials or energy
- To prevent contamination of the environment
- To ensure component or system reliability

Terminology. The following terms must be understood in their strict definitions within the field of leak testing:

- *Leak:* An actual through-wall discontinuity or passage through which a fluid flows or permeates; a leak is simply a special type of flaw
- *Leakage:* The fluid that has flowed through a leak
- *Leak rate:* The amount of fluid passing through the leak per unit of time under a given set of conditions; properly expressed in units of quantity or mass per unit of time
- *Minimum detectable leak:* The smallest hole or discrete passage that can be detected
- *Minimum detectable leak rate:* The smallest detectable fluid-flow rate

The amount of leakage required for a leak testing instrument to produce a minimum detectable signal can be determined. This amount is generally used to indicate the sensitivity of the instrument. Instrument sensitivity is independent of test conditions, but when an instrument is used in a test, the sensitivity of the test depends on existing conditions of pressure, temperature, and fluid flow.

Measurement of Leakage. A leak is measured by how much leakage it will pass under a given set of conditions. Because leakage will vary with conditions, it is necessary to state both the leak rate and the prevailing conditions to define a leak properly. At a given temperature, the product of the pressure and the volume of a given quantity of gas is proportional to its mass. Therefore, leak rate is often expressed as the product of some measure of pressure and volume per unit of time—for example, torr liters per second (torr · L/s), micron liters per second (μ L/s), and atmosphere cubic centimeters per second (atm cm³/s).

The two most commonly used units of leakage rate with pressure systems are standard cubic centimeters per second (std cm³/s) and its equivalent, standard atmosphere cubic centimeters per second (atm cm³/s). The most frequently used unit in vacuum leak testing is torr liters per second. The recent adoption of the *Système International d'Unités* (SI) system of units has resulted in a new measure of leakage, pascal cubic meters per second (Pa · m³/s). Another new unit is moles per second (mol/s), which has the advantage that information concerning temperature implied in other units is automatically included in this unit. The term used for leak rate in this article is standard atmosphere cubic centimeter per second, where

standard conditions are defined as 1 atm = 101.325 kPa and standard temperature is 273.15 K (0 °C). The conversion factor is $\text{std cm}^3/\text{s} = 4.46 \times 10^{-5} \text{ mol/s}$. Another unit of leak rate generally accepted is the gas-flow rate that causes a pressure rise per unit of time of 1 $\mu\text{m Hg/s}$ (40 $\mu\text{in. Hg/s}$) in a volume of 1 L (0.26 gal.). This is termed the lusec (liter microns per second). The clusec (centiliter microns per second) unit is equal to 0.01 lusec. Boyle's law ($PV = K$, where P is pressure, V is volume, and K is a constant) enables one to convert these units into more meaningful volumetric terms; these conversions are listed in Table 1, along with conversions for pressures and volumes.

Table 1 Conversion factors for quantities related to leak testing

std cm³/s	Pa · m³/s, at 0 °C (32 °F)	torr · L/s, at 0 °C (32 °F)
1	0.1	7.6×10^{-1}
1×10^{-1}	1×10^{-2}	7.6×10^{-2}
5×10^{-2}	5×10^{-3}	3.8×10^{-2}
1×10^{-2}	1×10^{-3}	7.6×10^{-3}
5×10^{-3}	5×10^{-4}	3.8×10^{-3}
1×10^{-3}	1×10^{-4}	7.6×10^{-4}
5×10^{-4}	5×10^{-5}	3.8×10^{-4}
1×10^{-4}	1×10^{-5}	7.6×10^{-5}
5×10^{-5}	5×10^{-6}	3.8×10^{-5}
1×10^{-5}	1×10^{-6}	7.6×10^{-6}
5×10^{-6}	5×10^{-7}	3.8×10^{-6}

1×10^{-7}	1×10^{-8}	7.6×10^{-8}
1×10^{-8}	1×10^{-9}	7.6×10^{-9}
1×10^{-9}	1×10^{-10}	7.6×10^{-10}

1×10^{-10}	1×10^{-11}	7.6×10^{-11}
1×10^{-11}	1×10^{-12}	7.6×10^{-12}
1×10^{-12}	1×10^{-13}	7.6×10^{-13}
1×10^{-13}	1×10^{-14}	7.6×10^{-14}

Types of Leaks. There are two basic types of leaks: real leaks and virtual leaks.

A real leak is an essentially localized leak, that is, a discrete passage through which fluid may flow (crudely, a hole). Such a leak may take the form of a tube, a crack, an orifice, or the like. As with flaws, all leaks are not the same. Leaks tend to grow over time, and they tend to operate differently under different conditions of pressure and temperature. A system may also leak because of permeation of a somewhat extended barrier; this type of real leak is called a distributed leak. A gas may flow through a solid having no holes large enough to permit more than a small fraction of the gas to flow through any one hole. This process involves diffusion through the solid and may also involve various surface phenomena, such as absorption, dissociation, migration, and desorption of gas molecules.

Virtual leaks involve the gradual desorption of gases from surfaces or escape of gases from nearly sealed components within a vacuum system. It is not uncommon for a vacuum system to have both real leaks and virtual leaks at the same time.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Types of Flow in Leaks

Types of flow in leaks include permeation, molecular flow, transitional flow, viscous flow, laminar flow, turbulent flow, and choked flow. The type of flow corresponding to a specific instance of leakage is a function of pressure differential, type of gas, and size and shape of the leak. Some of these types of flow (which are described in the following sections) also occur at locations such as piping connections and have characteristics similar to leaks.

Permeation is the passage of a fluid into, through, and out of a solid barrier having no holes large enough to permit more than a small fraction of the total leakage to pass through any one hole. This process involves diffusion through a solid and may involve other phenomena, such as absorption, dissociation, migration, and desorption.

Molecular Flow occurs when the mean free path of the gas is greater than the longest cross-sectional dimension of the leak. The mean free path is the average distance that a molecule will travel before colliding with another molecule. It is an inverse linear function of the pressure. In molecular flow, the leakage (flow) is proportional to the difference in the pressures. Molecular flow is a frequent occurrence in vacuum testing.

Transitional flow occurs when the mean free path of the gas is approximately equal to the cross-sectional dimension of the leak. The conditions for transitional flow are between those for laminar and molecular flow (see the section "The Equation of the State of an Ideal Gas" in this article).

Viscous flow occurs when the mean free path of the gas is smaller than the cross-sectional dimension of the leak. In viscous flow, the leakage (flow) is proportional to the difference of the squares of the pressures. Viscous flow occurs in high-pressure systems such as those encountered in detector probing applications. Above a critical value of the Reynolds number, N_{Re} (about 2100 for circular-pipe flow), flow becomes unstable, resulting in countless eddies or vortices.

Laminar and Turbulent Flow. Laminar flow occurs when the velocity distribution of the fluid in the cross section of the passage or orifice is parabolic. Laminar flow is one of two classes of viscous flow; the other is turbulent flow. Particles in turbulent flow follow very erratic paths, but particles in laminar flow follow straight lines. The term viscous flow is sometimes incorrectly used to describe laminar flow.

Choked flow, or sonic flow, occurs under certain conditions of configuration and pressure. Assume there exists a passage in the form of an orifice or a venturi, and assume that the pressure upstream is kept constant. If the pressure downstream is gradually lowered, the velocity of the fluid through the throat or orifice will increase until it reaches the speed of sound. The downstream pressure at the time the orifice velocity reaches the speed of sound is called the critical pressure. If the downstream pressure is lowered below this critical pressure, no further increase in orifice velocity can occur, the consequence being that the mass-flow rate has reached its maximum.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Principles of Fluid Dynamics

Leakage generally falls within the discipline of fluid dynamics. However, only the elementary principles of fluid dynamics are needed for most of the practical requirements of leak testing. Mathematical models are very helpful in testing gas systems, and the following discussion is mainly concerned with such systems.

The Equation of the State of an Ideal Gas (that is, a gas made up of perfectly elastic point particles) is:

$$PV = NRT \quad (\text{Eq 1})$$

where P is the gas absolute pressure, V is the volume of the vessel containing the gas, T is the absolute temperature of the gas, N is the number of moles of gas, and R is the universal gas constant. The constant, R , is the same for all (ideal) gases; the numerical value of R depends on the system of units in which P , V , and T are measured.

The number of moles of gas, N , is equal to the mass of the gas in grams divided by the gram-molecular weight of the gas. The gram-molecular weight is simply the number of grams numerically equal to the molecular weight of the gas. Regardless of the molecular weight, 1 mol of a gas always contains 6.022×10^{23} (Avogadro's number) molecules.

In leak testing, pressures are measured in terms of atmospheric pressure. By international agreement, the pressure of the standard atmosphere is $1,013,250 \text{ dyne/cm}^2$. This is equivalent to the pressure exerted by a 760 mm (30 in.) column of mercury, at 0°C (32°F), under a standard acceleration of gravity of 980.665 cm/s^2 (32.1740 ft/s^2). Another unit of pressure commonly used, especially in vacuum technology, is the torr, which is $1/760$ of a standard atmosphere, equivalent to 1 mm (0.04 in.) of mercury. (Conversion factors are given in Table 1.)

The numerical value of the gas constant, R , in two useful sets of units is:

$$\begin{aligned} R &= \frac{0.0820 \text{ atm} \cdot \text{L}}{\text{mol} \cdot \text{K}} \\ &= \frac{62.3 \text{ torr} \cdot \text{L}}{\text{mol} \cdot \text{K}} \end{aligned} \quad (\text{Eq 2})$$

Equations of state, in conjunction with measurements of pressure, volume, and temperature, are used to determine the total quantity of gas in a closed system. The quantity of gas of a given composition can be expressed in terms of the total number of molecules, the total mass of gas, or any quantity proportional to these. For example, suppose a pressure vessel of volume V_1 is pressurized to P_1 (greater than atmospheric pressure) at temperature T_1 and allowed to stand for a period of time. At the end of this period, the pressure is found to have decreased to P_2 . If the temperature of the system is

unchanged and the gas in the vessel has not changed in volume, the decrease in pressure must be the result of a loss of gas, and a leak must be presumed to be present. However, if temperature T_2 is less than T_1 , the decrease in pressure may be caused by a decrease in the gas volume as the result of cooling. If the quantity of gas has not changed, it follows from Eq 1 that P_1 , V_1 , T_1 , V_2 , and T_2 must satisfy the relation:

$$\frac{(P_1 V_1)}{T_1} = \frac{(P_2 V_2)}{T_2} \quad (\text{Eq 3})$$

If $V_1 = V_2$, as assumed, then the following relation exists:

$$\frac{P_1}{T_1} = \frac{P_2}{T_2} \quad (\text{Eq 4})$$

Thus, if P_2 has decreased in proportion to the decrease in temperature, the system can be presumed not to have leaked at a rate discernible by the pressure gage and thermometer used to monitor the system. If the precision and drift of these instruments are known, a maximum leak rate consistent with their indication of no leakage can be computed.

If the reduction in pressure cannot be accounted for by the reduction in temperature (that is, if Eq 4 is not satisfied), a leak or leaks may be presumed present, and the leak rate can be determined by computing the loss in quantity of gas. Referring to Eq 1, the loss of gas (expressed in number of moles) is given by:

$$\begin{aligned} \Delta N &= N_2 - N_1 \\ &= \left[\left(\frac{P_2}{T_2} \right) - \left(\frac{P_1}{T_1} \right) \right] \left(\frac{V}{R} \right) \end{aligned} \quad (\text{Eq 5})$$

where V is presumed constant.

If desired, ΔN can be converted to mass by multiplying by the mean gram-molecular weight of the gas. Dividing ΔN by the time span between measurements gives the average leak rate.

For most systems, the volume of the system is assumed to be constant. However, all pressure vessels expanded by some amount when they are pressurized; moreover, their volume may vary with thermal expansion or contraction. When very precise estimates of leak rate are required, explicit corrections for these effects must be made.

A given leak may exhibit several types of flow, depending on the pressure gradient, temperature, and fluid composition. Therefore, it is important to identify the type of flow that exists in order to predict the effect of changing these variables. Conversely, with constant temperature, pressure, and fluid composition, the configuration of the leak will determine the type of flow. Because the leak may be a crack, a hole, permeation, or a combination of these, its configuration is often impossible to ascertain, but general empirical guidelines can establish the type of flow for gases. If the leak rate is:

- Less than 10^{-6} atm cm³/s, the flow is usually molecular
- 10^{-4} to 10^{-6} atm cm³/s, the flow is usually transitional
- 10^{-2} to 10^{-6} atm cm³/s, the flow is usually laminar
- Greater than 10^{-2} atm cm³/s, the flow is usually turbulent

These types of gas flow are more accurately described by the Knudsen number:

$$N_K = \frac{\lambda}{d} \quad (\text{Eq 6})$$

where N_K is the Knudsen number, λ is the mean free path of the gas, and d is the diameter of the leak. The relationship between, N_K and flow regime is:

$$\begin{aligned} N_K &< 0.01 \text{ (laminar, or a higher regime)} \\ 0.01 &\leq N_K \leq 1.00 \text{ (transitional)} \\ N_K &> 1.00 \text{ (molecular)} \end{aligned}$$

Mean Free Path. Values of the mean free path for various gases and pressures are listed in Table 2. In a vacuum system, the mean free path will vary from inches to many feet; when the mean free path is very long, collisions with the chamber surfaces occur more frequently than collisions between molecules. This, in part, is the reason that neither a gas nor leakage diffuses evenly throughout a vacuum system at a rapid rate. The flow of gases in a vacuum is analogous to the flow of current in an electrical system. Every baffle or restriction in the system impedes gas diffusion. Consequently, if there are many impedances between the leak and the leak detector that reflect or absorb the molecules, movement of the gas molecules to the leak detector does not follow theoretical diffusion rates; instead, it is greatly dependent on the configuration of the vacuum system.

Table 2 Mean free path lengths of various atmospheric gases at 20 °C (68 °F) and various vacuum pressures

Gas	Mean free path length at indicated absolute pressure									
	1 μ Pa (7.5×10^{-9} torr)		1 mPa (7.5×10^{-6} torr)		1 Pa (7.5×10^{-3} torr)		1 kPa (7.5 torr)		100 kPa (750 torr) ^(a)

- (a) Approximately atmospheric pressure.
- (b) 1 nm (nanometer) = 10⁻⁹ m.

The level of vacuum is virtually always described in terms of absolute pressure. However, the mean free path or the concentration of molecules controls such vacuum properties as viscosity, thermal conductance, and dielectric strength. Furthermore, very few vacuum gages actually measure pressure, but instead measure the concentration of molecules. Therefore, in the context of vacuum systems, the term pressure is largely inaccurate, although it remains in use.

Leak Testing of Pressure Systems Without a Tracer Gas

Leak testing methods can be classified according to the pressure and fluid (gas or liquid) in the system. The following sections describe the common fluid-system leak testing methods in the general order shown in Table 3, which also lists methods used in the leak testing of vacuum systems (discussed in the section "Leak Testing of Vacuum Systems" in this article). Table 4 compares leak testing method sensitivities.

Leak detection by monitoring changes in the pressure of the internal fluid is often used when leak detection equipment is not immediately available. For the most part, detection can be accomplished with instruments that are already installed in the system.

Acoustic Methods

The turbulent flow of a pressurized gas through a leak produces sound of both sonic and ultrasonic frequencies (Fig. 1). If the leak is large, it can probably be detected with the ear. This is an economical and fast method of finding gross leaks. Sonic emissions are also detected with such instruments as stethoscopes or microphones, which have limited ability to locate as well as estimate the approximate size of a leak. Electronic transducers enhance detection sensitivity.

Fig. 1 Turbulence caused by fluid flow through an orifice

Smaller leaks can be found with ultrasonic probes operating in the range of 35 to 40 kHz, although actual emissions from leaks range to over 100 kHz. Ultrasonic detectors are considerably more sensitive than sonic detectors for detecting gas leaks and from distances of 15 m (50 ft) are capable of detecting air leaking through a 0.25 mm (0.010 in.) diam hole at 35 kPa (5 psi) of pressure. The performance of an ultrasonic leak detector as a function of detection distance, orifice diameter, and internal air pressure is shown in Fig. 2. The sound level produced is an inverse function of the molecular weight of the leaking gas. Therefore, a given flow rate of a gas such as helium will produce more sound energy than the

same flow rate of a heavier gas such as nitrogen, air, or carbon dioxide. If background noise is low, ultrasonic detectors can detect turbulent gas leakage of the order of 10^{-2} atm cm³/s. Ultrasonic leak detectors have also been successfully used with ultrasonic sound generators when the system to be tested could not be pressurized.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Bubble Testing

A simple method for leak testing small vessels pressurized with any gas is to submerge them in a liquid and observed bubbles. If the test vessels is sealed at atmospheric pressure, a pressure differential can be obtained by pumping a partial vacuum over the liquid or by heating the liquid. The sensitivity of this test is increased by reducing the pressure above the liquid, the liquid, density, the depth of immersion in the liquid, and the surface tension of the liquid.

Immersion Testing. Oils are a more sensitivity medium than ordinary water. Therefore, it is common practice to test electric components in a bath of hot perfluorocarbon. When testing by reducing the pressure above the liquid, several precautions must be observed, particularly if the reduced pressure brings the liquid close to its boiling point. If the liquid begins to boil, a false leak indication will be given. The test vessel must be thoroughly cleaned to increase surface wetting, to prevent bubbles from clinging to its surface, and to prevent contamination of the fluid. If water is used, it must be distilled or deionized and should be handled with minimal sloshing to reduce the absorbed-gas content. A small amount of wetting agent is normally added to water to reduce surface tension. With the addition of the proper wetting agent, water can be even more sensitive than oils. Water-base surfactant solutions can be used successfully to detect leaks as small as 10^{-6} atm cm³/s.

Immersion testing can be used on any internally pressurized item that would not be damaged by the test liquid. Although this test can be relatively sensitive, as previously stated, it is more commonly used as a preliminary test to detect gross leaks. This method is inexpensive, requires little operator skill for low-sensitivity testing, and enables an operator to locate a leak accurately.

Bubble-forming solutions can be applied to the surface of a pressurized vessels if it is too large or unwieldy to submerge. However, care must be taken to ensure that no bubbles are formed by the process itself. Spraying the bubble solution is not recommended; it should be flowed onto the surface. A sensitivity of about 10^{-5} atm cm³/s is possible with this method, if care is taken. Sensitivity may drop to about 10^{-3} atm cm³/s with an untrained worker or to 10^{-2} atm cm³/s if soap and water is used.

Like immersion testing, the use of bubble-forming solutions is inexpensive and does not require extensive training of the inspector. One disadvantage is that the test does not normally enable the operator to determine the size of a leak accuracy.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Flow Detection

Three separate methods are frequently grouped under the heading of flow detection:

- Pressure increase
- Pressure decrease
- Flow

The sensitivity for each of these method is not the same, nor can any one method always be substituted for the other. If an internally pressurized vessel or system is enclosed within a larger vessel that is then sealed except for a small duct, leakage from the vessel being tested will result in an increase in pressure within the larger enclosing vessel, and gas will flow through the attached duct. If a device sensitive to the movement or flow of gas is installed in the attached duct, it can serve as a leak-rate indicator. Extremely sensitive positive-displacement flowmeters have been developed for this purpose.

Alternatively, a volumetric-displacement meter, which consists essentially of a cylinder with a movable piston, can be used. When attached to the duct from the enclosing vessel, the piston moves as the pressure of the enclosing vessel rises, effectively increasing the volume of the vessel and returning the internal pressure to the ambient atmospheric pressure. The piston must be very nearly free of frictional drag, and its motion must be accurate horizontally. Sensitive volumetric-displacement meters are equipped with micrometric cathetometers, which can accurately measure extremely small

displacements of the piston. Some volumetric-displacement meters will detect leaks of about 10^{-4} atm cm³/s. This is a very simple method to use when it is inconvenient to measure directly the pressure change of the container being tested.

The simplest method of leak detection and measurement is the bubble tube. If the end of the duct from the outer enclosing vessel empties into a liquid bath, appreciable leakage will generate bubbles. Even very small leak rates can be detected simply by the movement of the liquid meniscus in the tube.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Leak Testing of Pressure Systems Using Specific-Gas Detectors

Many available types of leak detectors will react to either a specific gas or a group of gases that have some specific physical or chemical property in common. Leak-rate measurement techniques involving the use of tracer gases fall into two classifications:

- Static leak testing
- Dynamic leak testing

In static leak testing, the chamber into which tracer gas leaks and accumulates is sealed and is not subjected to pumping to remove the accumulated gases. In dynamic leak testing, the chamber into which tracer gas leaks is pumped continuously or intermittently to draw the leaking tracer gas through the leak detector. The leak-rate measurement procedure consists of first placing tracer gas within (Fig. 3a) or around the whole system being tested (Fig. 3b). A pressure differential across the system boundary is established either by pressurizing one side of the pressure boundary with tracer gas or by evacuating the other side. The concentration of tracer gas on the lower-pressure side of the pressure boundary is measured to determine the leak rate.

Fig. 3 Modes of leakage measurement used in dynamic leak testing techniques utilizing vacuum pumping. (a) Pressurized system mode for the leak testing of smaller components. (b) Pressurized envelope mode for the leak testing of larger-volume systems

Specific-Gas Detection Devices

Some of the more commonly used gas detectors are described below. These range from the simple utilization of the senses of sight and smell, when possible, to complex instrumentation such as mass spectrometers and gas chromatographs.

Odor Detection Via Olfaction. The human sense of smell can and should be used to detect odorous gross leaks. The olfactory nerves are quite sensitive to certain substances, and although not especially useful for leak locations, they can determine the presence of strong odors. However, the olfactory nerves fatigue quite rapidly, and if the leakage is not noted immediately, it will probably not be detected.

Color Change. Chemical reaction testing is based on the detection of gas seepage from inside a vessel by means of sensitive solutions or gas.

The ammonia color change method is probably the best known. In this method, the vessel surface is cleaned and then a calorimetric developer is applied to the surface of the vessel, where it forms an elastic film that is easily removed after the test. The developer is fairly fluid, and when applied with a spray gun it sets rapidly and adheres well to metal surfaces, forming a continuous coating. An air-ammonia mixture (usually varying from 1 to 5% NH_3) is then introduced into the dry vessel. Leakage of gas through the discontinuity causes the indicator to change color. The sensitivity of this method can be controlled by varying the concentration of ammonia, the pressure applied to the air-ammonia mixture, and the time allowed for development.

Indicator tapes are useful for the leak testing of welded joints; the method used for this application is as follows. After the surface of the joint to be tested has been cleaned with a solvent, the indicator tape is fixed on the weld either by a rubber solution applied on the edge of the tape or by a plastic film. Then the inspection gas, which consists of an ammonia-air mixture with 1 to 10% NH_3 , is fed into the vessel at excess pressure. If microdiscontinuities exist, the gas leaks out the reacts chemically with the indicator, forming colored spots that are clearly visible on the background of the tape.

The indicator tape method has the following advantages:

- Remote control is possible, ensuring safety for the operators
- Leaks of approximately 10^{-7} atm cm^3/s can be detected
- The color of the tape is not affected by contact with the hands, high humidity, or the passage of time
- Tapes can sometimes be used more than once; if there are spots caused by the action of ammonia, they can be removed by blowing the tape with dry compressed air

Ammonia and Hydrochloric Acid Reaction. Another method involves pressurizing the vessel with ammonia gas, then searching for the leak with an open bottle of hydrochloric acid. A leak will produce a white mist of ammonium chloride precipitate when the ammonia comes into contact with the hydrogen chloride vapor. Good ventilation is necessary because of the noxious characteristics of both hydrogen chloride vapor and ammonia gas.

Ammonia and Sulfur Dioxide Reaction. Another modification of the ammonia chemical indicator test involves the use of ammonia and sulfur dioxide gas to produce a white mist of ammonium sulfide. Sulfur dioxide is not as irritating or corrosive as hydrogen chloride, but it is still a noxious gas and should be used only in well-ventilated areas.

Halide Torch. Still another type of chemical reaction test uses the commercial halide torch, which consists of a gas tank and a brass plate (Fig. 4). Burning gas heats the brass plate; in the presence of halogen gas, the color of the flame changes because of the formation of copper halide. (The flame is also used to inspire gas through the probe, which is a length of laboratory tubing.) The halide torch locates leaks as small as 1×10^{-3} atm cm^3/s .

Fig. 4 Halide torch used for leak location

Halogen-Diode Testing. In halogen-diode testing, a leak detector is used that responds to most gases containing chlorine, fluorine, bromine, or iodine. Therefore, one of these halogen-compound gases is used as a tracer gas. When a vessel is pressurized with such a tracer gas, or a mixture of a halogen compound and air or nitrogen, the sniffing probe of the leak detector is used to locate the leak.

The leak detector sensing element operates on the principle of ion emission from a hot plate to a collector (Fig. 5). Positive-ion emission increases with an increase in the amount of halogen-compound gases present. This ion current is amplified to give an electrical leak signal. The sensitivity of halogen detectors operating at atmospheric pressure is about 10^{-6} atm cm³/s, but this will vary depending on the specific gas that is being used.

Fig. 5 Schematic of sensing element of a heated anode halogen leak detector used at atmospheric pressure for leak location with detector probe system. Positive-ion current from heated alkali electrode responds to refrigerant gases and other halogenated hydrocarbon tracer gases.

Several different types of halogen leak detectors are available. Each includes a control unit and a probe through which air is drawn at about 4.9×10^5 mm³/min (30 in.³/min). When searching for leaks from an enclosure pressurized with a tracer gas, the probe tip is moved over joints and seams suspected of leaking. The probe tip should lightly touch the surface of the metal as it is moved. Where forced ventilation is required to keep the air free of halogen vapors, it must be stopped during actual testing, or care must be taken to ensure that drafts do not blow the leaking gas away from the test probe. When the probe passes over the close to a leak, the tracer gas is drawn into the probe with the air and through a sensitive element, where it is detected. The leak signal is either audible or visual.

Certain precautions are necessary in this probe exploration. Probing too rapidly may result in missing small leaks. To avoid this risk, the speed at which the probe is moved must be in proportion to the minimum leak tolerance. When testing a vessel for allowable leaks of the order of 0.001 kg (0.04 oz) per year, the probe travel can be 25 to 50 mm/s (1 to 2 in./s), but for smaller leaks the probe speed should be reduced to 13 mm/s ($\frac{1}{2}$ in./s).

Sulfur hexafluoride detectors operate on the principle of electron-capture detectors, which are used widely in the field of gas chromatography. The sensing chamber of a sulfur hexafluoride detector consists of a cylindrical cell that has a centrally mounted insulated probe. The inner wall of the cell is coated with a radioactive element (10 gigabecquerel (GBq), or 300 millicuries (mCi), of tritium). Low-energy electrons emitted by the tritium are collected on the central probe by means of a polarizing voltage maintained between the probe and the cell wall. The resulting electric current is amplified and displayed on a conventional meter. Leak-rate sensitivity is 10^{-8} mL/s (3×10^{-10} oz/s), and concentration sensitivity is 1 part sulfur hexafluoride in 10^{10} parts air. The equipment is fully portable.

Pure nitrogen (oxygen free) is passed through the detector and the standing current is set by a zero control to a given position on the meter scale. When an electron-capturing compound such as sulfur hexafluoride enters the cell, the electrons forming the current are captured by the sulfur hexafluoride molecules, resulting in a reduction of the standing current, which is indicated by a meter deflection. This meter reading is proportional to the amount of sulfur hexafluoride entering the cell and is therefore an approximate indication of the size of the leak. The oxygen molecule also possesses the electron-capture characteristic, although to a lesser extent than sulfur hexafluoride; hence the requirement for purging the instrument with oxygen-free nitrogen during testing.

Combustible-gas detectors are often used as monitors or as leak locators where combustible fumes are likely to accumulate, as in basements. These instruments warn of potentially hazardous conditions by their ability to measure combustible-gas mixtures well below the dangerous concentration level. Catalytic combustible gas instruments measure the gas concentration as a percentage of its lower explosive limit. The temperature of a heated catalytic element will rise in the presence of a combustible gas. The minimum sensitivity of a catalytic bead is about 500 ppm, which is a leak rate of approximately 10^{-3} atm cm³/s. As leak locators, therefore, catalytic elements are not sufficiently sensitive. To locate a combustible gas, a solid-state sensor or flame ionization detector should be used. These sensors can detect a leak of approximately 10^{-5} atm cm³/s.

Thermal-Conductivity Gages. The thermal conductivity of a gas can be measured by a hot-wire bridge method (Fig. 6). A resistance element, usually a thin wire or filament, is heated electrically and exposed to the gas. The temperature, and therefore the resistance of the wire, depends on the thermal conductivity of the surrounding gas, provided the power input is held constant. Alternatively, the temperature (and resistance) of the wire can be maintained at a constant value, and the required power input measured either directly or indirectly in terms of applied voltage or current. Many types of thermal-conductivity detectors are commercially available, including differential detectors, simple Pirani gages, hydrogen Pirani gages, differential or trapped Pirani gages, charcoal Pirani gages, and thermocouple gages.

Fig. 6 Schematic of a thermal-conductivity gage using a Pirani-type detector. Thermal losses from the electrically heated resistance wire vary with heat conduction by gas molecules. Heat losses are reduced as gas pressure is lowered.

Pirani-Type Detectors. When Pirani-type detectors are used, the search gas should have low density, low viscosity, and low molecular weight. Most important, the gas should have a thermal conductivity markedly different from that of air.

The component or structure to be tested is filled with the tracer gas under positive pressure. This gas will consequently escape through even the most minute leak; hence the need for the desirable physical properties mentioned above. The escaping gas is drawn into the narrow-bore probe of the leak detector by a small suction pump. The sample is then allowed to expand into the sensing head, which contains an electrically heated filament. Simultaneously, a sample of pure air is drawn by the same pump into a second, identical chamber that also contains a heated filament. The two filaments form two arms of a conventional Wheatstone bridge circuit, which is initially balanced by an external variable resistance while both arms are simultaneously exposed to air. As soon as one arm receives a sample containing a trace of the tracer gas, such as helium, heat is extracted at a greater rate because of the substantially greater thermal conductivity of helium than air. This will cause a corresponding change in the resistance of the filament, thus unbalancing the Wheatstone bridge network. This is shown by an appropriate deflection on a center-zero milliammeter; simultaneously, an audio alarm circuit is triggered.

Infrared gas analyzers can detect a gas mixture that has a clear absorption band in the infrared spectrum by comparing it to the absorption characteristics of a pure standard sample of the same gas. The tracer gas used must possess a strong absorption in the infrared region. Nitrous oxide possesses this property markedly. The known characteristic is converted into a measurable response by allowing a heat source to radiate through two absorption tubes that contain the gases under comparison. These tubes are separated by a thin metal diaphragm that, in combination with an adjacent insulated metal plate, forms an electrical condenser. If the system is in balance (that is, if the same gas is in each tube), the heating effect will be equal and no pressure differential on the diaphragm will occur. However, if one tube contains nitrous oxide admixed with air, absorption of heat will occur to a greater extent than in the tube containing pure air. This will cause a higher pressure on one side of the diaphragm, as a result of the increase in temperature, and will cause it to move slightly in relation to the insulated plate. The resulting change in capacity of the condenser is amplified electronically and rendered visible on an output meter.

Infrared absorption is also a very sensitive way to measure small concentrations of hydrocarbons, such as methane. Infrared lasers are becoming more common as monitors for a variety of toxic and combustible gases. For some compounds, infrared laser spectroscopy can detect gas at parts per trillion levels.

Mass Spectrometer Testing. A mass spectrometer is basically a device for sorting charged particles. The sample gas enters the analyzer, where its molecules are bombarded by a stream of electrons emitted by a filament. The bombarded molecules lose an electron and become positively charged ions, which are electrostatically accelerated to a high velocity. Because the analyzer lies in a magnetic field perpendicular to the ion path, the ions travel in distinct, curved paths according to their mass. The radii of these paths are determined by ion mass, the magnitude of initial acceleration, and the strength of the magnetic field. With a constant magnetic field, any group of ions having the same mass can be made to travel the specific radius necessary to strike the ion collector. The positive charge of the ions is imparted to the target, or collector, and the resulting current flow is proportional to the quantity of the ions of that particular mass.

Specialized mass spectrometers are available, such as residual-gas analyzers, partial pressure analyzers, and helium mass spectrometers, which have been tuned to respond only to certain ranges of atomic mass units. In particular, the helium mass spectrometer is constructed so that it does not scan but is tuned to the helium peak. It will detect only helium; all other molecules passing through the detector tube will miss the target or collector because of their differences in mass or momentum from helium.

The theoretical sensitivity of the helium mass spectrometer is about 10^{-12} atm cm³/s; the sensitivity of the residual-gas analyzer is about one order of magnitude less. General-purpose mass spectrometers have a sensitivity even less than this, depending on the range of atomic mass units that the instrument is designed to measure. Helium mass spectrometers, however, may not detect leaks smaller than approximately 10^{-8} atm cm³/s in large systems. Because of background, outgassing of sorbed gases, noise, permeation, and other such factors, 10^{-8} to 10^{-9} atm cm³/s is often the minimum detectable vacuum leak rate for helium mass spectrometers.

Because mass spectrometers must operate in a vacuum, they are ideally suited to the leak testing of vacuum systems. They can also be adapted to testing systems pressurized with a tracer gas by using either a detector probe or enclosure to collect the leakage while monitoring with the mass spectrometer. When used to test a pressure system, the mass spectrometer is much less sensitive and the minimum detectable leak rate is approximately 10^{-4} atm cm³/s. Special assemblies containing a pump and permeation membrane, which are placed between the detector probe and the instrument manifold inlet, can decrease response time and increase the sensitivity for detector probe tests of pressure systems to 10^{-6} atm cm³/s. Small units, such as sealed electronic components or nuclear-fuel elements, are often internally pressurized with tracer gas; leakage is detected by placing these units in an evacuated bell jar and monitoring the outgassing with a mass spectrometer (Fig. 7). In general, the basic methods used in mass spectrometer leak testing include detector probe (sniffer) testing, encapsulator testing, tracer probe testing, hood testing, bell jar testing, accumulation testing, pressure vacuum testing, and differential sorption testing.

Fig. 7 Schematic of the leak testing of sealed components internally pressurized with helium tracer gas and enclosed in a bell jar

Radioisotope Testing. A number of leak testing techniques have been developed that involved the use of solutions containing radioactive tracers. In these tests, water is the liquid most commonly used, although hydrocarbons are extensively used in the petroleum industry. Soluble salts and compounds containing radioisotopes are added to the liquid. One of the most satisfactory isotopes that can be added to water is the sodium isotope ²⁴Na. The use of this radioisotope is safe because the concentration required for the detection of leaks is less than the drinking tolerance. Furthermore, this radioisotope has a short half-life (15 h) and can be retained in a vessel until its activity has been greatly reduced as a result of radioactive disintegration (decay).

Using this method, the vessel is filled with radioactive sodium bicarbonate solution and pressurized to the level required for a code proof test. After the vessel is held at pressure for a short period of time, it is drained and flushed with fresh water. A gamma-radiation detector is used to determine the location of leaks from the presence of gamma radiation emitted from the radioactive sodium bicarbonate solution that has accumulated around leaks in the vessel.

In another method, small components are backfilled with ⁸⁵Kr by placing them in a chamber and then pressurizing the chamber with ⁸⁵Kr (Fig. 8). If a component has a leak, gas will enter it. After the backfilling is complete, the components are air washed, and the leakage is measured with a radiation counter. Under carefully controlled conditions, the radiation counter has a sensitivity of about 10^{-12} atm cm³/s. The radiation counter is automated and enables rapid, sensitive testing of large quantities of small parts such as microcircuits.

Fig. 8 Schematic of basic steps in the ^{85}Kr tracer-gas bombing of hermetically sealed electronic components. (a) Load parts. (b) Evacuate and remove air. (c) Soak parts in radioactive gas. (d) Recover radioactive gas. (e) Return air

One disadvantage of this method is that organic coatings on the parts may absorb the ^{85}Kr , thus giving a false leak indication. The primary disadvantage of this method is the attendant health hazard. However, some pressurized systems such as pipelines, lend themselves to leak testing by this method.

Ionization Gage Testing. The Phillips vacuum gage is used to measure the pressure of a gas by the intensity of a gas discharge in a magnetic field. However, this form of gas discharge ceases when the gas pressure is reduced to a pressure of approximately 0.13 Pa (10^{-3} torr); therefore, the Phillips gage cannot be used for making measurements at low pressures.

Penning Gage. A vacuum gage based on the same principle as the Phillips gage, but useful at lower pressures, was constructed by replacing the electrode system with a system consisting of two parallel round metal disks (acting as cathode and anode) enclosed in a cylindrical glass jacket. To keep the distance between the pole shoes of the permanent magnet enveloping the glass tube as short as possible, the tube was punched at that point. This improved instrument is called the Penning gage, and it has a sensitivity about ten times greater than the original Phillips gage. The Penning gage covers a pressure range from 13 to 0.13 mPa (10^{-4} to 10^{-6} torr) and can probably be used even for pressures below $13 \text{ } \mu\text{Pa}$ (10^{-7} torr).

In any pumping installation, the vacuum gage can also be used to detect and locate leaks. This is done by replacing atmospheric air with tracer gas in each part of the apparatus. When the leak is reached, the tracer gas flows in, and the gage usually registers any change in pressure.

Additional Ionization Detectors. In addition to the Phillips and Penning gages, other ionization detectors include the oxygen-leak detector, the hot-filament ionization gage, the helium-ionization leak detector, the photometric leak detector, and the palladium-barrier detector.

Gas chromatographs are sometimes used for leak detection. In a gas chromatograph, a carrier gas is made to flow through an adsorbent column; then a tracer gas is injected into the carrier gas ahead of the adsorbent column. Next, a gas sample is fractionated into its constituents as a function of the residence time of each constituent in the adsorbent column. The constituents are detected as they leave the adsorbent column, usually by thermal-conductivity instruments, but they may also be detected by infrared analyzers or vapor-density balances. The advantage of the gas chromatograph is that, unlike the mass spectrometer, with proper calibration it will identify the tracer gas as a compound rather than as individual molecules. This can be beneficial if there are several gases in the system; their identification will often aid in locating the source of the leakage. Residual gas analyzers and partial pressure analyzers are used in the same manner.

Specific-Gas Detector Applications

The proper method for using a specific-gas detector is based on the function of the leak detector, the fluid that is leaking, and the type of vessel being tested. Some of the more important considerations in determining the best method of using leak detectors are discussed below.

Probing. Detector probes, which will react to a number of gases, can be used in either of two ways. The first is the scanning mode, and the second is the monitoring of an enclosure placed around the pressurized item (Fig. 9).

Fig. 9 Tracer-gas detection techniques used to locate leaks with sensitive electronic instruments. (a) Tracer probe. (b) Detector probe

Detector Probe Technique. In the detector probe mode, the external surface of the pressurized vessel is scanned either with a portable detector having a short probe attached or with a long probe connected to a stationary leak detector by flexible tubing (Fig. 10). In general, the connection of a long probe to a stationary detector reduces sensitivity because of the slow release of sorbed gases in the probe tubing, which results in a high background reading. Because a correspondingly longer time is required for the gas to flow up the tube to the sensing element, it is difficult to pinpoint the location of the leak. Also undesirable is the long time needed for purging a long-probe system of tracer gas. The purging occurs when a rather large leak is encountered and the probe tubing becomes filled with a high concentration of tracer gas. One minute or more may be required for the leak detector pump to clear the tracer gas from the sensing element. This in turn reduces scanning speed.

Fig. 10 Schematic showing a long detector probe connected by a flexible hose to a stationary leak detector for scanning the external surface of a pressurized vessel

There are means for offsetting some of the disadvantages of the long-probe method. When a helium mass spectrometer is used, carbon dioxide can be injected into the probe line near the tip. The carbon dioxide will act as a carrier fluid for the helium, thus purging the tube walls, and, in conjunction with a high-capacity pump, will carry the helium tracer gas to the leak detector very rapidly. The carbon dioxide is then selectively trapped with liquid nitrogen, leaving the helium. A probe of this type is several times faster than conventional probes and reduces background buildup.

When background buildup and sensitivity losses do occur, accurate measurements of leak rate are difficult to obtain. However, leak-rate measurement can be accomplished by placing a calibrated leak over the probe tip to calibrate the leak-detector-tube-probe system. The leakage can then be measured by placing a suction cup on the probe and applying it to the leak area.

Another, more recent, means of decreasing the disadvantages of the long-probe method is the use of an assembly between the probe and the mass spectrometer manifold port, which contains a permeation membrane and pump. The pump reduces the response time, and the permeation membrane reduces the pressure drop into the mass spectrometer and also causes accumulation of the entering tracer, which increases sensitivity.

Another disadvantage of the long-probe method is that the operator generally cannot observe the reaction of the leak detector. This can be circumvented with earphones, audible signals, and lights, but such devices must be triggered at some threshold level of detector response that may not correspond to the desired leak size. One person can operate the probe while another monitors the leak detector readout, but ideally one person should perform both tasks simultaneously.

Detector Probe Accumulation Technique. The second method of detector probing involves the use of a tracer-gas leak detector to monitor an enclosure that accumulates the leakage (Fig. 11). This method does not provide a means of locating the leak, but it is preferred for leakage measurement and, in many applications, for detecting the existence of a leak.

Fig. 11 Schematic of setup for detecting leaks by monitoring an enclosure placed around a vessel pressurized with tracer gas

A large unit can be tested by enclosing it in a plastic bag. The accumulation of tracer gas in the bag is monitored by a leak detector connected to the bag by a short probe or by piping. Leakage measurement consists of inserting a calibrated leak

into the enclosure and comparing the test-leak rate with the calibrated-leak rate. One of the problems associated with this method is the construction of a bag that does not leak and has low permeability with respect to tracer gas.

A small unit can be tested by placing it in an enclosure such as a sealed bell jar, which is monitored for the accumulation of tracer gas. Depending on the type of leak testing instrument used, the enclosure may be placed under a vacuum. If relatively large leaks are expected, a supply of tracer gas must be connected to the test unit to ensure that the concentration of its internal tracer gas and the pressure drop across the leak are constant.

Back pressuring is a method of pressure testing that is normally used with small, hermetically sealed electronic components, such as integrated circuits, relays, and transistors. In this method, the test unit is placed in a pressurized container filled with a tracer gas and is kept there for a time to allow tracer gas to flow into the unit through any leaks that may be present.

In using back pressuring, care must be taken to ensure that the leaking components contain tracer gas. Therefore, it is important that the time between back pressuring and leak testing be suitably controlled. For example, in a test specification for transistors, the transistors were subjected to a helium pressure of 690 kPa (100 psi) of 16 h, air washed for 4 min, and then leak tested within 3 h. If more than 3 h had elapsed before leak testing, the transistors were pressurized again. If there is doubt as to how much tracer gas will flow into the components under back pressurization, the following expression can be used for estimation purposes:

$$P_i = P_o \left(\frac{1 - e^{-AT}}{V} \right) \quad (\text{Eq 7})$$

where P_i is the partial pressure of tracer gas inside the component (in atmospheres), P_o is the pressure of the tracer gas surrounding the component (in atmospheres), A is the conductance of the leak (in cm^3/s) with a pressure differential of 1 atm, V is the internal free volume of the component (in cubic centimeters), and T is the time that pressure P_o is applied (in seconds).

Because leaks are generally expected to be quite small, very sensitive tracer-detector combinations must be used. The tracer gas normally used is helium or ^{85}Kr , and detection is accomplished with a helium mass spectrometer or a nuclear-radiation detector, respectively. Absolute values of the size of the leak are sometimes difficult to determine with back pressuring because of:

- Adsorption and absorption of the tracer gases
- Different detector response times for different leak directions.

When testing complex systems, each sealed component can be pressurized with a different tracer gas. Leak detection with a residual-gas analyzer will both detect leakage and provide a determination of which components are leaking.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Leak Testing of Pressure Systems by Quantity Loss

Determining the amount of fluid lost from a vessel is one means of establishing that leakage has occurred. Weighing a vessel to determine fluid loss is practical only if the vessel is of reasonable size and can be weighed on a suitable scale. The sensitivity and accuracy of this method are limited by those of the scale; in general, this method is unsatisfactory unless the weight of the vessel is comparable to or less than the weight of its contents.

Differential-Pressure Method. Gas-quantity loss can be determined by the differential-pressure method. This is done by connecting two identical containers together with a differential-pressure gage between them, as shown in Fig. 12.

Differential-pressure gages are sensitive to small pressure differences; therefore, if the two containers are maintained at equal ambient conditions, leaks as small as 10^{-4} atm cm³/s can be detected in systems operating at pressures up to 40 MPa (6 ksi). The primary advantages of this method are that temperature effects are largely cancelled and the actual working fluid can be used.

Fig. 12 Schematic showing the use of a differential-pressure gage between a reference vessel and the test vessel to detect leaks in the test vessel

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Visual Leak Testing of Pressure Systems

The simplest method of checking a liquid-filled vessel for leaks is visual observation. Like listening and smelling, this is a quick and simple method of testing for gross leaks in liquid-filled containers.

Vision is a variable commodity when considered from the viewpoint of a single individual and is even more variable when considered from the viewpoints of several individuals. This is because variations in the eye, as well as variations in the brain and nervous system, affect both optical resolution and color perception.

Optical aids to vision, such as mirrors, lenses, microscopes, borescopes, fiberoptics, and magnifiers, compensate for some of the limits of the human eye by enlarging small discontinuities. For example, borescopes permit direct visual inspection of the interior of hollow tubes, chambers, and other internal surfaces.

Hydrostatic leak testing requires that a component be completely filled with a liquid, such as water. The normal sensitivity for visual inspection using deionized water as the test fluid is 10^{-2} atm cm³/s. Therefore, only large discontinuities can be revealed with this method.

The sensitivity of the test can be improved by the addition of:

- A water developer applied to the outside that changes color when contacted by a small leak. This method has replaced the older lime wash method, which required a larger amount of water seepage to be visible

- A concentrate that lowers the surface tension of the water and provides a visible or fluorescent tracer

When conducted properly, the hydrostatic test can achieve the same sensitivity as a liquid penetrant leak test on large-volume specimens. The penetrant test is two orders of magnitude more sensitive on volumes of typical electronic components.

A recent variation of the hydrostatic test is the stand-pipe test, which is used to detect leaks in underground storage tanks. In this test, the storage tank is overfilled, and the liquid level is monitored by reference to an aboveground liquid column or stand pipe. This method is not very effective and has a sensitivity of between 10^{-1} and 10^{-2} atm cm³/s.

Detection by Water-Soluble Paper With Aluminum Foil. One method of detecting water leakage employs a strip of aluminum foil laid over a wider strip of water-soluble paper. The strips are then laid over the welded seams of a water-filled vessel, as shown in Fig. 13. If a leak exists, the water-soluble strip will dissolve, indicating the leak location, and the aluminum foil strip will be in electrical contact with the vessel. A corresponding change in resistance indicates that a leak is present.

Fig. 13 Cross section of a welded seam in a water-filled vessel showing strips of water-soluble paper and aluminum foil used to detect leaks in the seam

Liquid Penetrants. The use of a visible liquid penetrant for leak testing is only slightly limited by the configuration of the item to be inspected. Another advantage is that this method can be used on subassemblies prior to completion of the finished vessel. Leak testing with penetrants is equally suited to ferrous, nonferrous, and nonmetallic materials, provided the materials are not adversely affected by the penetrant. Leak testing by this method cannot be substituted for a pressure test when the applied stress and associated proof-test factors are significant.

The liquid penetrant should be applied in a manner that ensures complete coverage of one surface without allowing the penetrant to reach the opposite surface by passing around edges or ends or through holes or passages that are normal features of the design. A sufficient amount of penetrant should be applied to the surface during the period of the test to prevent drying. Immediately after application of the penetrant, the developer should be applied to the opposite surface. The developer must be prevented from contacting the penetrant at edges or ends or through designed holes or passages so that the test results are valid.

If greater sensitivity is desired than is provided by a color-contrast (visible) liquid penetrant test, fluorescent liquid penetrant can be used to increase the sensitivity approximately one-hundredfold. Additional information on the use of liquid penetrant for leak testing is available in the article "Liquid Penetrant Inspection" in this Volume.

Smoke bombs and candles can also be used for detecting leaks. Generally speaking, a volume of smoke sufficient to fill a volume five or six times larger than the area to be tested is required for a smoke test. Medium-size volumes, such as boilers and pressure vessels, can be tested by closing all vents, igniting a smoke candle or smoke bomb, and placing it inside the vessel. All openings should then be closed; almost immediately, escaping smoke will pinpoint any leaks within the sensitivity of this method. When testing boilers and similar equipment with volumes of 2800 m³ (100,000 ft³) and more, it is often desirable to apply air pressure.

Smoke candles can provide from 110 m³ (4000 ft³) of smoke in 30 s to 3700 m³ (130,000 ft³) in 2 to 3 min. The smoke will vary in color from white to gray, depending on density and lighting. It is generated by a chemical reaction, contains no explosive materials, and is nontoxic.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Leak Testing of Vacuum Systems

Vacuum systems are normally tested in the evacuated condition, rather than being internally pressurized. Because some leaks, particularly small ones, are directional, it is desirable to test with the leakage flowing in the operational direction.

Introduction of Tracer Gas Into System

There are two ways in which a tracer gas can be used. One is to tracer probe to both detect and locate the leak by spraying tracer gas over the outer surface of the vessel. The other is to envelop the entire test vessel (or a particular portion of it) in a bath of tracer gas by the use of either rigid or flexible enclosures to both detect and measure leak rate. Calibration is accomplished by injecting a known quantity of tracer gas into the vacuum system or by attaching a calibrated leak to that system.

Helium is one of the most commonly used tracer gases for the following reasons:

- It is basically inert and safe
- It has a small molecular size and thus can flow through very small leaks
- Its diffusion rate is high
- It is easily detected by a mass spectrometer

In testing a vacuum system, even the smallest leaks are important because they have a great influence on the ultimate vacuum that the system can reach. Therefore, the most sensitive test method--helium tracer gas in combination with a helium mass spectrometer--is normally used.

Certain characteristics of high vacuums and high-vacuum systems must be recognized and understood prior to testing such a system for leaks. These characteristics are briefly discussed below.

Tracer-gas diffusion rates are highly variable and are dependent on the type of gas used and the configuration of the system. The diffusion rates of such gases as helium and hydrogen are generally eight or nine times higher than those of the Freons.

Attachment of Mass Spectrometer. Mass spectrometers incorporate pumping systems that can be used to maintain the vacuum if small systems are being tested and the leakage is small. With large systems, it may be necessary to operate system diffusion vacuum pumps backed with forepump mechanical vacuum pumps while the system is being tested. In general, the mass spectrometer should be attached to the foreline of the diffusion pumps, parallel with the forepumps, and not to the test vessel (Fig. 14a). In this manner, the mass spectrometer will receive an amount of tracer gas that is proportional to the pumping rate of the spectrometer and the forepump according to:

$$T_G = \frac{100 S_1}{(S_2 + S_1)} \quad (\text{Eq 8})$$

where T_G is the percentage of total tracer-gas leakage flowing to the mass spectrometer, S_1 is the spectrometer pumping speed, and S_2 is the forepump pumping speed. If the mass spectrometer is connected directly to the test vessel, it will receive only a small amount of tracer gas because the spectrometer pumping speed is generally far lower than that of the

vacuum chamber diffusion pumps (Fig. 14b). Conversely, when the mass spectrometer is connected to the diffusion pump foreline, the compression of the evacuated gas increases the total gas pressure in the foreline and in turn increases the tracer gas partial pressure in that line, which makes it more detectable than if it were sensed directly from the vessel. If the system throughout is small, however, the system diffusion pumps and roughing pumps can be valved off or backed by the mass-spectrometer pumps, which in turn will maintain the desired vacuum.

Fig. 14 Schematics of correct (a) and incorrect (b) connections in pumping setups for the vacuum leak testing of large volumes

System Materials and Cleanliness. Both the vacuum system and the leak testing system should be maintained in a very clean state; otherwise, contaminant outgassing will result, reducing the system vacuum. The proper materials must also be selected to reduce hang-up of the tracer gas; glass or stainless steel is recommended. Grease coatings on seals and the use of rubber should be held to a minimum because these materials readily absorb helium and then slowly release it, giving a high background count.

Temperature and Tracer-Gas Concentration. For leak testing, the temperature should be held constant, when possible, preferably at the expected operating temperature of the item tested. Also, tracer-gas concentration should be as high as possible to ensure sufficient detector response.

Vacuum Leak Testing Methods

The equipment most commonly used for the leak testing of vacuum systems involves the use of manometers, halogen detectors, mass spectrometers, ionization gages, thermal-conductivity gages, residual gas analyzers, partial pressure analyzers, and gas chromatographs. The methods used with this equipment are listed in Table 3. Methods that can be used with both vacuum and pressure systems are discussed in detail in the section "Leak Testing of Pressure Systems Using Specific-Gas Detectors" in this article.

Manometers. Testing for leaks in systems under vacuum can be done by observing the manometers installed on the system. Although manometers are not as adaptable to locating a leak as regular leak detectors, some indication of leakage can be attained. Because most vacuum gages will react or change their reading in the presence of a tracer gas, spraying tracer gases over individual portions of the vacuum system will produce a gage response and will provide some indication of leak location. The location can also be roughly established by isolating various portions of the system and observing the gage response. The primary evidence of a leak in the system is failure of the system to achieve anticipated pressure levels in a certain pumping time as based on past or calculated performance. However, consideration must be given to other gas loads (virtual leaks) that may exist in the system. Sources of these gas loads are system contaminants, such as water, outgassing of chamber surfaces and test items, and outgassing of entrapped areas such as unvented O-ring grooves.

Pressure-change gages having a pressure-change sensitivity of 0.13 mPa (10^{-6} torr) are available for vacuum applications. Ionization gages will measure vacuums to 1.3 pPa (10^{-14} torr) and can be used to measure changes in pressure. The sensitivity of all pressure-change methods is time dependent (that is, the mass changes per unit of time); therefore, the longer the test duration, the more sensitive the method.

Halogen Detectors. Heated anode halogen detectors can also be used on vacuum systems. With special adapters, they can be used down to 0.13 Pa (10^{-3} torr). Leaks are detected by using an externally applied tracer gas.

Mass spectrometers are well suited for use as leak detectors in vacuum systems because the detector tube of a mass spectrometer must be maintained at a vacuum. Also, mass spectrometers usually have built-in vacuum-pumping systems that can be directly coupled to the system being tested. Helium mass spectrometers are most commonly used. Leaks are detected by spraying or enveloping the outer surface of the system with helium.

Ionization Gages. In addition to detecting leaks in vacuum systems by pressure-change instruments, ionization gages can be used to detect the presence of specific tracer gases. Because each gas traveling through the gage ionizes differently, equal flows of different gases will produce different readings. Leak rates for molecular or laminar flow can be related to ionization-gage readings in response to a tracer gas through:

$$Q_a = \frac{\Delta R S_a}{(\sigma - 1)} \text{ (Molecular)} \quad (\text{Eq 9})$$

$$Q_a = \frac{\Delta R S_a}{[(\sigma v/\mu) - 1]} \text{ (Laminar)} \quad (\text{Eq 10})$$

where Q_a is the flow of air (in torr liters per second), ΔR is the change in ionization-gage reading (in torr), S_a is the pumping speed (in liters per second), σ is the gage sensitivity factor, $v = \eta_a/\eta_t$ (where η_a is the viscosity of air and η_t is viscosity of tracer gas), and $\mu = (M_a/M_t)^{\frac{1}{2}}$ (where M_a is the molecular weight of air and M_t is the molecular weight of tracer gas). Values of σ for ionization gages, and of the gas factors $(\sigma - 1)$ and $[(\sigma v/\mu) - 1]$, for several gases are as follows:

Gas	Gas factor		
	σ	$(\sigma - 1)$	$[(\sigma/\mu) - 1]$
Helium	0.17	-0.83	-0.93
Argon	1.3	0.3	0.85
Carbon dioxide	1.4	0.4	0.4
Water vapor	0.9	-0.1	-0.72
Hydrocarbons	3-10	2-9	1-10
Hydrogen	0.5	-0.5	-0.94

By spraying tracer gas over the outside surface of a vacuum system, leaks can be located by observing the ionization-gage response. The gage reading should decrease in the presence of gases having a negative gas-factor value and should increase for gases having a positive value.

The palladium-barrier gage is a modified ionization gage that has a palladium barrier in front of the ionization chamber. Hydrogen is used as a tracer gas because it is the only gas that will permeate heated palladium into the ionization chamber.

Thermal-Conductivity Gages. The thermal conductivity of a gas is a function of its mean free path; therefore, gages measuring the thermal conductivity of the gas as it passes over a heated filament will indicate vacuum. Several types of these gages, including Pirani gages, are available (see the discussion on thermal-conductivity gages in the section "Leak Testing of Pressure Systems Without a Tracer Gas" in this article).

Gas chromatographs can be used as leak detectors in vacuum systems by condensing in a cold trap a sample of gas drawn from the vacuum system with a vacuum pump. The cold trap is then isolated from the vacuum system with valves, and the frozen gas is released to the chromatograph by warming the trap. The sensitivity of this instrument is limited essentially by the volume of sample drawn into the cold trap, the volume being proportional to the length of time the gas is drawn into the cold trap.

Residual gas analyzers and partial pressure analyzers are similar in operating principle to mass-spectrometer leak detectors. They have the added advantage of being able to scan the molecular peaks of all gases within the sample entering the instrument. This provides the leak-test operator with information as to whether the sample is predominantly leakage or contamination from system surfaces, O-rings, and cleaning agent residues. They have the disadvantage of having no integral pump system. They must be installed behind a pump system on the system being tested in order to obtain any kind of reasonable response time if they are to be used for leak detection and location.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Choosing the Optimum Leak Testing Method

The three major factors that determine the choice of leak testing method are:

- The physical characteristics of the system and the tracer fluid
- The size of the anticipated leak
- The reason for conducting the test (that is, locating or detecting a leak or measuring a leak rate)

System and Tracer-Fluid Characteristics. The physical characteristics of the system play a large role in the selection of leak detection methods. If a tracer fluid, either gas or liquid, is used, it must be nonreactive with the test item or system components. In general, the items or systems should be leak tested with the actual working fluid. This eliminates any errors that might be caused by converting from tracer-fluid leakage to working-fluid leakage. It is also possible that tracer-fluid leakage will occur while working-fluid leakage will not, and vice versa.

If tracer gas is to be used, consideration should be given to the characteristics of the gas. In most cases, gases with high diffusion rates and small molecular size, such as hydrogen and helium, are desirable. On the other hand, when probing the surface of a container filled with tracer gas, it may be desirable to use a persistent gas or a gas with a low diffusion rate. A persistent gas will remain in the leak area longer and may facilitate leak detection and location because of an increase in tracer-gas concentration.

Leak Size. The method and instrument must match or be responsive to the size of the leak. The approximate working ranges of several leak detectors or leak detection methods are given in Fig. 15. If leakage is too great, the leak detector will be swamped. This is normally self-evident because the detector will go to full scale and stay there until it is removed from the leakage source. Some combustible-gas detectors, however, may return to zero in the presence of a high concentration of leakage. For example, if the vapor-to-air ratio of gasoline vapor becomes richer than about one part vapor to nine parts air, the mixture is no longer combustible, and the catalytic detector may indicate zero or some nominal value, despite the fact that high concentrations of gasoline vapor exist.

Fig. 15 Approximate working ranges of various leak detectors or leak detection methods

Small leaks may also produce no response on a given detector, thus eliminating any possibility of finding the leak. It should not be assumed, however, that the leakage is zero. There is universal agreement that the terms zero leakage and no leakage are inaccurate. Specifications or test procedures should define leakage with such terms as minimum detectable leakage or a maximum leak rate.

Leak Location. If leak location is the purpose of the test, methods that include the use of probes or portable detectors are necessary so that the surface of the test vessel can be scanned. In vacuum systems, tracer gas can be sprayed over the vessel surface and its entry point detected by observing the leak detector reaction as the tracer-gas spray is moved along

the surface. In pressure systems, bubbles, immersion, liquid penetrants, and chemical indicators provide means of locating leaks through visual observation. Figure 16 outlines various methods of leak detection and leakage rate measurement in terms of methods, sensitivity, and cost.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

System Response

The response of a leaking system to a leak is important in leak testing; if the response is too slow, it can be very time consuming to locate the leak, or the leak can be missed. A number of factors affect system response, including size of the leak, diffusion rate of the tracer gas, absorption and adsorption of the tracer gas, cleanup time of the detector, pumping speed, and volume of the system. Attention must be given to these factors to minimize response time.

Leak Size. Theoretically, leak size does not affect system response time; it only affects the magnitude of the detector readout. However, if some type of leakage accumulation (or mass loss) method is being employed, leak size will affect response time because sufficient leakage must be accumulated (or lost) before the detector will respond.

The smallest leakage to which the detector will respond is termed the minimum detectable leakage and is measured by observing the leak detector reaction to a calibrated or known leakage. When calculating the minimum detectable leakage of a mass spectrometer, it is conventional practice that the noise and random-background count rate be doubled. The sensitivity of the mass-spectrometer detector is defined by:

$$S = \frac{Q}{(D - B_s)} \quad (\text{Eq 11})$$

where S is the sensitivity (in atmosphere cubic centimeters per second per scale division), D is the total deflection produced by the calibrated leak (in scale divisions), Q is the calibrated leakage flow (in atmosphere cubic centimeters per second), and B_s is the steady background reading (in scale divisions). In terms of S , the minimum detectable leakage (MDL) can be expressed as:

$$\text{MDL} = 2(N + B_R)(S) \quad (\text{Eq 12})$$

where N is the scale deflection produced by instability or noise in system (in scale divisions) and B_R is the random background deflection (in scale divisions).

Tracer-Gas Diffusion Rate. In large, open vessels, gas diffusion is not a major problem. However, in tortuous systems, one investigator found that even after 24 h neither helium nor Freon had evenly diffused throughout the system.

Absorption and adsorption of tracer gas are responsible for hang-up in the system; they can also materially reduce tracer-gas concentration. Permeation also causes difficulties; for example, helium permeates through a 25 mm (1 in.) diam O-ring in about 1 h, thus producing a detectable reading in the system.

Detector cleanup time (the time required for the leak detector to purge itself of tracer gas) can range from a few seconds to several minutes, thus affecting the time between searches for a leak. Cleanup time is usually defined as the time it takes for the meter reading to decay to 37% of its maximum value.

Pumping Speed. It can be shown that a leak detector will exhibit a readout deflection that is 63% of its maximum value at some characteristic time, t , known as the response time. Response time can be calculated as $t = V/S$, where V is the system volume in liters and S is the pumping speed in liters per second. Increasing the pumping speed will decrease the response time, but will introduce a corresponding decrease in the maximum signal. Increasing the pumping speed by a factor of ten will reduce the readout deflection of the detector by a factor of ten, which may cause problems. Calculation of the response time is useful for determining the length of time that a tracer gas must be sprayed over the external surface of a vessel under vacuum in order to detect a leak. For example, if the vessel has a volume 1000 L and the leak detector has a pumping speed of 5 L/s, then the suspected leak area should be sprayed with search gas for about 200 s (1000/5) for the detector to reach 63% of its maximum value.

System Volume. The larger the volume of the system, the smaller the concentration of leakage. This can be alleviated by closing off part of the system when possible. The enclosures used to trap the leakage should be as small as possible. For example, if the leakage of tracer gas is 10^{-5} atm cm³, if the enclosure volume minus the test unit volume is 10⁶ cm³, and if the detector can detect 1 ppm of search gas, then the tracer gas will take about 28 h to reach detectable concentration.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Measurement of Leak Rate Using Calibrated Leaks

Leak-rate measurement can be accomplished with almost any of the standard leak detecting methods in conjunction with a calibrated or known leak. If the leakage is inward, it can be measured by tracer-gas concentration inside the vessel or system vacuum. If the leakage is outward, it can be collected in an enclosure and the concentration rise within the

enclosure monitored; it can also be measured by placing the leak detector probe directly over the leak and isolating the surrounding area with a suction cup. In addition, leaks can be measured by mass change methods.

To calibrate a leak testing instrument to measure leakage rates, its response to a known leakage must be found. Furthermore, the instrument should be calibrated with the smallest leakage to which it will respond, preferably using the fluid that will be utilized during testing, because most leak detectors respond differently to different fluids. Leak detectors for measuring gross changes in mass or flow can be calibrated in a conventional manner by using dead-weight testers, nozzles, orifices, and manometers. The more sensitive gas or tracer-gas detectors can be calibrated by injecting known amounts of tracer gas into the system or by using standard or calibrated leaks.

A standard leak can be made by constructing a device with a small orifice or nozzle; by maintaining constant upstream pressure, the flow will be constant. Another method is to maintain the upstream pressure at a level high enough to produce flow of sonic velocity at the nozzle throat, thus making the leakage independent of upstream pressure. Very small calibrated leaks are produced by flow through a capillary tube or by permeation through a membrane (normally glass). The capillary type may or may not have a self-contained gas supply. There is an advantage to capillary-type leaks not having a self-contained gas supply, because a variety of gases can be used with them, although a constant tracer-gas pressure must be supplied. Capillary tubes may be purchased with leak rates ranging from about 10^{-2} to 10^{-7} atm cm³/s. Specific leak sizes are also available; these calibrated leaks can normally be supplied to match any specified leakage within about 20%. Permeation-type standard leaks are supplied with their own self-contained gas supply, usually helium. Although the flow through the membrane is molecular and therefore pressure dependent, typical helium loss is only 10% in 10 years. These leaks have a flow in the range of 10^{-6} to 10^{-10} atm cm³/s.

Leak Testing

Revised by Gerald L. Anderson, American Gas and Chemical Company

Common Errors in Leak Testing

The most common errors encountered in leak testing are:

- Use of a method that is too sensitive
- Use of only one leak-testing method
- Failure to control the environment in the vicinity of the leak

Because sensitive methods cannot be used in the presence of gross leaks, leak testing should be conducted in two or more stages, beginning with gross testing and progressing to the more sensitive methods. This procedure saves both time and money.

Control of environment in the vicinity of the leak consists of a number of steps, depending on the test method employed. If a tracer gas is being used, the atmosphere must be controlled to prevent contamination by the tracer gas that might be erroneously reported as a leak. If sonic or ultrasonic methods are being used, background noise must be controlled. If small leaks are present, airborne contaminants may cause temporary plugging of the leak. For example, breathing on a molecular leak may cause it to plug due to water vapor in the breath. Particulate matter in the air may plug or partially plug a leak. Table 5 lists the differences in leak tightness requirements for a variety of industrial products.

Table 5 Leak tightness requirements for various products

Leak testing term	Vessel or part (material contained)	Minimum detectable leakage rate, std cm ³ /s
Large	Truck (gravel)	1×10^3

	Hourglass (sand)	1×10^2
	Car window (air)	1×10^{-1}
Gross	Tuck (oil)	1×10^{-2}
	Bucket (water)	1×10^{-3}
	Storage tank (gasoline)	1×10^{-4}
Small	Pipeline (gas)	1×10^{-5}
	Tanker (liquified natural gas)	1×10^{-6}
Fine	Storage tank (NH ₃)	1×10^{-8}
	Heart pacemaker (gas)	1×10^{-11}

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrox Inc., and Gail Jordan, Howmet Corporation

Introduction

LIQUID PENETRANT INSPECTION is a nondestructive method of revealing discontinuities that are open to the surfaces of solid and essentially nonporous materials. Indications of a wide spectrum of flaw sizes can be found regardless of the configuration of the workpiece and regardless of flaw orientations. Liquid penetrants seep into various types of minute surface openings by capillary action. Because of this, the process is well suited to the detection of all types of surface cracks, laps, porosity, shrinkage areas, laminations, and similar discontinuities. It is extensively used for the inspection of wrought and cast products of both ferrous and nonferrous metals, powder metallurgy parts, ceramics, plastics, and glass objects.

In practice, the liquid penetrant process is relatively simple to utilize and control. The equipment used in liquid penetrant inspection can vary from an arrangement of simple tanks containing penetrant, emulsifier, and developer to sophisticated computer-controlled automated processing and inspection systems. Establishing procedures and standards for the inspection of specific parts or products is critical for optimum end results.

The liquid penetrant method does not depend on ferromagnetism (as does, for example, magnetic particle inspection), and the arrangement of the discontinuities is not a factor. The penetrant method is effective not only for detecting surface flaws in non-magnetic metals but also for revealing surface flaws in a variety of other nonmagnetic materials. Liquid penetrant inspection is also used to inspect items made from ferromagnetic steels; generally, its sensitivity is greater than that of magnetic particle inspection.

The major limitation of liquid penetrant inspection is that it can detect only imperfections that are open to the surface; some other method must be used for detecting subsurface flaws. Another factor that can limit the use of liquid penetrants is surface roughness or porosity. Such surfaces produce excessive background and interfere with inspection.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Physical Principles

Liquid penetrant inspection depends mainly on a penetrant's effectively wetting the surface of a solid workpiece or specimen, flowing over that surface to form a continuous and reasonably uniform coating, and then migrating into cavities that are open to the surface. The cavities of interest are usually exceedingly small, often invisible to the unaided eye. The ability of a given liquid to flow over a surface and enter surface cavities depends principally on the following:

- Cleanliness of the surface
- Configuration of the cavity
- Cleanliness of the cavity
- Size of surface opening of the cavity
- Surface tension of the liquid
- Ability of the liquid to wet the surface
- Contact angle of the liquid

The cohesive forces between molecules of a liquid cause surface tension. An example of the influence of surface tension is the tendency of free liquid, such as a droplet of water, to contract into a sphere. In such a droplet, surface tension is counterbalanced by the internal hydrostatic pressure of the liquid. When the liquid comes into contact with a solid surface, the cohesive force responsible for surface tension competes with the adhesive force between the molecules of the liquid and the solid surface. These forces jointly determine the contact angle, θ , between the liquid and the surface (Fig. 1). If θ is less than 90° (Fig. 1a), the liquid is said to wet the surface, or to have good wetting ability; if the angle is equal to or greater than 90° (Fig. 1b and c), the wetting ability is considered poor.

Fig. 1 Wetting characteristics as evaluated by the angle, θ , between a droplet of liquid and a solid surface. Good wetting is obtained when $\theta < 90^\circ$ (a); poor wetting, when $\theta \geq 90^\circ$ (b) and (c).

Closely related to wetting ability is the phenomenon of capillary rise or depression (Fig. 2). If the contact angle, θ , between the liquid and the wall of the capillary tube is less than 90° (that is, if the liquid wets the tube wall), the liquid meniscus in the tube is concave, and the liquid rises in the tube (Fig. 2a). If θ is equal to 90° , there is no capillary

depression or rise (Fig. 2b). If θ is greater than 90° , the liquid is depressed in the tube and does not wet the tube wall, and the meniscus is convex (Fig. 2c). In capillary rise (Fig. 2a), the meniscus does not pull the liquid up the tube; rather, the hydrostatic pressure immediately under the meniscus is reduced by the distribution of the surface tension in the concave surface, and the liquid is pushed up the capillary tube by the hydraulically transmitted pressure of the atmosphere at the free surface of the liquid outside the capillary tube. Figure 3 clearly shows the forces that cause liquid to rise in a capillary tube.

Fig. 2 Rise or depression in small vertical capillary tubes, determined by the contact angle θ , between a liquid and the wall of a capillary tube. (a) $\theta < 90^\circ$: capillary rise. (b) $\theta = 90^\circ$: no capillary depression or rise. (c) $\theta > 90^\circ$: capillary depression

Downward force (F_d) is equal to the weight of the liquid column:

$$F_d = 2\pi r^2 h g \rho$$

Upward force (F_u) is equal to the surface tension times the perimeter of the meniscus:

$$F_u = (T \cos \theta) (2\pi r)$$

Where r is the inside radius of the capillary tube, h is the height of the liquid in the tube, g is acceleration due to gravity, ρ is density of the liquid, T is surface tension, and θ is the contact angle.

Fig. 3 Schematic showing the forces involved in capillary rise: the downward force from weight of the liquid column, and the upward force from surface tension along the meniscus perimeter

The height to which the liquid rises is directly proportional to the surface tension of the liquid and to the cosine of the angle of contact, and it is inversely proportional to the density of the liquid and to the radius of the capillary tube. If, as in Fig. 4, the capillary tube is closed, a wetting liquid will still rise in the tube; however, there will be extra pressure resulting from the air and vapor compressed in the closed end of the tube, and the capillary rise will not be as great.

Fig. 4 Schematic showing that the rise and depression of liquids in closed capillary tubes are affected by the compressed air entrapped in the closed end. Compare height of liquid in tube shown in Fig. 3 with that in the tube here.

These examples of surface wetting and capillary rise illustrate the basic physical principles by which a penetrant enters fine surface discontinuities even though the practical circumstances encountered in the use of liquid penetrants are more complex than these examples may suggest. Cracks, for example, are not capillary tubes, but simulate the basic interaction between a liquid and a solid surface, which is responsible for the migration of penetrants into fine surface cracks.

The viscosity of the liquid is not a factor in the basic equation of capillary rise. Viscosity is related to the rate at which a liquid will flow under some applied unbalanced stress; in itself, viscosity has a negligible effect on penetrating ability. In general, however, very viscous liquids are unsuitable as penetrants because they do not flow rapidly enough over the surface of the workpiece; consequently, they require excessively long periods of time to migrate into fine flaws.

Another necessary property of a penetrant is its capability of dissolving an adequate amount of suitable fluorescent or visible-dye compounds. Finally, the penetrant liquid must be removable with a suitable solvent/remover or emulsifier without precipitating the dye.

Just as it is important that a penetrant enter surface flaws, it is also important that the penetrant be retained in the flaws and emerge from the flaw after the superficial coating is removed from the surface and the developer is applied. It is apparently a paradox that the same interaction between a liquid and a surface that causes the liquid to enter a fine opening is also responsible for its emergence from that opening. The resolution of the paradox is simple: Once the surface has been freed of excess penetrant it becomes accessible to the entrapped liquid, which, under the effect of the adhesive forces between liquid and solid, spreads over the newly cleaned surface until an equilibrium distribution is attained (Fig. 5).

Fig. 5 Bead of liquid penetrant formed when, after excess penetrant has been removed from a workpiece surface, the penetrant remaining in a discontinuity emerges to the surface until an equilibrium is established.

Although in some cases the amount of penetrant in a surface bead at equilibrium is sufficient to be detected visually, sensitivity is vastly increased by the use of a developer, of which there are several types available (forms A, B, C, and D). When applied, a developer forms a fine surface film, that is, a spongelike system of very fine, random capillary paths. If the penetrant contacts the powder, the powder then competes with the freshly cleaned surface of the workpiece for the penetrant as it flows out of the defect. If the developer is properly designed, it readily adsorbs the penetrant from the flaw. The penetrant continues to migrate by capillary action, spreading through the developer until an equilibrium is reached. This migrating action is illustrated schematically in Fig. 6. The visibility of the entrapped penetrant within the flaw is greatly increased by the spreading or enlargement of the indication.

Fig. 6 Sectional view showing result of the migrating action of a liquid penetrant through a developer

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Evolution of the Process

The exact origin of liquid penetrant inspection is not known, but it has been assumed that the method evolved from the observation that the rust on a crack in a steel plate in outdoor storage was somewhat heavier than the rust on the adjacent surfaces as a result of water seeping into the crack and forcing out the oxide it had helped to produce. The obvious conclusion was that a liquid purposely introduced into surface cracks and then brought out again would reveal the locations of those cracks.

The only material that fulfilled the known criteria of low viscosity, good wettability, and ready availability was kerosene. It was found, however, that although wider cracks showed up easily, finer ones were sometimes missed because of the difficulty of detecting, by purely visual means, the small amounts of kerosene exuding from them. The solution was to provide a contrasting surface that would reveal smaller seepages. The properties and availability of whitewash made it the logical choice. This method, known as the kerosene-and-whiting test, was the standard for many years. The sensitivity of the kerosene-and-whiting test could be increased by hitting the object being tested with a hammer during testing. The resulting vibration brought more of the kerosene out of the cracks and onto the whitewash. Although this test was not as sensitive as those derived from it, it was quick, inexpensive, and reasonably accurate. Thus, it provided a vast improvement over ordinary visual examination.

The first step leading to the methods now available was the development of the fluorescent penetrant process by R.C. Switzer. This liquid, used jointly with a powder developer, brought penetrant inspection from a relatively crude procedure to a more scientific operation. With fluorescent penetrant, minute flaws could be readily detected when exposed to ultraviolet light (commonly called black light). This development represented a major breakthrough in the detection of surface flaws.

Switzer's work also included the development of the visible-color contrast method, which allowed for inspection under white light conditions. Although not as sensitive as fluorescent penetrant inspection, it is widely used in industry for noncritical inspection. Through the developments described above, liquid penetrant inspection has become a major nondestructive inspection method.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Penetrant Methods

Because of the vast differences among applications for penetrant inspection, it has been necessary to refine and develop the two types of penetrants (type I, fluorescent, and type II, visible) into four basic methods to accommodate the wide variations in the following principal factors:

- Surface condition of the workpiece being inspected
- Characteristics of the flaws to be detected
- Time and place of inspection
- Size of the workpiece
- Sensitivity required

The four methods are broadly classified as:

- Water washable, method A
- Postemulsifiable lipophilic, method B
- Solvent removable, method C
- Postemulsifiable hydrophilic, method D

These four methods are described below.

Water-washable penetrant (method A) is designed so that the penetrant is directly water washable from the surface of the workpiece; it does not require a separate emulsification step, as does the postemulsifiable penetrant methods. It can be used to process workpieces quickly and efficiently. It is important, however, that the washing operation be carefully controlled because water-washable penetrants are susceptible to overwashing. The essential operations involved in this method are illustrated schematically in Fig. 7.

Fig. 7 Five essential operations for liquid penetrant inspection using the water-washable system

Postemulsifiable penetrants (methods B and D) are designed to ensure the detection of minute flaws in some materials. These penetrants are not directly water washable. Because of this characteristic, the danger of overwashing the penetrant out of the flaws is reduced. The difference between the water-washable and postemulsifiable method lies in the use of an emulsifier prior to final rinsing. The emulsifier makes the residual surface penetrant soluble in water so that the excess surface penetrant can be removed by the water rinse. Therefore, the emulsification time must be carefully controlled so that the surface penetrant becomes water soluble but the penetrant in the flaws does not. The operations involved in the postemulsifiable method are illustrated schematically in Fig. 8 for the lipophilic system and in Fig. 9 for the hydrophilic system. Despite the additional processing steps involved with the postemulsifiable methods B and D, these methods are the most reliable for detecting minute flaws.

Fig. 8 Operations (in addition to precleaning) for the postemulsifiable, method B, lipophilic liquid penetrant system

Fig. 9 Operations (in addition to precleaning) for the postemulsifiable, method D, hydrophilic liquid penetrant system

Solvent-removable penetrant (method C) is available for use when it is necessary to inspect only a localized area of a workpiece or to inspect a workpiece at the site rather than on a production inspection basis. Normally, the same type of solvent is used for precleaning and for removing excess penetrant. This penetrant process is convenient and broadens the range of applications of penetrant inspections. However, because the solvent-removable method is labor intensive, it is not practical for many production applications. When properly conducted and when used in the appropriate applications, the solvent-removable method can be one of the most sensitive penetrant methods available. The operations for this process are illustrated schematically in Fig. 10.

Fig. 10 Operations (in addition to precleaning) for the solvent-removable liquid penetrant system

Whichever penetrant method is chosen, the degree and speed of excess penetrant removal depend on such processing conditions as spray nozzle characteristics, water pressure and temperature, duration of the rinse cycle, surface condition of the workpiece, and inherent removal characteristics of the penetrant employed.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Description of the Process

Regardless of the type of penetrant used, that is, fluorescent (type I) or visible (type II), penetrant inspection requires at least five essential steps, as follows.

Surface Preparation. All surfaces to be inspected, whether localized or the entire workpiece, must be thoroughly cleaned and completely dried before being subjected to penetrant inspection. Flaws exposed to the surface must be free from oil, water, or other contaminants if they are to be detected.

Penetration. After the workpiece has been cleaned, penetrant is applied in a suitable manner so as to form a film of the penetrant over the surface. This film should remain on the surface long enough to allow maximum penetration of the penetrant into any surface openings that are present.

Removal of Excess Penetrant. Excess penetrant must be removed from the surface. The removal method is determined by the type of penetrant used. Some penetrants can be simply washed away with water; others require the use of emulsifiers (lipophilic or hydrophilic) or solvent/remover. Uniform removal of excess surface penetrant is necessary for effective inspection, but overremoval must be avoided.

Development. Depending on the form of developing agent to be used, the workpiece is dried either before or directly after application of the developer. The developer forms a film over the surface. It acts as a blotter to assist the natural seepage of the penetrant out of surface openings and to spread it at the edges so as to enhance the penetrant indication.

Inspection. After it is sufficiently developed, the surface is visually examined for indications of penetrant bleedback from surface openings. This examination must be performed in a suitable inspection environment. Visible penetrant inspection is performed in good white light. When fluorescent penetrant is used, inspection is performed in a suitably darkened area using black (ultraviolet) light, which causes the penetrant to fluoresce brilliantly.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Materials Used in Penetrant Inspection

In addition to the penetrants themselves, liquids such as emulsifiers, solvent/cleaners and removers, and developers are required for conducting liquid penetrant inspection.

Penetrants

There are two basic types of penetrants:

- Fluorescent, type I
- Visible, type II

Each type is available for any one of the four methods (water washable, postemulsifiable lipophilic, and postemulsifiable hydrophilic, and solvent removable) mentioned in the section "Penetrant Methods" in this article.

Type I fluorescent penetrant utilizes penetrants that are usually green in color and fluoresce brilliantly under ultraviolet light. The sensitivity of a fluorescent penetrant depends on its ability to form indications that appear as small sources of light in an otherwise dark area. Type I penetrants are available in different sensitivity levels classified as follows:

- *Level $\frac{1}{2}$* : Ultralow
- *Level 1*: Low
- *Level 2*: Medium
- *Level 3*: High
- *Level 4*: Ultrahigh

Type II visible penetrant employs a penetrant that is usually red in color and produces vivid red indications in contrast to the light background of the applied developer under visible light. The visible penetrant indications must be viewed under adequate white light. The sensitivity of visible penetrants is regarded as Level 1 and adequate for many applications.

Penetrant selection and use depend on the criticality of the inspection, the condition of the workpiece surface, the type of processing, and the desired sensitivity (see the section "Selection of Penetrant Method" in this article).

Method A, water-washable penetrants are designed for the removal of excess surface penetrant by water rinsing directly after a suitable penetration (dwell) time. The emulsifier is incorporated into the water-washable penetrant. When this type of penetrant is used, it is extremely important that the removal of excess surface penetrant be properly controlled to prevent overwashing, which can cause the penetrant to be washed out of the flaws.

Methods B and D, lipophilic and hydrophilic postemulsifiable penetrants are insoluble in water and therefore not removable by water rinsing alone. They are designed to be selectively removed from the surface of the workpiece by the use of a separate emulsifier. The emulsifier, properly applied and left for a suitable emulsification time, combines with the excess surface penetrant to form a water-washable surface mixture that can be rinsed from the surface of the workpiece. The penetrant that remains within the flaw is not subject to overwashing. However, proper emulsification time must be established experimentally and maintained to ensure that overemulsification, which results in the loss of flaws, does not occur.

Method C, solvent-removable penetrants are removed by wiping with clean, lint-free material until most traces of the penetrant have been removed. The remaining traces are removed by wiping with clean, lint-free material lightly moistened with solvent. This type of penetrant is primarily used where portability is required and for the inspection of localized areas. To minimize the possibility of removing the penetrant from discontinuities, the use of excessive amounts of solvent must be avoided.

Physical and Chemical Characteristics. Both fluorescent and visible penetrants, whether water washable, postemulsifiable, or solvent removable, must have certain chemical and physical characteristics if they are to perform their intended functions. The principal requirements of penetrants are as follows:

- Chemical stability and uniform physical consistency
- A flash point not lower than 95 °C (200 °F); penetrants that have lower flash points constitute a potential fire hazard
- A high degree of wettability
- Low viscosity to permit better coverage and minimum dragout

- Ability to penetrate discontinuities quickly and completely
- Sufficient brightness and permanence of color
- Chemical inertness with materials being inspected and with containers
- Low toxicity to protect personnel
- Slow drying characteristics
- Ease of removal
- Inoffensive odor
- Low cost
- Resistance to ultraviolet light and heat fade

Emulsifiers

Emulsifiers are liquids used to render excess penetrant on the surface of a workpiece water washable. There are two methods used in the postemulsifiable method: method B, lipophilic, and method D, hydrophilic. Both can act over a range of durations from a few seconds to several minutes, depending on the viscosity, concentration, method of application, and chemical composition of the emulsifier, as well as on the roughness of the workpiece surface. The length of time an emulsifier should remain in contact with the penetrant depends on the type of emulsifier employed and the roughness of the workpiece surface.

Method B, lipophilic emulsifiers are oil based, are used as supplied, and function by diffusion (Fig. 11). The emulsifier diffuses into the penetrant film and renders it spontaneously emulsifiable in water. The rate at which it diffuses into the penetrant establishes the emulsification time. The emulsifier is fast acting, thus making the emulsification operation very critical. The emulsifier continues to act as long as it is in contact with the workpiece; therefore, the rinse operation should take place quickly to avoid overemulsification.

Fig. 11 Elements in the functioning of lipophilic emulsifiers

Method D, hydrophilic emulsifiers are water based and are usually supplied as concentrates that are diluted in water to concentrations of 5 to 30% for dip applications and 0.05 to 5% for spray applications. Hydrophilic emulsifiers function by displacing excess penetrant from the surface of the part by detergent action (Fig. 12). The force of the water spray or

the air agitation of dip tanks provides a scrubbing action. Hydrophilic emulsifier is slower acting than the lipophilic emulsifier; therefore, it is easier to control the cleaning action. In addition to the emulsifier application, method D also requires a prerinse. Utilizing a coarse water spray, the prerinse helps remove the excess penetrant to minimize contamination of the emulsifier. Of greater significance, only a very thin and uniform layer of penetrant will remain on the surface, thus allowing easy removal of the surface layer with minimum opportunity of removing penetrant from the flaws. This step is required because the penetrant is not miscible with the hydrophilic emulsifier.

Fig. 12 Elements in the functioning of hydrophilic emulsifiers

The penetrant manufacturer should recommend nominal emulsification times for the specific type of emulsifier in use. Actual emulsification times should be determined experimentally for the particular application. The manufacturer should also recommend the concentrations for hydrophilic emulsifiers.

Solvent Cleaner/Removers

Solvent cleaner/removers differ from emulsifiers in that they remove excess surface penetrant through direct solvent action. There are two basic types of solvent removers: flammable and nonflammable. Flammable cleaners are essentially free of halogens but are potential fire hazards. Nonflammable cleaners are widely used. However, they do contain halogenated solvents, which may render them unsuitable for some applications.

Excess surface penetrant is removed by wiping, using lint-free cloths slightly moistened with solvent cleaner/remover. It is not recommended that excess surface penetrant be removed by flooding the surface with solvent cleaner/remover, because the solvent will dissolve the penetrant within the defect and indications will not be produced.

Developers

The purpose of a developer is to increase the brightness intensity of fluorescent indications and the visible contrast of visible-penetrant indications. The developer also provides a blotting action, which serves to draw penetrant from within the flaw to the surface, spreading the penetrant and enlarging the appearance of the flaw.

The developer is a critical part of the inspection process; borderline indications that might otherwise be missed can be made visible by the developer. In all applications of liquid penetrant inspection, use of a developer is desirable because it decreases inspection time by hastening the appearance of indications.

Required Properties. To carry out its functions to the fullest possible extent, a developer must have the following properties or characteristics (rarely are all these characteristics present to optimum degrees in any given material or formulation, but all must be considered in selecting a developer):

- The developer must be adsorptive to maximize blotting
- It must have fine grain size and a particle shape that will disperse and expose the penetrant at a flaw to produce strong and sharply defined indications of flaws
- It must be capable of providing a contrast background for indications when color-contrast penetrants are used
- It must be easy to apply
- It must form a thin, uniform coating over a surface
- It must be easily wetted by the penetrant at the flaw (the liquid must be allowed to spread over the particle surfaces)
- It must be nonfluorescent if used with fluorescent penetrants
- It must be easy to remove after inspection
- It must not contain ingredients harmful to parts being inspected or to equipment used in the inspection operation
- It must not contain ingredients harmful or toxic to the operator

Developer Forms. There are four forms of developers in common use:

- Form A, dry powder
- Form B, water soluble
- Form C, water suspendible
- Form D, nonaqueous solvent suspendible

The characteristics of each form are discussed below.

Dry powder developers (form A) are widely used with fluorescent penetrants, but should not be used with visible-dye penetrants because they do not produce a satisfactory contrast coating on the surface of the workpiece. Ideally, dry powder developers should be light and fluffy to allow for ease of application and should cling to dry surfaces in a fine film. The adherence of the powder should not be excessive, as the amount of black light available to energize fluorescent indications will be reduced.

For purposes of storage and handling as well as applications, powders should not be hygroscopic, and they should remain dry. If they pick up moisture when stored in areas of high humidity, they will lose their ability to flow and dust easily, and they may agglomerate, pack, or lump up in containers or in developer chambers.

For reasons of safety, dry powder developers should be handled with care. Like any other dust particle, it can dry the skin and irritate the lining of the air passages, causing irritation. If an operator will be working continuously at a developer station, rubber gloves and respirators may be desirable. Modern equipment often includes an exhaust system on the developer spray booth or on the developer dust chamber that prevents dust from escaping. Powder recovery filters are included in most such installations.

Water-soluble developers (form B) can be used for both fluorescent (type I) or visible (type II) postemulsifiable or solvent-removable penetrants. Water-soluble developers are not recommended for use with water-washable penetrants, because of the potential to wash the penetrant from within the flaw if the developer is not very carefully controlled. Water-soluble developers are supplied as a dry powder concentrate, which is then dispersed in water in recommended proportions, usually from 0.12 to 0.24 kg/L (1 to 2 lb/gal.). The bath concentration is monitored for specific gravity with

the appropriate hydrometer. Necessary constituents of the developers include corrosion inhibitors and biocides. The advantages of this form of developer are as follows:

- The prepared bath is completely soluble and therefore does not require any agitation
- The developer is applied prior to drying, thus decreasing the development time
- The dried developer film on the workpiece is completely water soluble and is thus easily and completely removed following inspection by simple water rinsing

Water-suspendible developers (form C) can be used with either fluorescent (type I) or visible (type II) penetrants. With fluorescent penetrant, the dried coating of developer must not fluoresce, nor may it absorb or filter out the black light used for inspection.

Water-suspendible developers are supplied as a dry powder concentrate, which is then dispersed in water in recommended proportions, usually from 0.04 to 0.12 kg/L ($\frac{1}{3}$ to 1 lb/gal.). The amount of powder in suspension must be carefully maintained. Too much or too little developer on the surface of a workpiece can seriously affect sensitivity. Specific gravity checks should be conducted routinely, using a hydrometer to check the bath concentration. Water-soluble developers contain dispersing agents to help retard settling and caking as well as inhibitors to prevent or retard corrosion of workpieces and equipment, and biocides to extend the working life of the aqueous solutions. In addition, wetting agents are present to ensure even coverage of surfaces and ease of removal after inspection.

Water-suspendible developer is applied before drying; therefore, developing time can be decreased because the heat from the drier helps to bring penetrant back out of surface openings. In addition, with the developer film already in place, the developing action begins at once. Workpieces are ready for inspection in a shorter period of time.

Nonaqueous solvent-suspendible developers (form D) are commonly used for both the fluorescent and the visible penetrant process. This form of developer produces a white coating on the surface of the part. This coating yields the maximum white color contrast with the red visible penetrant indication and extremely brilliant fluorescent indication.

Nonaqueous solvent-suspendible developers are supplied in the ready-to-use condition and contain particles of developer suspended in a mixture of volatile solvents. The solvents are carefully selected for their compatibility with the penetrants. Nonaqueous solvent-suspendible developers also contain surfactants in a dispersant whose functions are to coat the particles and reduce their tendency to clump or agglomerate.

Nonaqueous solvent-suspendible developers are the most sensitive form of developer used with type I fluorescent penetrants because the solvent action contributes to the absorption and adsorption mechanisms. In many cases where tight, small flaws occur, the dry powder (form A), water-soluble (form B), and water-suspendible (form C) developers do not contact the entrapped penetrant. This results in the failure of the developer to create the necessary capillary action and surface tension that serve to pull the penetrant from the flaw. The nonaqueous solvent-suspendible developer enters the flaw and dissolves into the penetrant. This action increases the volume and reduces the viscosity of the penetrant. The manufacturer must carefully select and compound the solvent mixture. There are two types of solvent-base developers: nonflammable (chlorinated solvents) and flammable (nonchlorinated solvents). Both types are widely used. Selection is based on the nature of the application and the type of alloy being inspected.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Selection of Penetrant Method

The size, shape, and weight of workpieces, as well as the number of similar workpieces to be inspected, often influence the selection of a penetrant method.

Sensitivity and Cost. The desired degree of sensitivity and cost are usually the most important factors in selecting the proper penetrant method for a given application. The methods capable of the greatest sensitivity are also the most costly. Many inspection operations require the ultimate in sensitivity, but there are a significant number in which extreme sensitivity is not required and may even produce misleading results.

On a practical basis, the fluorescent penetrant methods are employed in a wider variety of production inspection operations than the visible penetrant methods, which are utilized primarily for localized inspections. As stated earlier, penetrants are classified on the basis of penetrant type:

- *Type I:* Fluorescent
- *Type II:* Visible
- *Method A:* Water washable
- *Method B:* Postemulsifiable-lipophilic
- *Method C:* Solvent removable
- *Method D:* Postemulsifiable-hydrophilic

Penetrants are also classified in terms of sensitivity levels:

- *Level $\frac{1}{2}$:* Ultralow
- *Level 1:* Low
- *Level 2:* Medium
- *Level 3:* High
- *Level 4:* Ultrahigh

Advantages and Limitations of Penetrant Methods. Each penetrant method, whether postemulsifiable (either lipophilic or hydrophilic), solvent removable, or water washable, using fluorescent or visible-dye penetrants, has inherent advantages and limitations.

The postemulsifiable fluorescent penetrant method is the most reliable and sensitive penetrant method. This procedure will locate wide, shallow flaws as well as tight cracks and is ideal for high-production work. On the other hand, emulsification requires an additional operation, which increases cost. Also, this method requires a water supply and facilities for inspection under black light. The postemulsifiable, lipophilic fluorescent penetrant method is less sensitive and less reliable than the hydrophilic method. Its use is therefore declining.

The solvent-removable fluorescent penetrant method employs a procedure similar to that used for the postemulsifiable fluorescent method, except that excess penetrant is removed with a solvent/remover. This method is especially recommended for spot inspection or where water cannot be conveniently used. It is more sensitive than the water-washable system, but the extreme caution and additional time required for solvent removal often preclude its use.

The water-washable fluorescent penetrant method is the fastest of the fluorescent procedures. It is also highly sensitive, reliable, and reasonably economical. It can be used for both small and large workpieces and is effective on most part surfaces. However, it will not reliably reveal open, shallow flaws if overwashed and in some cases, depending on the sensitivity level of the penetrant, will not locate the very tightest cracks. There is also the danger of overwashing by applying water for an excessive period of time or with a pressure sufficient to remove the penetrant from the flaws.

The postemulsifiable visible penetrant method is used whenever sensitivity required is greater than that provided by the water-washable visible penetrant method. However, the additional step of applying emulsifier makes this system more costly than the water-washable visible penetrant dye method that requires water, but otherwise no location limitations are imposed.

The solvent-removable visible penetrant method has a distinct advantage in that all the necessary ingredients are portable; accordingly, it can be used in a practically limitless number of locations, both in the shop and in the field. Because of the problems involved in penetrant removal, however, the method is generally confined to spot inspection or to inspection under circumstances that prohibit the use of other methods because of workpiece size or location.

The water-washable visible penetrant system is the fastest and simplest of all penetrant techniques. It is, however, the least sensitive because the penetrant is likely to be removed from wide, shallow flaws. Therefore, it is most useful in those applications where shallow and relatively wide flaws are not significant. This method is also the least sensitive for locating tight cracks. It requires a water source, but can be performed in almost any location because neither a darkened area nor electricity is required.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Equipment Requirements

The equipment used in the penetrant inspection process varies from spray or aerosol cans to complex, automated, computer-driven processing systems. Some of the more generally used types of equipment are described in the following sections.

Portable Equipment

For occasional inspections, especially in the field, where equipment portability is necessary, minimal kits for either visible or fluorescent penetrant inspection are commercially available. (Generally, portable penetrant applications are limited to localized areas or spot inspections rather than entire part surfaces.)

Such a kit for visible penetrant inspection work includes a precleaner, a penetrant, and a penetrant remover and developer, all in pressurized spray cans. Penetrant removal requires wiping with lint-free cloths or paper towels.

A similar kit is available for fluorescent work; a precleaner, a penetrant, penetrant remover and developer are likewise supplied in pressurized cans. Cleaning is accomplished by wiping with lint-free cloths or paper towels. This kit includes a small, portable black light for conducting the inspection.

Stationary Inspection Equipment

The type of equipment most frequently used in fixed installations consists of a series of modular subunits. Each subunit performs a special task. The number of subunits in a processing line varies with the type of penetrant method used. The subunits are:

- Drain and/or dwell stations
- Penetrant and emulsifier stations
- Pre- and post-wash stations
- Drying station
- Developer station
- Inspection station
- Cleaning stations

The drain or dwell stations are actually roller-top benches that hold the parts during the processing cycle. The usual arrangement is to position a drain or dwell station following each of the dip tanks, the wash station, and the drying oven. The subunits are described in more detail below.

Penetrant Station. The principal requirement of a penetrant station is that it provide a means for coating workpieces with penetrant—either all over, for small workpieces, or over small areas of large workpieces when only local inspection is required. In addition, means should be provided for draining excess penetrant back into the penetrant reservoir, unless the expendable technique is being used. Draining racks usually serve the additional purpose of providing a storage place for parts during the time required for penetration (dwell time).

Small workpieces are easily coated by dipping them into a reservoir of penetrant. This may be done individually or in batches in a wire basket.

The penetrant container should be equipped with an easily removable cover to reduce evaporation when not in use. A drain cock should also be provided to facilitate draining of the tank for cleaning. Containers are usually made of steel, but stainless steel containers should be used with water-base penetrants.

For large workpieces, penetrant is often applied by spraying or flowing. This is done mainly for convenience but also for economy, because the volume of penetrant needed to immerse a large object may be so great as to increase unnecessarily the original cost of installation. A small reservoir of penetrant equipped with a pump, a hose, and a spray or flow nozzle is usually almost as fast a means of coating large objects as the dipping operation. For this type of operation, the penetrant station consists of a suitably ventilated booth with a rotatable grill platform on which the workpiece is set. A drain under the platform returns penetrant runoff to the sump, from which it is pumped back to the spray nozzle. The booth enclosure prevents the overspraying of penetrant on areas outside the penetrant station.

In some applications, it has been found that only a small amount of penetrant is recoverable and reusable, and this has led to the adoption of the expendable technique for some very large workpieces. In this technique, penetrant is sprayed over the workpiece in a penetrant station similar to the one mentioned previously. The penetrant is stored in a separate pressure tank fitted with a hose and a spray nozzle. The spray booth is not equipped with a sump to recover excess penetrant. Instead, the booth is fitted with water spray nozzles and a drain so that it can serve the multiple purpose of draining and washing. A decision to use the expendable technique and related equipment should be based on a careful analysis and consideration of cost, time, rate of production, and handling problems.

Emulsifier Station. The emulsifier liquid is contained in a tank of sufficient size and depth to permit immersion of the workpieces, either individually or in batches. Covers are sometimes provided to reduce evaporation, and drain valves are supplied for cleanout when the bath has become contaminated. Suitable drain racks are also a part of this station and are used to permit excess emulsifier to drain back into the tank.

If large workpieces must be coated with emulsifier, methods must be devised to achieve the fastest possible coverage. Multiple spraying or copious flowing of emulsifier from troughs or perforated pipes can be used on some types of automatic equipment. For the local coating of large workpieces, spraying is often satisfactory, using the expendable technique described for the application of penetrant.

Pre- and Postrinse Stations. The water rinsing (washing) of small workpieces is frequently done by hand, either individually or in batches in wire baskets. The workpieces are held in the wash tank and cleaned with a hand-held spray using water at tap pressure and temperature. The wash trough or sink should be large enough and deep enough so that workpieces can be easily turned to clean all surfaces. Splash shields should separate the rinse station from preceding (penetrant or emulsifier) and succeeding (wet developer) stations. Rinse stations are always equipped with at least one ultraviolet light so that the progress of removal of fluorescent penetrant can be easily followed.

The automatic rinsing of small workpieces is satisfactorily accomplished by means of a rotating table. The basket is placed on the table, and water-spray heads are properly located so as to rinse all surfaces of the workpieces thoroughly.

Specially built automatic washers for rinsing workpieces that are large and of irregular contour are often installed. Spray nozzles must be located to suit the individual application.

The removal of excess penetrant by simply submerging the workpiece in water is generally not recommended. However, in some cases, simple submersion in an air-agitated water bath is satisfactory.

The rinse station is subject to corrosion. All steel should be protected by rustproofing and painting. Most satisfactory, but more costly, is the use of stainless steel equipment.

Drying Station. The recirculating hot-air drier is one of the most important equipment components. The drier must be large enough to easily handle the type and number of workpieces being inspected. Heat input, air flow, and rate of movement of workpieces through the drier, as well as temperature control, are all factors that must be balanced. The drier may be of the cabinet type, or it may be designed so that the workpieces pass through on a conveyor. If conveyor operation is used, the speed must be considered with the required drying cycle.

Electric-resistance elements are frequently used as sources of heat, but gas, hot water, and steam are also used. Heat input is controlled by suitably located thermostats and is determined by workpiece size, composition, and rate of movement.

Integrated equipment invariably includes the recirculating hot-air drier mentioned previously. Makeshift driers are sometimes used--often because nothing better is available. Electric or gas hot-air blowers of commercial design have been used, but because no control of temperature is possible, these are very unsatisfactory and are ordinarily used only on an emergency basis. Infrared lamps are not suitable for drying washed workpieces, because the radiant heat cannot be readily controlled.

Equipment designed to handle workpieces of special size and shape requires a specially designed drier. Each drier is a separate engineering problem involving a special combination of workpiece composition, mass, surface area, speed of movement, and other considerations unique to the circumstances.

Developer Station. The type and location of the developer station depend on whether dry or wet developer is to be used. For dry developer, the developer station is downstream from the drier, but for wet developer it immediately precedes the drier, following the rinse station.

The dry-developer station usually consists of a simple bin containing the powder. Dried workpieces are dipped into the powder, and the excess powder is shaken off. Larger workpieces may not be so easily immersed in the powder, so a scoop is usually provided for throwing powder over the surfaces, after which the excess is shaken off. The developer bin should be equipped with an easily removable cover to protect the developer from dust and dirt when not in use.

Dust control systems are sometimes needed when dry developer is used. Control is accomplished by a suction opening across the back of the bin at the top, which draws off any developer dust that rises out of the bin. The dust-laden air is passed through filter bags, from which the developer dust can be reclaimed for further use (Fig. 13).

Fig. 13 Dry-developer bin equipped with dust control and reclaimer system

Developer powder can also be applied with air pressure. This system requires no bin, but it does require a booth or a cabinet and also makes dust collection mandatory.

Equipment for the automatic application of dry developer consists of a cabinet through which the dried workpieces are passed on a conveyor. The air in the cabinet is laden with dust that is kept agitated by means of a blower. As workpieces pass through, all surfaces are brought into contact with developer powder carried by the air. Air must be exhausted from the cabinet and either recirculated or cleaned by being passed through a dust-collecting filter.

Wet developer, when used, is contained in a tank similar to that used for penetrant or emulsifier. The tank should be deep enough to permit workpieces to be submerged in the developer. There should also be a rack or conveyor on which parts can rest after dipping. This will permit excess developer to run back into the tank.

Suspendible developer baths settle out when not in use; therefore, a paddle for stirring should be provided. Continuous agitation is essential because the settling rate is rapid. Pumps are sometimes incorporated into the developer station for flowing the developer over large workpieces through a hose and nozzle and for keeping the developer agitated.

In automatic units, special methods of applying developer are required. Flow-on methods are frequently used. This technique requires a nozzle arrangement that permits the workpieces to be covered thoroughly and quickly.

Inspection Station. Essentially, the inspection station is simply a worktable on which workpieces can be handled under proper lighting. For fluorescent methods, the table is usually surrounded by a curtain or hood to exclude most of the white light from the area. For visible-dry penetrants, a hood is not necessary.

Generally, black (ultraviolet) lights (100 W or greater) are mounted on brackets from which they can be lifted and moved about by hand. Because of the heat given off by black lights, good air circulation is essential in black light booths.

For automatic inspection, workpieces are moved through booths equipped with split curtains, either by hand, monorail, or by conveyor. In some large inspection installations, fully enclosed rooms have been built for black light inspection. Access to the room is provided by a light lock. Inspection rooms must be laid out efficiently to prevent rejected workpieces from reentering the production line. Figures 14 and 15 illustrate typical penetrant inspection components and their layout in an inspection station installation.

Fig. 14 Typical seven-station package equipment unit for inspecting workpieces by the water-washable fluorescent penetrant system

Fig. 15 Arrangement of equipment used in one foundry for the liquid penetrant inspection of a large variety of castings to rigid specifications. Many of the castings require handling by crane or roller conveyor.

Automated Inspection Equipment

For many years, the penetrant inspection of production parts has been a manual operation of moving parts from station to station through the penetrant line. Properly trained and motivated operators will do an excellent job of processing and inspecting parts as well as controlling the process. There are, however, many situations in which manual processing simply cannot keep up with the production rates required or control the process properly.

The use of automated inspection systems, therefore, has become a significant factor in performing penetrant inspections of high-volume production parts. Modern automated penetrant inspection systems provide precise and repeatable process control, improved inspection reliability, increased productivity, and lower inspection costs.

Automated penetrant inspection systems incorporate programmable logic control (PLC) units, which are programmed to control the handling of parts through the system, to control the processing cycle precisely, and to monitor the functions at each processing station. Figures 16, 17, and 18 show typical automated penetrant systems currently in use.

Fig. 16 Automated inspection equipment setup (upper left) with close-up of operator checking PLC panel (upper right), which includes a screen display (lower right). The setup incorporates material handling devices

such as the robot shown (lower left) to transfer workpieces from station to station and to apply penetrants and other solutions needed to inspect components.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrox Inc., and Gail Jordan, Howmet Corporation

Precleaning

Regardless of the penetrant chosen, adequate precleaning of workpieces prior to penetrant inspection is absolutely necessary for accurate results. Without adequate removal of surface contamination, relevant indications may be missed because:

- The penetrant does not enter the flaw
- The penetrant loses its ability to identify the flaw because it reacts with something already in it
- The surface immediately surrounding the flaw retains enough penetrant to mask the true appearance of the flaw

Also, nonrelevant (false) indications may be caused by residual materials holding penetrants.

Cleaning methods are generally classified as chemical, mechanical, solvent, or any combination of these.

Chemical cleaning methods include alkaline or acid cleaning, pickling or chemical etching, and molten salt bath cleaning.

Mechanical cleaning methods include tumbling, wet blasting, dry abrasive blasting, wire brushing, and high-pressure water or steam cleaning. Mechanical cleaning methods should be used with care because they often mask flaws by smearing adjacent metal over them or by filling them with abrasive material. This is more likely to happen with soft metals than with hard metals.

Solvent cleaning methods include vapor degreasing, solvent spraying, solvent wiping, and ultrasonic immersion using solvents. Probably the most common method is vapor degreasing. However, ultrasonic immersion is by far the most effective means of ensuring clean parts, but it can be a very expensive capital equipment investment.

Cleaning methods and their common uses are listed in Table 1. A major factor in the selection of a cleaning method is the type of contaminant to be removed and the type of alloy being cleaned. This is usually quite evident, but costly errors can be avoided by accurate identification of the contaminant. Before the decision is made to use a specific method, it is good practice to test the method on known flaws to ensure that it will not mask the flaws.

Table 1 Applications of various methods of precleaning for liquid penetrant inspection

Method	Use
Mechanical methods	
Abrasive tumbling	Removing light scale, burrs, welding flux, braze stopoff, rust, casting mold, and core material; should not be used on soft metals such as aluminum, magnesium, or titanium
Dry abrasive grit blasting	Removing light or heavy scale, flux, stopoff, rust, casting mold and core material, sprayed coatings, carbon deposits--in general, any friable deposit. Can be fixed or portable
Wet abrasive grit blasting	Same as dry except, where deposits are light, better surface and better control of dimensions are required
Wire brushing	Removing light deposits of scale, flux, and stopoff
High-pressure water and steam	Ordinarily used with an alkaline cleaner or detergent; removing typical machine shop soils such as cutting oils, polishing compounds, grease, chips, and deposits from electrical discharge machining; used when surface finish must be maintained; inexpensive
Ultrasonic cleaning	Ordinarily used with detergent and water or with a solvent; removing adherent shop soil from large quantities of small parts

Chemical methods	
Alkaline cleaning	Removing braze stopoff, rust, scale, oils, greases, polishing material, and carbon deposits; ordinarily used on large articles where hand methods are too laborious; also used on aluminum for gross metal removal
Acid cleaning	Strong solutions for removing heavy scale; mild solutions for light scale; weak (etching) solutions for removing lightly smeared metal
Molten salt bath cleaning	Conditioning and removing heavy scale
Solvent methods	
Vapor degreasing	Removing typical shop soil, oil, and grease; usually employs chlorinated solvents; not suitable for titanium
Solvent wiping	Same as for vapor degreasing except a hand operation; may employ nonchlorinated solvents; used for localized low-volume cleaning

Equally important in choosing a cleaning method is knowledge of the composition of the workpiece being cleaned. For example, abrasive tumbling can effectively remove burrs from a machined steel casting and leave a surface that is fully inspectable. This method, however, is not suitable for aluminum or magnesium, because it smears these metals and frequently hides flaws. Particular care must be taken in selecting a cleaning method for workpieces fabricated from more than one alloy (brazed assemblies are notable examples); a chemical cleaning method to remove scale, stopoff material, or flux must be chosen carefully to ensure that neither the braze nor the components of the assembly will be attacked.

The surface finish of the workpiece must always be considered. When further processing is scheduled, such as machining or final polishing, or when a surface finish of 3.20 μm (125 $\mu\text{in.}$) or coarser is allowed, an abrasive cleaning method is frequently a good choice. Generally, chemical cleaning methods have fewer degrading effects on surface finish than mechanical methods (unless the chemical used is strongly corrosive to the material being cleaned). Steam cleaning and solvent cleaning rarely have any effect on surface finish.

Some materials are subject to delayed reactions as a result of improper cleaning. Two notable examples are high-strength steel and titanium. If it is ever necessary to chemically etch a high-strength steel workpiece, it should be baked at an appropriate temperature for a sufficient time to avoid hydrogen embrittlement. This should be done as soon after etching as possible but no later than 1 h. Titanium alloys can be subject to delayed cracking if they retain halogenated compounds and are then exposed to temperatures exceeding 480 °C (900 °F). Consequently, halogenated solvents should not be used for titanium and its alloys if their complete removal cannot be ensured.

Choice of cleaning method may be dictated by Occupational Safety and Health Administration and Environmental Protection Agency health and safety regulations. Quantities of materials that will be used, toxicity, filtering, neutralization and disposal techniques, and worker protection all are crucial factors.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrox Inc., and Gail Jordan, Howmet Corporation

Penetrant Inspection Processing Parameters

It is extremely important to understand the significance of adhering to the established process parameters for a given application. Failure to control the process parameters will affect the quality of the inspection. For example, excessive overwashing or overemulsification can remove the penetrant from the flaws; minimal washing or underemulsification can result in excessive background, which could mask the flaws and render them undetectable.

Processing time in each station, the equipment used, and other factors can vary widely, depending on workpiece size and shape, production quantities of similar workpieces, and required customer specifications for process parameters.

Postemulsifiable Method

The processing cycles for the postemulsifiable processes, method B (lipophilic) and method D (hydrophilic) are illustrated in the processing flow diagrams (Fig. 19 and 20, respectively). The major difference between the two methods, as described below, is the additional prerinse step utilized in method D.

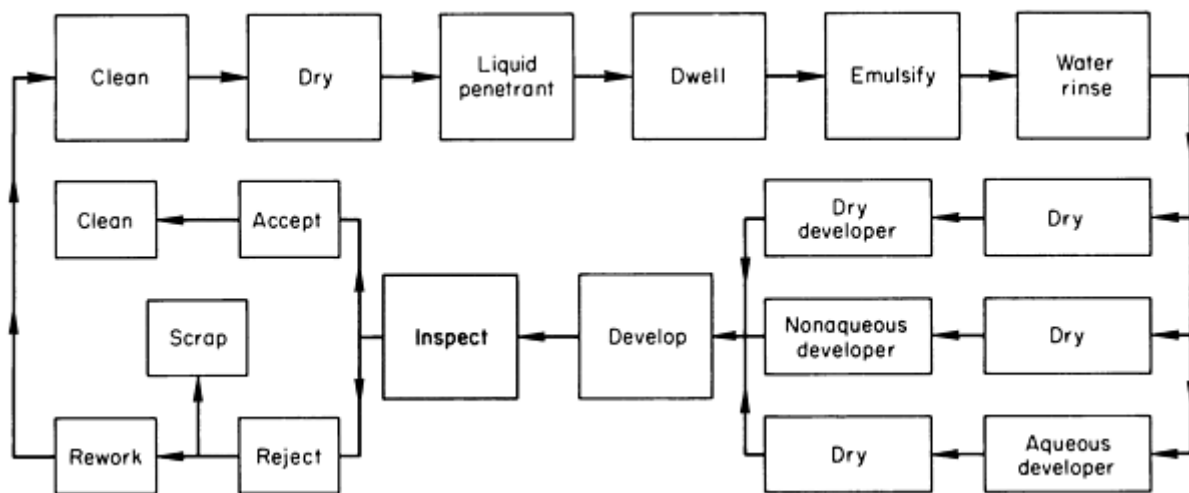

Fig. 19 Processing flow diagram for the postemulsifiable, method B, lipophilic liquid penetrant system

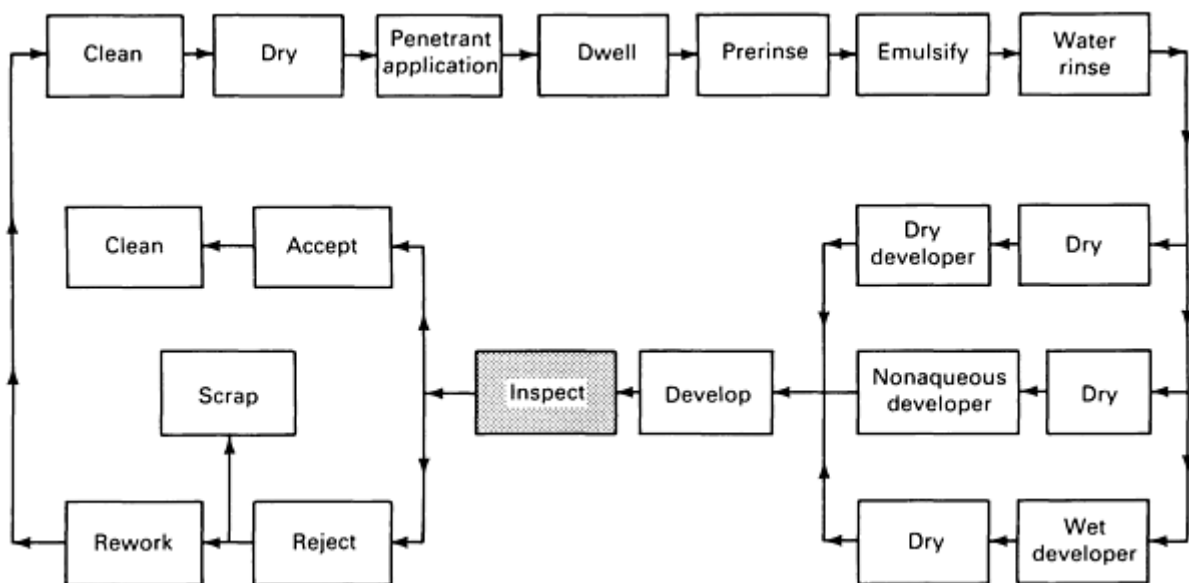

Fig. 20 Processing flow diagram for the postemulsifiable, method D, hydrophilic liquid penetrant system

Application of Penetrant. Workpieces should be thoroughly and uniformly coated with penetrant by flowing, brushing, swabbing, dipping, or spraying. Small workpieces requiring complete surface inspection are usually placed in a basket and dipped in the penetrant. Larger workpieces are usually brushed or sprayed. Electrostatic spray application is also very effective and economical. After the workpiece has been coated with a light film of penetrant, it should be positioned so that it can drain and so that excess penetrant cannot collect in pools. Workpieces should not be submerged during the entire penetration dwell time. Heating the workpiece is also not necessary or recommended, because certain disadvantages can occur, such as volatilization of the penetrant, difficulty in washing, and a decrease in fluorescence.

Dwell Time. After the penetrant has been applied to the workpiece surface, it should be allowed to remain long enough for complete penetration into the flaws. Dwell time will vary, depending mainly on the size of the defects sought, cleanliness of the workpiece, and sensitivity and viscosity of the penetrant. In most cases, however, a minimum of 10 min and a maximum of 30 min is adequate for both fluorescent- and visible-penetrant types. A lengthy dwell time could cause the penetrant to begin drying on the surface, resulting in difficult removal. If drying does occur, it is necessary to reapply the penetrant to wet the surface and then begin the removal steps. Recommendations from the penetrant supplier will help establish the time, but experimentation will determine optimum dwell time.

Prerinse. When using method D (hydrophilic), a coarse waterspray prerinse is needed to assist in penetrant removal and to reduce contamination of the emulsifier. A coarse water spray is recommended, using a pressure of 275 to 345 kPa (40 to 50 psi). The prerinse water temperature should be 10 to 40 °C (50 to 100 °F). The prerinse time should be kept to a minimum (that is, 30 to 90 s) because the purpose is to remove excess penetrant so that the emulsifier does not become contaminated quickly.

Emulsifier Application. It is very important that all surfaces of the workpiece be coated with the emulsifier at the same time. Small workpieces are dipped individually or in batches in baskets or on racks, whichever is the most convenient. For large workpieces, methods must be devised to achieve the fastest possible coverage; two methods often used are spraying or immersing. Localized emulsification of large workpieces can be achieved by spraying. The temperature of the emulsifier is not extremely critical, but a range of 20 to 30 °C (70 to 90 °F) is referred.

Emulsification Time. The length of time the emulsifier is allowed to remain on the workpiece and in contact with the penetrant is the emulsification time and depends mainly on the type of emulsifier employed, its concentration, and on the surface condition of the workpieces. Recommendations by the manufacturer of the emulsifier can serve as guidelines, but the optimum time for a specific workpiece must be established by experimentation. The surface finish, size, and composition of the workpiece will determine more precisely the choice of emulsifier and emulsification time. Emulsification time ranges from approximately 30 s to 3 min and is directly related to the concentration of the emulsifier. If emulsification time is excessive, penetrant will be removed from the flaws, making detection impossible.

Rinsing. For all methods, removing the penetrant from the workpiece is probably the most important step in obtaining reproducible results. If penetrant removal is performed properly, penetrant will be stripped from the surface and will remain only in the flaws. More variability in individual technique enters into this particular phase of inspection than any other step. Therefore, removal must be performed with the same sequence of operations time after time if results are to be reproducible. This is especially important when inspecting for tight or shallow flaws.

Rinse time should be determined experimentally for specific workpieces; it usually varies from 10 s to 2 min. For spray rinsing, water pressure should be constant. A pressure of about 275 kPa (40 psi) is desirable; too much pressure may remove penetrants from the flaws. A coarse water spray is recommended and can be assisted with air (the combined water and air pressure should not exceed the pressure recommended for water alone). Water temperature should be maintained at a relatively constant level. Most penetrants can be removed effectively with water in a range of 10 to 40 °C (50 to 100 °F).

Drying is best done in a recirculating hot-air drier that is thermostatically controlled. The temperature in the drier is normally between 65 and 95 °C (150 and 200 °F). The temperature of the workpieces should not be permitted to exceed 70 °C (160 °F). Workpieces should not remain in the drier any longer than necessary; drying is normally accomplished within a few minutes. Excessive drying at high temperatures can impair the sensitivity of the inspection. Because drying time will vary, the exact time should be determined experimentally for each type of workpiece.

Developing depends on the form of developer to be used. Various types of developers are discussed below.

Dry-developer powder (form A) is applied after the workpiece has been dried and can be applied in a variety of ways. The most common is dusting or spraying. Electrostatic spray application is also very effective. In some cases, application by immersing the workpiece into the dry powder developer is permissible. For simple applications, especially when only a portion of the surface of a large part is being inspected, applying with a soft brush is often adequate. Excess developer can be removed from the workpiece by a gentle air blast (140 kPa, or 20 psi, maximum) or by shaking or gentle tapping. Whichever means of application is chosen, it is important that the workpiece be completely and evenly covered by a fine film of developer.

Water-soluble developer (form B) is applied just after the final wash and immediately prior to drying by dip, flow-on, or spray techniques. No agitation of the developer bath is required. Removal of the developer coating from the surface of the workpiece is required and easily accomplished because the dried developer coating is water soluble and therefore completely removable by a water rinse.

Water-suspendible developer (form C) is applied just after the final wash and immediately before drying. Dip, flow-on, and spray are common methods of application. Care must be taken to agitate the developer thoroughly so that all particles are in suspension; otherwise, control of the concentration of the applied coating is impossible. Removal of the water-suspendible developer can best be achieved by water spray rinsing. If allowed to remain indefinitely on the workpiece, the developer can become difficult to remove.

Solvent-suspendible nonaqueous developer (form D) is always applied after drying by spraying, either with aerosol containers or by conventional or electrostatic methods. Proper spraying produces a thin, uniform layer that is very sensitive in producing either fluorescent or red visible indications. The volatility of the solvent makes it impractical to use in open tanks. Not only would there be solvent loss, reducing the effectiveness of the developer, but there would also be a hazardous vapor condition. Dipping, pouring, and brushing are not suitable for applying solvent-suspendible developer.

Developing Time. In general, 10 min is the recommended minimum developing time regardless of the developer form used. The developing time begins immediately after application of the developer. Excessive developing time is seldom necessary and usually results in excessive bleeding of indications, which can obscure flaw delineation.

Inspections. After the prescribed development time, the inspection should begin. The inspection area should be properly darkened for fluorescent penetrant inspection. Recommended black light intensity is 1000 to 1600 $\mu\text{W}/\text{cm}^2$. The intensity of the black light should be verified at regular intervals by the use of a suitable black light meter such as a digital radiometer. The intensity of the black light should be allowed to warm up prior to use--generally for about 10 min. The inspector should allow time for adapting to darkness; a 1-min period is usually adequate. White light intensity should not exceed 20 lx (2 ftc) to ensure the best inspection environment.

Visible-penetrant systems provide vivid red indications that can be seen in visible light. Lighting intensity should be adequate to ensure proper inspection; 320 to 540 lx (30 to 50 ftc) is recommended. Lighting intensity should be verified at regular intervals by the use of a suitable white light meter such as a digital radiometer. Detailed information on inspection techniques is available in the sections "Inspection and Evaluation" and "Specifications and Standards" in this article.

Water-Washable Method

As indicated by the flow diagram in Fig. 21, the processing cycle for the water-washable method is similar to that for the postemulsifiable method. The difference lies in the penetrant removal step. As discussed in the section "Materials Used in Penetrant Inspection" in this article, the water-washable penetrants have a built-in emulsifier, thus eliminating the need for an emulsification step. One rinse operation is all that is required, and the washing operation should be carefully controlled because water-washable penetrants are susceptible to overwashing.

Fig. 21 Processing flow diagram for the water-washable liquid penetrant system

Rinse time should be determined experimentally for a specific workpiece; it usually varies from 10 s to 2 min. The best practical way of establishing rinse time is to view the workpiece under a black light while rinsing and washing only until the fluorescent background is removed to a satisfactory degree. On some applications, such as castings, an immersion rinse followed by a final spray rinsing is desirable to remove tenacious background fluorescence. This technique, however, must be very carefully controlled to ensure that overwashing does not occur.

For spray rinsing, a nominal water pressure of 140 to 275 kPa (20 to 40 psi) is recommended; too much pressure can result in overwashing, that is, the removal of penetrant from within flaws. Hydro-air spray guns can be used. The air pressure, however, should not exceed 170 kPa (25 psi). The temperature of the water should be controlled to 10 to 40 °C (50 to 100 °F). Drying, developing, and inspection process parameters are the same as the postemulsifiable method process parameters described in the section "Postemulsifiable Method" in this article.

Solvent-Removable Method

The basic sequence of operations for the solvent-removable penetrant system is generally similar to that followed for the other methods. A typical sequence is shown by the flow diagram in Fig. 22. A notable difference is that with the solvent-removable method the excess penetrant is removed by wiping with clean, lint-free material moistened with solvent. It is important to understand that flooding the workpiece to remove excess surface penetrant will also dissolve the penetrant from within the flaws.

Fig. 22 Processing flow diagram for the solvent-removable liquid penetrant system

The processing parameters for the use of developer are the same as those described above for the postemulsifiable method. Dry-powder developers, however, are not recommended for use with the visible solvent-removable penetrant method.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Penetrant Inspection Processing Parameters

It is extremely important to understand the significance of adhering to the established process parameters for a given application. Failure to control the process parameters will affect the quality of the inspection. For example, excessive overwashing or overemulsification can remove the penetrant from the flaws; minimal washing or underemulsification can result in excessive background, which could mask the flaws and render them undetectable.

Processing time in each station, the equipment used, and other factors can vary widely, depending on workpiece size and shape, production quantities of similar workpieces, and required customer specifications for process parameters.

Postemulsifiable Method

The processing cycles for the postemulsifiable processes, method B (lipophilic) and method D (hydrophilic) are illustrated in the processing flow diagrams (Fig. 19 and 20, respectively). The major difference between the two methods, as described below, is the additional prerinse step utilized in method D.

Fig. 19 Processing flow diagram for the postemulsifiable, method B, lipophilic liquid penetrant system

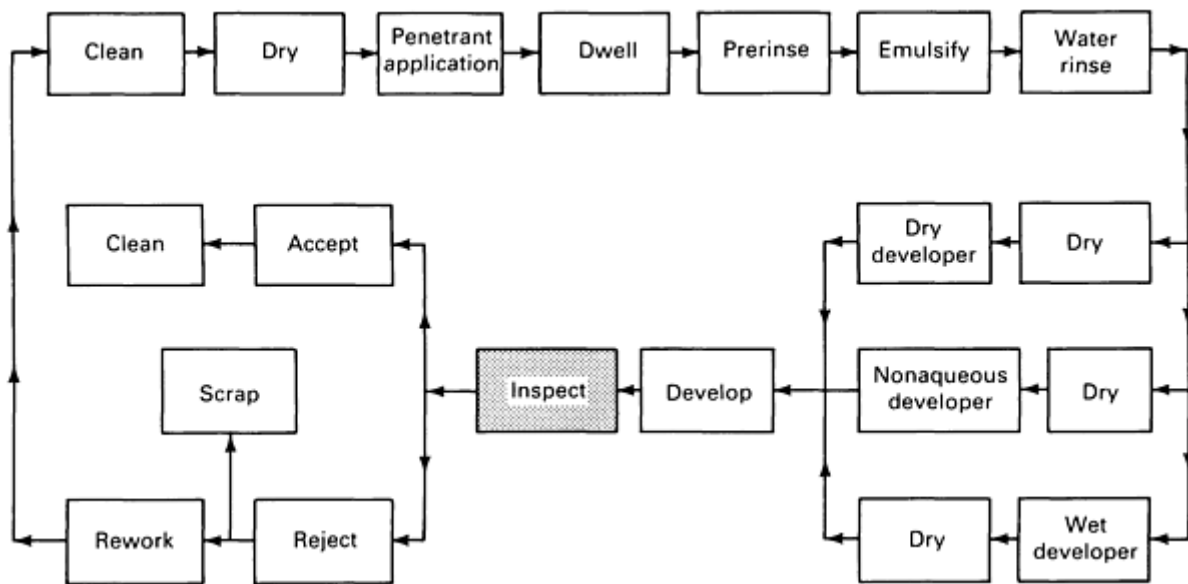

Fig. 20 Processing flow diagram for the postemulsifiable, method D, hydrophilic liquid penetrant system

Application of Penetrant. Workpieces should be thoroughly and uniformly coated with penetrant by flowing, brushing, swabbing, dipping, or spraying. Small workpieces requiring complete surface inspection are usually placed in a basket and dipped in the penetrant. Larger workpieces are usually brushed or sprayed. Electrostatic spray application is also very effective and economical. After the workpiece has been coated with a light film of penetrant, it should be positioned so that it can drain and so that excess penetrant cannot collect in pools. Workpieces should not be submerged during the entire penetration dwell time. Heating the workpiece is also not necessary or recommended, because certain disadvantages can occur, such as volatilization of the penetrant, difficulty in washing, and a decrease in fluorescence.

Dwell Time. After the penetrant has been applied to the workpiece surface, it should be allowed to remain long enough for complete penetration into the flaws. Dwell time will vary, depending mainly on the size of the defects sought, cleanliness of the workpiece, and sensitivity and viscosity of the penetrant. In most cases, however, a minimum of 10 min and a maximum of 30 min is adequate for both fluorescent- and visible-penetrant types. A lengthy dwell time could cause the penetrant to begin drying on the surface, resulting in difficult removal. If drying does occur, it is necessary to reapply the penetrant to wet the surface and then begin the removal steps. Recommendations from the penetrant supplier will help establish the time, but experimentation will determine optimum dwell time.

Prerinse. When using method D (hydrophilic), a coarse waterspray prerinse is needed to assist in penetrant removal and to reduce contamination of the emulsifier. A coarse water spray is recommended, using a pressure of 275 to 345 kPa (40 to 50 psi). The prerinse water temperature should be 10 to 40 °C (50 to 100 °F). The prerinse time should be kept to a minimum (that is, 30 to 90 s) because the purpose is to remove excess penetrant so that the emulsifier does not become contaminated quickly.

Emulsifier Application. It is very important that all surfaces of the workpiece be coated with the emulsifier at the same time. Small workpieces are dipped individually or in batches in baskets or on racks, whichever is the most convenient. For large workpieces, methods must be devised to achieve the fastest possible coverage; two methods often used are spraying or immersing. Localized emulsification of large workpieces can be achieved by spraying. The temperature of the emulsifier is not extremely critical, but a range of 20 to 30 °C (70 to 90 °F) is referred.

Emulsification Time. The length of time the emulsifier is allowed to remain on the workpiece and in contact with the penetrant is the emulsification time and depends mainly on the type of emulsifier employed, its concentration, and on the surface condition of the workpieces. Recommendations by the manufacturer of the emulsifier can serve as guidelines, but the optimum time for a specific workpiece must be established by experimentation. The surface finish, size, and composition of the workpiece will determine more precisely the choice of emulsifier and emulsification time. Emulsification time ranges from approximately 30 s to 3 min and is directly related to the concentration of the emulsifier. If emulsification time is excessive, penetrant will be removed from the flaws, making detection impossible.

Rinsing. For all methods, removing the penetrant from the workpiece is probably the most important step in obtaining reproducible results. If penetrant removal is performed properly, penetrant will be stripped from the surface and will remain only in the flaws. More variability in individual technique enters into this particular phase of inspection than any other step. Therefore, removal must be performed with the same sequence of operations time after time if results are to be reproducible. This is especially important when inspecting for tight or shallow flaws.

Rinse time should be determined experimentally for specific workpieces; it usually varies from 10 s to 2 min. For spray rinsing, water pressure should be constant. A pressure of about 275 kPa (40 psi) is desirable; too much pressure may remove penetrants from the flaws. A coarse water spray is recommended and can be assisted with air (the combined water and air pressure should not exceed the pressure recommended for water alone). Water temperature should be maintained at a relatively constant level. Most penetrants can be removed effectively with water in a range of 10 to 40 °C (50 to 100 °F).

Drying is best done in a recirculating hot-air drier that is thermostatically controlled. The temperature in the drier is normally between 65 and 95 °C (150 and 200 °F). The temperature of the workpieces should not be permitted to exceed 70 °C (160 °F). Workpieces should not remain in the drier any longer than necessary; drying is normally accomplished within a few minutes. Excessive drying at high temperatures can impair the sensitivity of the inspection. Because drying time will vary, the exact time should be determined experimentally for each type of workpiece.

Developing depends on the form of developer to be used. Various types of developers are discussed below.

Dry-developer powder (form A) is applied after the workpiece has been dried and can be applied in a variety of ways. The most common is dusting or spraying. Electrostatic spray application is also very effective. In some cases, application by immersing the workpiece into the dry powder developer is permissible. For simple applications, especially when only a portion of the surface of a large part is being inspected, applying with a soft brush is often adequate. Excess developer can be removed from the workpiece by a gentle air blast (140 kPa, or 20 psi, maximum) or by shaking or gentle tapping. Whichever means of application is chosen, it is important that the workpiece be completely and evenly covered by a fine film of developer.

Water-soluble developer (form B) is applied just after the final wash and immediately prior to drying by dip, flow-on, or spray techniques. No agitation of the developer bath is required. Removal of the developer coating from the surface of the workpiece is required and easily accomplished because the dried developer coating is water soluble and therefore completely removable by a water rinse.

Water-suspendible developer (form C) is applied just after the final wash and immediately before drying. Dip, flow-on, and spray are common methods of application. Care must be taken to agitate the developer thoroughly so that all particles are in suspension; otherwise, control of the concentration of the applied coating is impossible. Removal of the water-suspendible developer can best be achieved by water spray rinsing. If allowed to remain indefinitely on the workpiece, the developer can become difficult to remove.

Solvent-suspendible nonaqueous developer (form D) is always applied after drying by spraying, either with aerosol containers or by conventional or electrostatic methods. Proper spraying produces a thin, uniform layer that is very sensitive in producing either fluorescent or red visible indications. The volatility of the solvent makes it impractical to use in open tanks. Not only would there be solvent loss, reducing the effectiveness of the developer, but there would also be a hazardous vapor condition. Dipping, pouring, and brushing are not suitable for applying solvent-suspendible developer.

Developing Time. In general, 10 min is the recommended minimum developing time regardless of the developer form used. The developing time begins immediately after application of the developer. Excessive developing time is seldom necessary and usually results in excessive bleeding of indications, which can obscure flaw delineation.

Inspections. After the prescribed development time, the inspection should begin. The inspection area should be properly darkened for fluorescent penetrant inspection. Recommended black light intensity is 1000 to 1600 $\mu\text{W}/\text{cm}^2$. The intensity of the black light should be verified at regular intervals by the use of a suitable black light meter such as a digital radiometer. The intensity of the black light should be allowed to warm up prior to use--generally for about 10 min. The inspector should allow time for adapting to darkness; a 1-min period is usually adequate. White light intensity should not exceed 20 lx (2 ftc) to ensure the best inspection environment.

Visible-penetrant systems provide vivid red indications that can be seen in visible light. Lighting intensity should be adequate to ensure proper inspection; 320 to 540 lx (30 to 50 ftc) is recommended. Lighting intensity should be verified at regular intervals by the use of a suitable white light meter such as a digital radiometer. Detailed information on inspection techniques is available in the sections "Inspection and Evaluation" and "Specifications and Standards" in this article.

Water-Washable Method

As indicated by the flow diagram in Fig. 21, the processing cycle for the water-washable method is similar to that for the postemulsifiable method. The difference lies in the penetrant removal step. As discussed in the section "Materials Used in Penetrant Inspection" in this article, the water-washable penetrants have a built-in emulsifier, thus eliminating the need for an emulsification step. One rinse operation is all that is required, and the washing operation should be carefully controlled because water-washable penetrants are susceptible to overwashing.

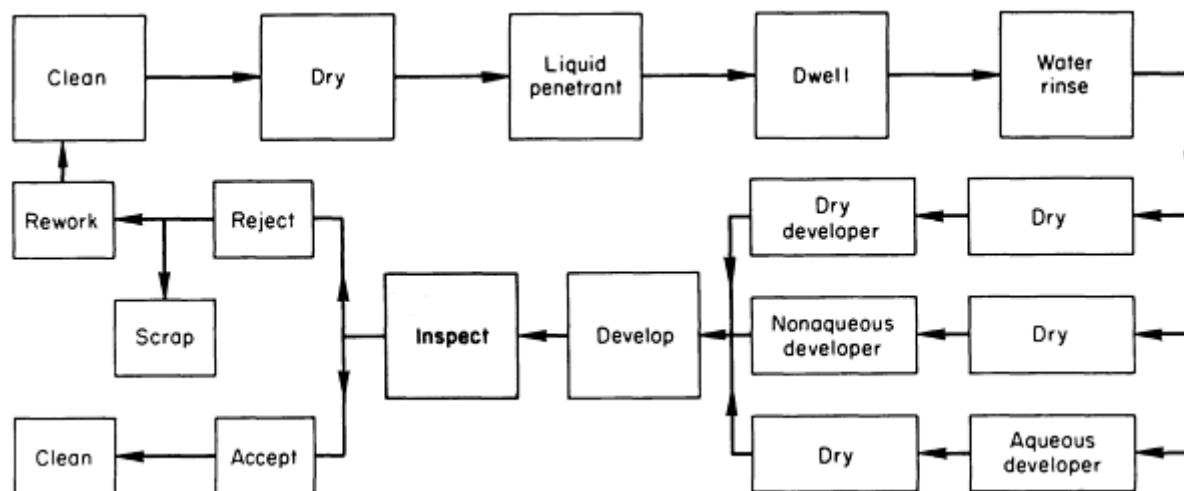

Fig. 21 Processing flow diagram for the water-washable liquid penetrant system

Rinse time should be determined experimentally for a specific workpiece; it usually varies from 10 s to 2 min. The best practical way of establishing rinse time is to view the workpiece under a black light while rinsing and washing only until the fluorescent background is removed to a satisfactory degree. On some applications, such as castings, an immersion rinse followed by a final spray rinsing is desirable to remove tenacious background fluorescence. This technique, however, must be very carefully controlled to ensure that overwashing does not occur.

For spray rinsing, a nominal water pressure of 140 to 275 kPa (20 to 40 psi) is recommended; too much pressure can result in overwashing, that is, the removal of penetrant from within flaws. Hydro-air spray guns can be used. The air pressure, however, should not exceed 170 kPa (25 psi). The temperature of the water should be controlled to 10 to 40 °C (50 to 100 °F). Drying, developing, and inspection process parameters are the same as the postemulsifiable method process parameters described in the section "Postemulsifiable Method" in this article.

Solvent-Removable Method

The basic sequence of operations for the solvent-removable penetrant system is generally similar to that followed for the other methods. A typical sequence is shown by the flow diagram in Fig. 22. A notable difference is that with the solvent-removable method the excess penetrant is removed by wiping with clean, lint-free material moistened with solvent. It is important to understand that flooding the workpiece to remove excess surface penetrant will also dissolve the penetrant from within the flaws.

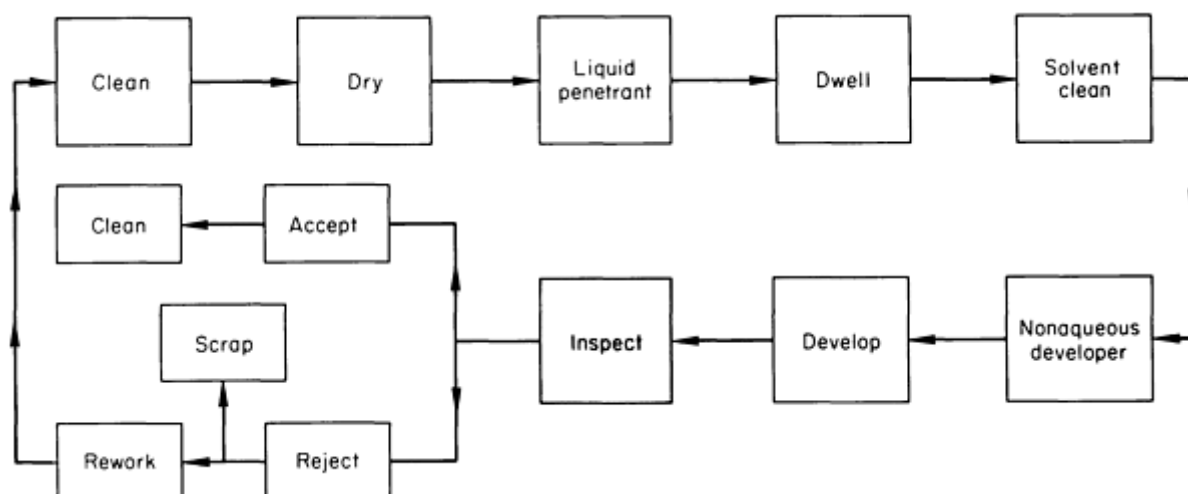

Fig. 22 Processing flow diagram for the solvent-removable liquid penetrant system

The processing parameters for the use of developer are the same as those described above for the postemulsifiable method. Dry-powder developers, however, are not recommended for use with the visible solvent-removable penetrant method.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Postcleaning

Some residue will remain on workpieces after penetrant inspection is completed. In many cases, this residue has no deleterious effects in subsequent processing or in service. There are, however, instances in which postcleaning is required. Residues can result in the formation of voids during subsequent welding or unwanted stopoff in brazing, in the contamination of surfaces (which can cause trouble in heat treating), or in unfavorable reactions in chemical processing operations.

Drastic chemical or mechanical methods are seldom required for postcleaning. When justified by the volume of work, an emulsion cleaning line is effective and reasonable in cost. In special circumstances, ultrasonic cleaning may be the only satisfactory way of cleaning deep crevices or small holes. However, solvents or detergent-aided steam or water is almost always sufficient. The use of steam with detergent is probably the most effective of all methods. It has a scrubbing action that removes developers, the heat and detergent remove penetrants, it leaves a workpiece hot enough to promote rapid, even drying, and it is harmless to nearly all materials. Vapor degreasing is very effective for removing penetrants, but it is practically worthless for removing developers. It is frequently used in combination with steam cleaning. If this combination is used, the steam cleaning should always be done first because vapor degreasing bakes on developer films.

Where conditions do not warrant or permit permanent cleaning installations, hand wiping with solvents is effective. Dried developer films can be brushed off, and residual penetrants can be rinsed off by solvent spraying or wiped off with a solvent-dampened cloth.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Quality Assurance of Penetrant Inspection Materials

It is important to provide the controls necessary to ensure that the penetrant materials and equipment are operating at an acceptable level of performance. The frequency of the required checks should be based on a facility operating for a full, one-shift operation daily. In general, it is good practice to check the overall system performance on a daily basis. This check should be performed by processing a known defect standard through the line, using appropriate processing parameters and comparing the indications thus obtained to those obtained with fresh, unused penetrant material samples. When the performance of the in-use materials falls below that of the unused materials, the in-use material quality should be checked with the appropriate tests (as described below) and corrected prior to conducting any further penetrant inspection.

Key quality assurance tests to be periodically conducted on in-use penetrants, emulsifiers, and developers are listed in Table 2. Also listed are the intervals at which the light sources and the overall system performance should be checked.

Table 2 Intervals at which solutions, light sources, and system performance should be checked

Test	Minimum test frequency	Requirement
Penetrants		
Fluorescent brightness	Quarterly	Not less than 90% of reference standard
Sensitivity	Monthly	Equal to reference standard
Removability (method A water wash only)	Monthly	Equal to reference standard
Water content (method A water wash penetrant only)	Monthly	Not to exceed 5%
Contamination	Weekly	No noticeable tracers
Emulsifiers		
Removability	Weekly	Equal to reference standard
Water content (method B, lipophilic)	Monthly	Not to exceed 5%
Concentration (method D, hydrophilic)	Weekly	Not greater than 3% above initial concentration
Contamination	Weekly	No noticeable tracers
Developers		
Dry-developer form	Daily	Must be fluffy, not caked

Contamination	Daily	Not more than ten fluorescent specks observed in a 102 mm (4 in.) circle of sample
Aqueous (soluble and suspended) developer		
Wetting/coverage	Daily	Must be uniform/wet and must coat part
Contamination	Daily	Must not show evidence of fluorescence contaminates
Concentration	Weekly	Concentration shall be maintained as specified
Other		
Black lights	Daily	Minimum 1000 $\mu\text{W}/\text{cm}^2$ at 381 mm (15 in.)
White light	Weekly	Minimum 2200 lx (200 ftc)
System performance	Daily	Must equal reference standards

Military standard 6866 specifies the specific test procedure to use for the tests defined in Table 2. Penetrants applied by spray application from sealed containers are not likely to be exposed to the same working environment as with open dip tanks and are therefore not required to be tested as defined in Table 2 unless contamination is suspected.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrox Inc., and Gail Jordan, Howmet Corporation

Maintenance of Materials

With constant open-tank use, penetrant materials are inherently subject to potential deterioration. Such factors as evaporation losses and contamination from various sources can contribute to deterioration. It is essential, therefore, to monitor the condition of these materials as described in Table 2.

The evaporation of the volatile constituents of penetrants can alter their chemical and performance characteristics, thus resulting in changes in inherent brightness, removability, and sensitivity. Liquid penetrant materials qualified to MIL-I-25135D (and subsequent revisions) have a flash point requirement of a minimum of 95 °C (200 °F) (per Pensky Martens flash point test procedure), assuring the minimization of evaporation losses.

The contamination of water-washable penetrant with water is the most frequent source of difficulty. When present beyond a critical percentage, this contamination will render the penetrant tank useless. For postemulsifiable penetrants, water contamination is not as critical a problem, because water is usually not miscible with postemulsifiable penetrants and will separate from the penetrant, which can then be subsequently removed. Water contamination can be minimized by implementing and following proper processing procedures.

It is important to recognize that acid contamination (carryover from precleaning) will render fluorescent penetrants ineffective. Acid contamination changes the consistency of the penetrant and damages or destroys the fluorescent dye.

Dust, dirt and lint, and similar foreign materials get into the penetrant in the ordinary course of shop usage. These contaminants do no particular harm unless present to the extent that the bath is scummy with floating or suspended foreign material. Reasonable care should be taken to keep the penetrant clean. Workpieces containing adhering sand and dirt from the shop floor should be cleaned before being dipped into the penetrant.

Contamination of the emulsifier must also be considered. Method B, lipophilic emulsifiers inherently become contaminated by penetrant through the normal processing of parts coated with penetrant being dipped into the emulsifier. It is imperative, therefore, that the lipophilic emulsifier have a high tolerance (that is, 10%) for penetrant contamination. Water contamination of the lipophilic emulsifier is always a potential problem due to the nature of the process. Generally, 5% water contamination can be tolerated.

Method D, hydrophilic emulsifiers are not normally subject to appreciable amounts of penetrant contamination, mainly because of the prerinse processing step, which removes most of the excess surface penetrant before emulsification. Because hydrophilic emulsifiers are water based, water contamination is not a problem, except for the fact that the bath concentration must be maintained at the prescribed limits.

In general, emulsifiers that become severely contaminated will not properly emulsify the surface penetrant on the parts. Periodic monitoring is essential.

Developer must also be maintained to ensure proper performance. Contamination of the dry-powder developer with water or moisture in the air can result in caking. Dry developers must remain fluffy and free flowing if they are to perform properly. In addition, contamination from the fluorescent penetrant must not occur. Fluorescent specks in the developer powder could be misinterpreted as an indication. Wet developer (soluble or suspendible) must not become contaminated with penetrant or any contaminant that could affect its ability to wet and evenly cover the workpiece.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrox Inc., and Gail Jordan, Howmet Corporation

Training and Certification of Personnel

The apparent simplicity of the penetrant method is deceptive. Very slight variations in performing the penetrant process and the inspection can invalidate the inspection results by failing to indicate all flaws. Therefore, many companies require that penetrant inspection be conducted only by trained and certified personnel. Minimum requirements for personnel training and certification are described by various military and industry specifications (such as MIL-STD-410 and ASNT SNT-TC-1A). The following are examples of the most commonly followed training programs; however, specific customer training requirements are usually defined within the contract.

Training is minimal for level I penetrant inspection operators (personnel responsible for the processing). However, the penetrant process must be correctly performed to ensure accurate inspection. Operator training consists of the satisfactory completion of a period of on-the-job training, as determined by immediate supervision, conducted under the guidance of a certified level I inspector.

Training for level II inspectors (personnel responsible for the inspection and evaluation) is more extensive than that for the level I operators. Training usually consists of 40 h of formal training, followed by several weeks of on-the-job training under the supervision of a designated trainer, usually a certified level II operator.

Certification. Personnel of sufficient background and training in the principles and procedures of penetrant inspection are usually certified by the successful completion of a practical test, which demonstrates their proficiency in penetrant techniques, and a written test, which documents their knowledge of penetrant inspection. Certified personnel are also normally required to pass a periodic eye examination, which includes a color-vision test. Certification can be obtained on-site through a certified level III inspector who may be with an outside source contracted to certify personnel or a company employee who has been certified as a level III inspector by the appropriate agency.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Inspection and Evaluation

After the penetrant process is completed, inspection and evaluation of the workpiece begin. Table 3 lists the more common types of flaws that can be found by penetrant inspection, together with their likely locations and their characteristics.

Table 3 Common types, locations, and characteristics of flaws or discontinuities revealed by liquid penetrant inspection

Type	Locations	Characteristics
Relevant indications		
Shrinkage cracks	Castings (all metals)--on flat surfaces	Open
Hot tears	Castings (all metals)--at inside corners	Open
Cold shuts	Castings (all metals)--at changes in cross section	Tight, shallow
Folds	Castings (all metals)--anywhere	Tight, shallow
Inclusions	Castings, forgings, sheet, bar--anywhere	Tight, shallow, intermittent
Microshrinkage pores	Castings--anywhere	Spongy
Laps	Forgings, bar--anywhere	Tight, shallow
Forging cracks	Forgings--at inside or outside corners and at changes in cross section	Tight or open
Pipe	Forgings, bar--near geometric center	Irregular shape
Laminations	Sheet--at edges	Tight or open
Center bead cracks	Welds--at center of reinforcement	Tight or open
Cracks in heat-affected zone	Welds--at edge of reinforcement	Tight or open
Crater cracks	Welds--at end of bead	Star-shaped

Porosity	Castings, welds	Spherical
Grinding cracks	Any hard metal--ground surfaces	Tight, shallow, random
Quench cracks	Heat treated steel	Tight to open, oxidized
Stress-corrosion cracks	Any metal	Tight to open; may show corrosion
Fatigue cracks	Any metal	Tight
Nonrelevant indications ^(a)		
Weld spatter	Arc welds	Spherical or surface
Incomplete penetration	Fillet welds	Open, full weld length
Surface expulsion	Resistance welds	Raised metal at weld edge
Scuff marks	Seam welds	Surface of seam welds
Press-fit interface	Press fits	Outlines press fit
Braze runoff	Brazed parts	Edge of excess braze
Burrs	Machined parts	Bleeds heavily
Nicks, dents, scratches	All parts	Visible without penetrant aids

(a) These may be prohibited flaws, but are usually considered nonrelevant in penetrant testing.

Inspection Tools. An inspector must have tools that are capable of providing the required accuracy. These tools usually include suitable measuring devices, a flashlight, small quantities of solvent, small quantities of dry developers or aerosol cans of nonaqueous wet developers, pocket magnifiers ranging from 3 to 10×, and a suitable black light for fluorescent penetrants or sufficient white light for visible penetrants. Photographic standards or workpieces that have specific known flaws are sometimes used as inspection aids.

A typical inspection begins with an overall examination to determine that the workpiece has been properly processed and is in satisfactory condition for inspection. Inspection should not begin until the wet developers are completely dry. If developer films are too thick, if penetrant bleedout appears excessive, or if the penetrant background is excessive, the workpiece should be cleaned and reprocessed. When the inspector is satisfied that the workpiece is inspectable, it is examined according to a specified plan to be sure no areas have been missed. An experienced inspector can readily determine which indications are within acceptable limits and which ones are not. The inspector then measures all other indications. If the length or diameter of an indication exceeds allowable limits, it must be evaluated. One of the most

common and accurate ways of measuring indications is to lay a flat gage of the maximum acceptable dimension of discontinuity over the indication. If the indication is not completely covered by the gage, it is not acceptable.

Evaluation. Each indication that is not acceptable should be evaluated. It may actually be unacceptable, it may be worse than it appears, it may be false, it may be real, but nonrelevant, or it may actually be acceptable upon closer examination. One common method of evaluation includes the following steps:

- Wipe the area of the indication with a small brush or clean cloth that is dampened with a solvent
- Dust the area with a dry developer or spray it with a light coat of nonaqueous developer
- Remeasure under lighting appropriate for the type of penetrant used

If the discontinuity originally appeared to be of excessive length because of bleeding of penetrant along a scratch, crevice, or machining mark, this will be evident to a trained eye. Finally, to gain maximum assurance that the indication is properly interpreted, it is good practice to wipe the surface again with solvent-dampened cotton and examine the indication area with a magnifying glass and ample white light. This final evaluation may show that the indication is even larger than originally measured, but was not shown in its entirety because the ends were too tight to hold enough penetrant to reach the surface and become visible.

Disposition of Unacceptable Workpieces. A travel ticket will usually accompany each workpiece or lot of workpieces. Provision should be made on this ticket to indicate the future handling of unacceptable material, that is, scrapping, rework, repair, or review board action. There is often room on such tickets for a brief description of the indication. More often, indications are identified directly on the workpiece by circling them with some type of marking that is harmless to the material and not easily removed by accident, but removable when desired.

Reworking an unacceptable flaw is often allowable to some specified limit; indications can be removed by sanding, grinding, chipping, or machining. Repair welding is sometimes needed; in this case, the indication should be removed as in reworking before it is repair welded, or welding may move the flaw to a new location. In addition, it is imperative that all entrapped penetrant be removed prior to repair welding, because entrapped penetrant is likely to initiate a new flaw. Verification that the indication and the entrapped penetrant have been removed is required.

Because reworking is usually required, it is good practice to finish it off with moderately fine sanding, followed by chemical etching to remove smeared metal. All traces of the etching fluid should be rinsed off, and the area should be thoroughly dried before reprocessing for reinspection. Reprocessing can be the same as original processing for penetrant inspection, or can be done locally by applying the materials with small brushes or swabs.

False and Nonrelevant Indications. Because penetrant inspection provides only indirect indications or flaws, it cannot always be determined at first glance whether an indication is real, false, or nonrelevant. A real indication is caused by an undesirable flaw, such as a crack. A false indication is an accumulation of penetrant not caused by a discontinuity in the workpiece, such as a drop of penetrant left on the workpiece inadvertently. A nonrelevant indication is an entrapment of penetrant caused by a feature that is acceptable even though it may exceed allowable indication lengths, such as a press-fit interface.

Liquid Penetrant Inspection

Revised by J.S. Borucki, Ardrex Inc., and Gail Jordan, Howmet Corporation

Specifications and Standards

It has not been practical to establish any type of universal standardization, because of the wide variety of components and assemblies subjected to penetrant inspection, the differences in the types of discontinuities common to them, and the differences in the degree of integrity required. Generally, quality standards for the types of discontinuities detected by penetrant inspection are established by one or more of the following methods:

- Adoption of standards that have been successfully used for similar workpieces

- Evaluation of the results of penetrant inspection by destructive examination
- Experimental and theoretical stress analysis

Specifications. Normally, a specification is a document that delineates design or performance requirements. A specification should include the methods of inspection and the requirements based on the inspection or test procedure. With penetrant inspection, this becomes difficult. Too often the wording in quality specifications is ambiguous and meaningless, such as "workpieces shall be free from detrimental defects" or "workpieces having questionable indications shall be held for review by the proper authorities."

Specifications applicable to penetrant inspection are generally divided into two broad categories: those involving materials and equipment, and those concerning methods and standards. There are, however, several standards and specifications that are in common use; some of these are listed in Table 4. Because the equipment used for penetrant inspection covers such a broad scope, that is, ranging from small dip-tank setups to large automated installations, most emphasis in standards and specifications has been placed on the materials used in this inspection process.

Table 4 Partial listing of standards and specifications for liquid penetrant inspection

Number	Title or explanation of standard or specification
ASTM standards	
ASTM E 165	Standard Practice for Liquid-Penetrant Inspection Method
ASTM E 270	Standard Definitions of Terms Relating to Liquid-Penetrant Inspection
ASTM E 1208	Standard Method for Fluorescent Liquid-Penetrant Examination Using the Lipophilic Post-Emulsification Process
ASTM E 1209	Standard Method for Fluorescent-Penetrant Examination Using the Water-Washable Process
ASTM E 1210	Standard Method for Fluorescent-Penetrant Examination Using the Hydrophilic Post-Emulsification Process
ASTM E 1219	Standard Method for Fluorescent-Penetrant Examination Using the Solvent-Removable Process
ASTM E 1220	Standard Method for Visible-Penetrant Examination Using the Solvent-Removable Process
ASTM E 1135	Standard Test Method for Comparing the Brightness of Fluorescent Penetrants
ASTM D 2512	Compatibility of Materials with Liquid Oxygen (Impact-Sensitivity Threshold Technique)
Test for AMS-SAE specifications	
AMS 2647	Fluorescent Penetrant Inspection--Aircraft and Engine Component Maintenance

ASME specifications	
ASME SEC V	ASME Boiler and Pressure Vessel Code Section V, Article 6
U.S. military and government specifications	
MIL-STD-6866	Military Standard Inspection, Liquid Penetrant
MIL-STD-410	Nondestructive Testing Personnel Qualifications & Certifications
MIL-I-25135	Inspection Materials, Penetrant
MIL-I-25105	Inspection Unit, Fluorescent Penetrant, Type MA-2
MIL-I-25106	Inspection Unit, Fluorescent Penetrant, Type MA-3
MIL-STD-271 (Ships)	Nondestructive Testing Requirements for Metals

Control Systems. In conjunction with the specifications listed in Table 4, several methods and several types of standards are used to check the effectiveness of liquid penetrants. One of the oldest and most frequently used methods involves chromium-cracked panels, which are available in sets containing fine, medium, and coarse cracks. Many other types of inspection standards have been produced--often for specific indications needed for a unique application. A comparison of indications from two water-washable penetrants of different sensitivity that were applied to a chromium-cracked panel containing fine cracks is shown in Fig. 23.

Fig. 23 Comparison of indications on chromium-cracked panels developed with water-washable liquid penetrants of low sensitivity (panel at left) and high sensitivity (panel at right)

Acceptance and rejection standards for liquid penetrant inspection are usually established for each individual item or group of items by the designer. In most cases, acceptance and rejection standards are based on experience with similar items, the principal factor being the degree of integrity required. At one extreme, for certain noncritical items, the standard may permit some specific types of discontinuities all over the workpiece or in specified areas. Inspection is often applied only on a sampling basis for noncritical items. At the opposite extreme, items are subjected to 100% inspection, and requirements are extremely stringent to the point of defining the limitations on each specific area.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Introduction

MAGNETIC PARTICLE INSPECTION is a method of locating surface and subsurface discontinuities in ferromagnetic materials. It depends on the fact that when the material or part under test is magnetized, magnetic discontinuities that lie in a direction generally transverse to the direction of the magnetic field will cause a leakage field to be formed at and above the surface of the part. The presence of this leakage field, and therefore the presence of the discontinuity, is detected by the use of finely divided ferromagnetic particles applied over the surface, with some of the particles being gathered and held by the leakage field. This magnetically held collection of particles forms an outline of the discontinuity and generally indicates its location, size, shape, and extent. Magnetic particles are applied over a surface as dry particles, or as wet particles in a liquid carrier such as water or oil.

Ferromagnetic materials include most of the iron, nickel, and cobalt alloys. Many of the precipitation-hardening steels, such as 17-4 PH, 17-7 PH, and 15-4 PH stainless steels, are magnetic after aging. These materials lose their ferromagnetic properties above a characteristic temperature called the Curie point. Although this temperature varies for different materials, the Curie point for most ferromagnetic materials is approximately 760 °C (1400 °F).

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Method Advantages and Limitations

Nonferromagnetic materials cannot be inspected by magnetic particle inspection. Such materials include aluminum alloys, magnesium alloys, copper and copper alloys, lead, titanium and titanium alloys, and austenitic stainless steels.

In addition to the conventional magnetic particle inspection methods described in this article, there are several proprietary methods that employ ferromagnetic particles on a magnetized testpiece. Three of these methods--magnetic rubber inspection, magnetic printing, and magnetic painting--are described in the Appendix to this article.

Applications. The principal industrial uses of magnetic particle inspection are final inspection, receiving inspection, in-process inspection and quality control, maintenance and overhaul in the transportation industries, plant and machinery maintenance, and inspection of large components.

Although in-process magnetic particle inspection is used to detect discontinuities and imperfections in materials and parts as early as possible in the sequence of operations, final inspection is needed to ensure that rejectable discontinuities or imperfections detrimental to the use or function of the part have not developed during processing. During receiving inspection, semifinished purchased parts and raw materials are inspected to detect any initially defective material. Magnetic particle inspection is extensively used on incoming rod and bar stock, forging blanks, and rough castings.

The transportation industries (truck, railroad, and aircraft) have planned overhaul schedules at which critical parts are magnetic particle inspected for cracks. Planned inspection programs are also used in keeping plant equipment in operation without breakdowns during service. Because of sudden and severe stress applications, punch-press crankshafts, frames,

and flywheels are vulnerable to fatigue failures. A safety requirement in many plants is the inspection of crane hooks; fatigue cracks develop on the work-hardened inside surfaces of crane hooks where concentrated lifting loads are applied. The blading, shaft, and case of steam turbines are examined for incipient failure at planned downtimes.

Advantages. The magnetic particle method is a sensitive means of locating small and shallow surface cracks in ferromagnetic materials. Indications may be produced at cracks that are large enough to be seen with the naked eye, but exceedingly wide cracks will not produce a particle pattern if the surface opening is too wide for the particles to bridge.

Discontinuities that do not actually break through the surface are also indicated in many cases by this method, although certain limitations must be recognized and understood. If a discontinuity is fine, sharp, and close to the surface, such as a long stringer of nonmetallic inclusions, a clear indication can be produced. If the discontinuity lies deeper, the indication will be less distinct. The deeper the discontinuity lies below the surface, the larger it must be to yield a readable indication and the more difficult the discontinuity is to find by this method.

Magnetic particle indications are produced directly on the surface of the part and constitute magnetic pictures of actual discontinuities. There is no electrical circuitry or electronic readout to be calibrated or kept in proper operating condition. Skilled operators can sometimes make a reasonable estimate of crack depth with suitable powders and proper technique. Occasional monitoring of field intensity in the part is needed to ensure adequate field strength.

There is little or no limitation on the size or shape of the part being inspected. Ordinarily, no elaborate precleaning is necessary, and cracks filled with foreign material can be detected.

Limitations. There are certain limitations to magnetic particle inspection the operator must be aware of; for example, thin coatings of paint and other nonmagnetic coverings, such as plating, adversely affect the sensitivity of magnetic particle inspection. Other limitations are:

- The method can be used only on ferromagnetic materials
- For best results, the magnetic field must be in a direction that will intercept the principal plane of the discontinuity; this sometimes requires two or more sequential inspections with different magnetizations
- Demagnetization following inspection is often necessary
- Postcleaning to remove remnants of the magnetic particles clinging to the surface may sometimes be required after testing and demagnetization
- Exceedingly large currents are sometimes needed for very large parts
- Care is necessary to avoid local heating and burning of finished parts or surfaces at the points of electrical contact
- Although magnetic particle indications are easily seen, experience and skill are sometimes needed to judge their significance

Specifications and standards for magnetic particle inspection have been developed by several technical associations and divisions of the U.S. Department of Defense. Sections III, V, and VIII of the ASME Boiler and Pressure Vessel Code contain specifications for nondestructive inspection of the vessels. Several Aerospace Material Specifications (published by the Society of Automotive Engineers) and standards from the American Society for Testing and Materials cover magnetic particle inspection. Various military standards include specifications for vendors to follow in establishing inspection procedures for military equipment and supplies. American Society for Nondestructive Testing Recommended Practice SNT-TC-1A is a guide to the employer for establishing in-house procedures for training, qualification, and certification of personnel whose jobs require appropriate knowledge of the principles underlying the nondestructive inspection they perform.

Magnetic Particle Inspection

Description of Magnetic Fields

Magnetic fields are used in magnetic particle inspection to reveal discontinuities. Ferromagnetism is the property of some metals, chiefly iron and steel, to attract other pieces of ferromagnetic materials. A horseshoe magnet will attract magnetic materials to its ends, or poles. Magnetic lines of force, or flux, flow from the south pole through the magnet to the north pole.

Magnetized Ring. When a magnetic material is placed across the poles of a horseshoe magnet having square ends, forming a closed or ringlike assembly, the lines of force flow from the north pole through the magnetic material to the south pole (Fig. 1a). (Magnetic lines of force flow preferentially through magnetic material rather than through nonmagnetic material or air.) The magnetic lines of force will be enclosed within the ringlike assembly because no external poles exist, and iron filings or magnetic particles dusted over the assembly are not attracted to the magnet even though there are lines of magnetic force flowing through it. A ringlike part magnetized in this manner is said to contain a circular magnetic field that is wholly within the part.

Fig. 1 Schematics of magnetic lines of force. (a) Horseshoe magnet with a bar of magnetic material across poles, forming a closed, ringlike assembly, which will not attract magnetic particles. (b) Ringlike magnet assembly with an air gap, to which magnetic particles are attracted

If one end of the magnet is not square and an air gap exists between that end of the magnet and the magnetic material, the poles will still attract magnetic materials. Magnetic particles will cling to the poles and bridge the gap between them, as shown in Fig. 1(b). Any radial crack in a circularly magnetized piece will create a north and a south magnetic pole at the edges of a crack. Magnetic particles will be attracted to the poles created by such a crack, forming an indication of the discontinuity in the piece.

The fields set up at cracks or other physical or magnetic discontinuities in the surface are called leakage fields. The strength of a leakage field determines the number of magnetic particles that will gather to form indications; strong indications are formed at strong fields, weak indications at weak fields. The density of the magnetic field determines its strength and is partly governed by the shape, size, and material of the part being inspected.

Magnetized Bar. A straight piece of magnetized material (bar magnet) has a pole at each end. Magnetic lines of force flow through the bar from the south pole to the north pole. Because the magnetic lines of force within the bar magnet run the length of the bar, it is said to be longitudinally magnetized or to contain a longitudinal field.

If a bar magnet is broken into two pieces, a leakage field with north and south poles is created between the pieces, as shown in Fig. 2(a). This field exists even if the fracture surfaces are brought together (Fig. 2b). If the magnet is cracked but not broken completely in two, a somewhat similar result occurs. A north and a south pole form at opposite edges of the crack, just as though the break were complete (Fig. 2c). This field attracts the iron particles that outline the crack. The strength of these poles will be different from that of the fully broken pieces and will be a function of the depth of the crack and the width of the air gap at the surface.

Fig. 2 Leakage fields between two pieces of a broken bar magnet. (a) Magnet pieces apart. (b) Magnet pieces together (which would simulate a flaw). (c) Leakage field at a crack in a bar magnet

The direction of the magnetic field in an electromagnetic circuit is controlled by the direction of the flow of magnetizing current through the part to be magnetized. The magnetic lines of force are always at right angles to the direction of current flow. To remember the direction taken by the magnetic lines of force around a conductor, consider that the conductor is grasped with the right hand so that the thumb points in the direction of current flow. The fingers then point in the direction taken by the magnetic lines of force in the magnetic field surrounding the conductor. This is known as the right-hand rule.

Circular Magnetization. Electric current passing through any straight conductor such as a wire or bar creates a circular magnetic field around the conductor. When the conductor of electric current is a ferromagnetic material, the passage of current induces a magnetic field in the conductor as well as in the surrounding space. A part magnetized in this manner is said to have a circular field or to be circularly magnetized, as shown in Fig. 3(a).

Fig. 3 Magnetized bars showing directions of magnetic field. (a) Circular. (b) Longitudinal

Longitudinal Magnetization. Electric current can also be used to create a longitudinal magnetic field in magnetic materials. When electric current is passed through a coil of one or more turns, a magnetic field is established lengthwise or longitudinally, within the coil, as shown in Fig. 3(b). The nature and direction of the field around the conductor that forms the turns of the coil produce longitudinal magnetization.

Effect of Flux Direction. To form an indication, the magnetic field must approach a discontinuity at an angle great enough to cause the magnetic lines of force to leave the part and return after bridging the discontinuity. For best results, an intersection approaching 90° is desirable. For this reason, the direction, size, and shape of the discontinuity are important. The direction of the magnetic field is also important for optimum results, as is the strength of the field in the area of the discontinuity.

Figure 4(a) illustrates a condition in which the current is passed through the part, causing the formation of a circular field around the part. Under normal circumstances, a discontinuity such as A in Fig. 4(a) would give no indication of its presence, because it is regular in shape and lies parallel to the magnetic field. If the discontinuity has an irregular shape but is predominantly parallel to the magnetic field, such as B, there is a good possibility that a weak indication would form. Where the predominant direction of the discontinuity is at a 45° angle to the magnetic field, such as C, D, and E, the conditions are more favorable for detection regardless of the shape of the discontinuity. Discontinuities whose predominant directions, regardless of shape, are at a 90° angle to the magnetic field produce the most pronounced indications (F, G, and H, Fig. 4a).

Fig. 4 Effect of direction of magnetic field or flux flow on the detectability of discontinuities with various orientations. (a) Circular magnetization. (b) Longitudinal magnetization. See text for discussion.

A longitudinally magnetized bar is shown in Fig. 4(b). Discontinuities L, M, and N, which are at about 45° to the magnetic field, would produce detectable indications as they would with a circular field. Discontinuities J and K would display pronounced indications, and weak indications would be produced at discontinuities P, Q, and R.

Magnetization Methods. In magnetic particle inspection, the magnetic particles can be applied to the part while the magnetizing current is flowing or after the current has ceased, depending largely on the retentivity of the part. The first technique is known as the continuous method; the second, the residual method.

If the magnetism remaining in the part after the current has been turned off for a period of time (residual magnetism) does not provide a leakage field strong enough to produce readable indications when magnetic particles are applied to the surface, the part must be continuously magnetized during application of the particles. Consequently, the residual method can be used only on materials having sufficient retentivity; usually the harder the material, the higher the retentivity. The continuous method can be used for most parts.

Magnetizing Current

Both direct current (dc) and alternating current (ac) are suitable for magnetizing parts for magnetic particle inspection. The strength, direction, and distribution of magnetic fields are greatly affected by the type of current used for magnetization.

The fields produced by direct and alternating current differ in many respects. The important difference with regard to magnetic particle inspection is that the fields produced by direct current generally penetrate the cross section of the part,

while the fields produced by alternating current are confined to the metal at or near the surface of the part, a phenomenon known as the skin effect. Therefore, alternating current should not be used in searching for subsurface discontinuities.

Direct Current. The best source of direct current is the rectification of alternating current. Both the single-phase (Fig. 5a) and three-phase types of alternating current (Fig. 5b) are furnished commercially. By using rectifiers, the reversing alternating current can be converted into unidirectional current, and when three-phase alternating current is rectified in this manner (Fig. 5c), the delivered direct current is entirely the equivalent of straight direct current for purposes of magnetic particle inspection. The only difference between rectified three-phase alternating current and straight direct current is a slight ripple in the value of the rectified current, amounting to only about 3% of the maximum current value.

Fig. 5 Alternating current wave forms. (a) Single-phase. (b) Three-phase. (c) Three-phase rectified. (d) Half-wave rectified single-phase. (e) Full-wave rectified single-phase

When single-phase alternating current is passed through a simple rectifier, current is permitted to flow in one direction only. The reverse half of each cycle is completely blocked out (Fig. 5d). The result is unidirectional current (called half-wave current) that pulsates; that is, it rises from zero to a maximum and then drops back to zero. During the blocked-out reverse of the cycle, no current flows, then the half-cycle forward pulse is repeated, at a rate of 60 pulses per second. A rectifier for alternating current can also be connected so that the reverse half of the cycle is turned around and fed into the circuit flowing in the same direction as the first half of the cycle (Fig. 5e). This produces pulsating direct current, but with no interval between the pulses. Such current is referred to as single-phase full-wave direct current or full-wave rectified single-phase alternating current.

There is a slight skin effect from the pulsations of the current, but it is not pronounced enough to have a serious impact on the penetrations of the field. The pulsation of the current is useful because it imparts some slight vibration to the magnetic particles, assisting them in arranging themselves to form indications. Half-wave current, used in magnetization with prods and dry magnetic particles, provides the highest sensitivity for discontinuities that are wholly below the surface, such as those in castings and weldments.

Magnetization employing surges of direct current can be used to increase the strength of magnetic fields; for example, a rectifier capable of continuously delivering 400-A current can put out much more than 400 A for short intervals. Therefore, it is possible, by suitable current-control and switching devices, to pass a very high current for a short period (less than a second) and then reduce the current, without interrupting it, to a much lower value.

Alternating current, which must be single-phase when used directly for magnetizing purposes, is taken from commercial power lines and usually has a frequency of 50 or 60 Hz. When used for magnetizing, the line voltage is stepped down, by means of transformers, to the low voltages required. At these low voltages, magnetizing currents of several thousand amperes are often used.

One problem encountered when alternating current is used is that the resultant residual magnetism in the part may not be at a level as high as that of the magnetism generated by the peak current of the ac cycle. This is because the level of residual magnetism depends on where in the cycle the current was discontinued.

Power Sources

Early power sources were general-purpose units designed to use either alternating or direct current for magnetization. When direct current was used, it was derived directly from a bank of storage batteries, and a carbon-pile rheostat was used to regulate current level. Subsequent advances in technology have made the storage battery obsolete as a power supply and have given rise to many innovations, especially in the area of current control. Portable, mobile, and stationary equipment is currently available, and selection among these types depends on the nature and location of testing.

Portable equipment is available in light-weight (16 to 40 kg, or 35 to 90 lb) power source units that can be readily taken to the inspection site. Generally, these portable units are designed to use 115-, 230-, or 460-V alternating current and to supply magnetizing-current outputs of 750 to 1500 A in half-wave or alternating current. Machines capable of supplying half-wave current and alternating current and having continuously variable (infinite) current control can be used for magnetic particle inspection in a wide range of applications. Primary application of this equipment is hand-held prod inspection utilizing the half-wave output in conjunction with dry powder. In general, portable equipment is designed to operate with relatively short power supply cables, and the output is very limited when it is necessary to use longer cables.

The major disadvantage of portable equipment is the limited amount of current available. For the detection of deep-lying discontinuities and for coverage of a large area with one prod contact, a machine with higher-amperage output is required. Also, portable equipment cannot supply the full-wave direct current necessary for some inspections and does not have the accessories found on larger mobile equipment.

Mobile units are generally mounted on wheels to facilitate transportation to various inspection sites. Mobile equipment usually supplies half-wave or alternating magnetizing-current outputs. Inspection of parts is accomplished with flexible cables, yokes, prod contacts, contact clamps, and coils. Instruments and controls are mounted on the front of the unit. Magnetizing current is usually controlled by a remote-control switch connected to the unit by an electric cord. Quick-coupling connectors for connecting magnetizing cables are on the front of the unit.

Mobile equipment is usually powered by single-phase, 60-Hz alternating current (230 or 460 V) and has an output range of 1500 to 6000 A. On some units, current control is provided by a power-tap switch, which varies the voltage applied to the primary coil of the power transformer; most of these have either 8 or 30 steps of current control. However, current control on more advanced units is provided either by solid-state phase control of the transformer or by use of a saturable-core reactor to control the transformer. Phase control of the transformer is achieved by silicon-controlled rectifiers or triacs in series with the transformer. A solid-state control circuit is used to rapidly switch the ac supply on and off for controlled fractions of each cycle. A triac provides current control in both directions, while a saturable-core reactor provides current control in one direction only. In a circuit employing a saturable-core reactor to control magnetizing-current output, a silicon-controlled rectifier is used in conjunction with phase control to control a saturable-core reactor that is in series with, and that controls the input to, the power transformer.

Standard instruments and controls on mobile equipment are as follows:

- Ammeters to indicate the magnetizing current flowing through the yokes, prods, or coil as being alternating, half-wave, or direct current
- Switches for controlling the magnetizing or demagnetizing current
- Pilot light to indicate when power to the unit is on
- Current control, either stepped or continuously variable, for controlling the amount of magnetizing and demagnetizing current
- Remote-control cable receptacle that permits turning the magnetizing current on and off at some distance from the unit
- Receptacles to permit the connection of the magnetizing-current cables

Built-in demagnetizers as contained in mobile equipment for magnetic particle inspection are available that demagnetize by one of four methods:

- Low-voltage high-amperage alternating current with a motor-driven power-tap switch, arranged to automatically provide periods of current-on and periods of current-off in succession, with the amount of demagnetizing current reduced with each successive step
- Low-voltage high-amperage alternating current provided by a continuously variable current control that affords complete control of the demagnetization current from full-on to zero
- Current-decay method, in which low-voltage high-amperage alternating current is caused to decay from some maximum value to zero in an automatic and controlled manner. Because the entire cycle can be completed in a few seconds, the current-decay method offers an advantage over some of the more time-consuming methods
- Low-voltage high-amperage direct current, with which demagnetization is accomplished by a motor-driven power-tap switch in conjunction with means for reversing the current direction from positive to negative as the current is systematically reduced in steps of current-on periods followed by current-off periods

Stationary equipment can be obtained as either general-purpose or special-purpose units. The general-purpose unit is primarily intended for use in the wet method and has a built-in tank that contains the bath pump, which continuously agitates the bath and forces the fluid through hoses onto the part being inspected. Pneumatically operated contact heads, together with a rigid-type coil, provide capabilities for both circular and longitudinal magnetization. Self-contained ac or dc power supplies are available in amperage ratings from 2500 to 10,000 A. Maximum opening between contact plates varies from 0.3 to 3.7 m (1 to 12 ft).

Optional features that are available include self-regulating current control, automatic magnetizing circuit, automatic bath applicator, steady rests for heavy parts, and demagnetizing circuitry. Other options are curtains or hoods and an ultraviolet light; these are used during inspection with fluorescent particles.

Stationary power packs serve as sources of high-amperage magnetizing current to be used in conjunction with special fixtures or with cable-wrap or clamp-and-contact techniques. Rated output varies from a customary 4000 to 6000 A to as high as 20,000 A. The higher-amperage units are used for the overall magnetization of large forgings or castings that would otherwise require systematic prod inspection at much lower current levels.

Multidirectional Magnetizing. Some units feature up to three output circuits that are systematically energized in rapid sequence, either electrically or mechanically, for effectively magnetizing a part in several directions in the same time frame. This reveals discontinuities lying in any direction after only a single processing step.

Special-purpose stationary units are designed for handling and inspecting large quantities of similar items. Generally, conveyors, automatic markers, and alarm systems are included in such units to expedite the handling of parts.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Methods of Generating Magnetic Fields

One of the basic requirements of magnetic particle inspection is that the part undergoing inspection be properly magnetized so that the leakage fields created by discontinuities will attract the magnetic particles. Permanent magnets serve some useful purpose in this respect, but magnetization is generally produced by electromagnets or the magnetic field associated with the flow of electric current. Basically, magnetization is derived from the circular magnetic field generated when an electric current flows through a conductor. The direction of this field is dependent on the direction of current flow, which can be determined by applying the right-hand rule (see the section "Description of Magnetic Fields" in this article). General applications, advantages, and limitations of the various methods of magnetizing parts for magnetic particle inspection are summarized in Table 1. Additional information can be found in the article "Magnetic Field Testing" in this Volume.

Table 1 General applications, advantages, and limitations of the various magnetizing methods used in magnetic particle inspection

Application	Advantages	Limitations
Coils (single or multiple loop)		
Medium-size parts whose length predominates, such as a crankshaft or camshaft	All generally longitudinal surfaces are longitudinally magnetized to locate transverse discontinuities.	Part should be centered in coil to maximize length effectively magnetized during a given shot. Length may dictate additional shots as coil is repositioned.
Large castings, forgings, or shafts	Longitudinal field easily attained by wrapping with a flexible cable.	Multiple processing may be required because of part shape.
Miscellaneous small parts	Easy and fast, especially where residual method is applicable. Noncontact with part. Relatively complex parts can usually be processed with same ease as simple cross section.	Length-to-diameter (<i>L/D</i>) ratio is important in determining adequacy of ampere-turns; effective ratio can be altered by utilizing pieces of similar cross-sectional area. Sensitivity diminishes at ends of part because of general leakage field pattern. Quick break of current is desirable to minimize end effect on short parts with low <i>L/D</i> ratios.
Yokes		
Inspection of large surface areas for surface discontinuities	No electrical contact. Highly portable. Can locate discontinuities in any direction, with proper yoke orientation	Time consuming. Yoke must be systematically repositioned to locate discontinuities with random orientation.
Miscellaneous parts requiring inspection of localized areas	No electrical contact. Good sensitivity to surface discontinuities. Highly portable. Wet or dry method can be used. Alternating current yoke can also serve as demagnetizer in some cases.	Yoke must be properly positioned relative to orientation of discontinuity. Relatively good contact must be established between part and poles of yoke; complex part shape may cause difficulty. Poor sensitivity to subsurface discontinuities except in isolated areas

Central conductors		
Miscellaneous short parts having holes through which a conductor can be threaded, such as bearing rings, hollow cylinders, gears, large nuts, large clevises, and pipe couplings	No electrical contact, so that possibility of burning is eliminated. Circumferentially directed magnetic field is generated in all surfaces surrounding the conductor. Ideal for parts for which the residual method is applicable. Lightweight parts can be supported by the central conductor. Multiple turns can be used to reduce the amount of current required.	Size of conductor must be ample to carry required current. Ideally, conductor should be centrally located within hole. Large-diameter parts require several setups with conductor near or against inner surface and rotation of part between setups. Where continuous method is being employed, inspection is required after each setup.
Long tubular parts such as pipe, tubing, hollow shafts	No electrical contact. Both inside (ID) and outside (OD) surfaces can be inspected. Entire length of part is circularly magnetized.	Sensitivity of outer surface to indications may be somewhat diminished relative to inner surface for large-diameter and thick-wall parts.
Large valve bodies and similar parts	Good sensitivity to inner-surface discontinuities	Same as for long tubular parts, above
Direct contact, head shot		
Solid, relatively small parts (cast, forged, or machined) that can be inspected on a horizontal wet-method unit	Fast, easy process. Complete circular field surrounds entire current path. Good sensitivity to surface and near-surface discontinuities. Simple as well as relatively complex parts can usually be easily inspected with one or more shots.	Possibility of burning part exists if proper contact conditions are not met. Long parts should be inspected in sections to facilitate bath application without resorting to an excessively long current shot.
Direct contact, clamps and cables		
Large castings and forgings	Large surface areas can be inspected in a relatively short time.	High amperage requirements (8000-20,000 A) dictate use of special direct current power pack.
Long tubular parts such as tubing, pipe, and hollow shafts	Entire length can be circularly magnetized by contacting end-to-end.	Effective field is limited to outer surface so process cannot be used to inspect inner surface. Part ends must be shaped to permit electrical contact and must be able to carry required current without excessive heating.
Long solid parts such as billets, bars, and shafts	Entire length can be circularly magnetized by contacting end-to-end. Amperage requirements are independent of length. No loss of magnetism at ends	Voltage requirements increase as length increases because of greater impedance of cable and part. Ends of parts must have shape that permits electrical contact and must be capable of carrying required current without excessive heating.
Prod contacts		
Welds, for cracks, inclusions, open roots, or inadequate joint penetration	Circular field can be selectively directed to weld area by prod placement. In conjunction with half-wave current and dry powder, provides excellent sensitivity to subsurface discontinuities. Prods, cables, and power packs can be brought to	Only small area can be inspected at one time. Arc burn can result from poor contact. Surface must be dry when dry powder is being used. Prod spacing must be in accordance with

	inspection site.	magnetizing-current level.
Large castings or forgings	Entire surface area can be inspected in small increments using nominal current values. Circular magnetic field can be concentrated in specific areas likely to contain discontinuities. Prods, cables, and power packs can be brought to the inspection site.	Coverage of large surface areas requires a multiplicity of shots, which can be very time consuming. Arc burn can result from poor contact. Surface must be dry when dry powder is being used.
Induced current		
Ring-shaped parts, for circumferential discontinuities	No electrical contact. All surfaces of part are subjected to a toroidal magnetic field. 100% coverage is obtained in single magnetization. Can be automated	Laminated core is required through ring to enhance magnetic path. Type of magnetizing current must be a compatible with magnetic hardness or softness of metal inspected. Other conductors encircling field must be avoided.
Balls	No electrical contact. Permits 100% coverage for indications of discontinuities in any direction by use of a three-step process with reorientation of ball between steps. Can be automated	For small-diameter balls, use is limited to residual method of magnetization.
Disks and gears	No electrical contact. Good sensitivity at or near periphery or rim. Sensitivity in various areas can be varied by selection of core or pole piece. In conjunction with half-wave current and dry powder, provides excellent sensitivity to discontinuities lying just below the surface	100% coverage may require two-step process. Type of magnetizing current must be compatible with magnetic hardness or softness of metal inspected.

Yokes

There are two basic types of yokes that are commonly used for magnetizing purposes: permanent-magnet and electromagnetic yokes. Both are hand held and therefore quite mobile.

Permanent-magnet yokes are used for applications where a source of electric power is not available or where arcing is not permissible (as in an explosive atmosphere). The limitations of permanent-magnet yokes include the following:

- Large areas or masses cannot be magnetized with enough strength to produce satisfactory crack indications
- Flux density cannot be varied at will
- If the magnet is very strong, it may be difficult to separate from a part
- Particles may cling to the magnet, possibly obscuring indications

Electromagnetic yokes (Fig. 6) consist of a coil wound around a U-shaped core of soft iron. The legs of the yoke can be either fixed or adjustable. Adjustable legs permit changing the contact spacing and the relative angle of contact to accommodate irregularly-shaped parts. Unlike a permanent-magnet yoke, an electromagnetic yoke can readily be switched on or off. This feature makes it convenient to apply and remove the yoke from the testpiece.

Fig. 6 Electromagnetic yoke showing position and magnetic field for the detection of discontinuities parallel to a weld bead. Discontinuities across a weld bead can be detected by placing the contact surfaces of the yoke next to and on either side of the bead (rotating yoke about 90° from position shown here).

The design of an electromagnetic yoke can be based on the use of either direct or alternating current or both. The flux density of the magnetic field produced by the direct current type can be changed by varying the amount of current in the coil. The direct current type of yoke has greater penetration while the alternating current type concentrates the magnetic field at the surface of the testpiece, providing good sensitivity for the disclosure of surface discontinuities over a relatively broad area. In general, discontinuities to be disclosed should be centrally located in the area between pole pieces and oriented perpendicular to an imaginary line connecting them (Fig. 6). Extraneous leakage fields in the immediate vicinity of the poles cause an excessive buildup of magnetic particles.

In operation, the part completes the magnetic path for the flow of magnetic flux. The yoke is a source of magnetic flux, and the part becomes the preferential path completing the magnetic circuit between the poles. (In Fig. 6, only those portions of the flux lines near the poles are shown.) Yokes that use alternating current for magnetization have numerous applications and can also be used for demagnetization.

Coils

Single-loop and multiple-loop coils (conductors) are used for the longitudinal magnetization of components (Fig. 3b and 4b). The field within the coil has a definite direction, corresponding to the direction of the lines of force running through it. The flux density passing through the interior of the coil is proportional to the product of the current, I , in amperes, and the number of turns in the coil, N . Therefore, the magnetizing force of such a coil can be varied by changing either the current or the number of turns in the coil. For large parts, a coil can be produced by winding several turns of a flexible cable around the part, but care must be taken to ensure that no indications are concealed beneath the cable.

Portable magnetizing coils are available that can be plugged into an electrical outlet. These coils can be used for the in-place inspection of shaftlike parts in railroad shops, aircraft maintenance shops, and shops for automobile, truck, and tractor repair. Transverse cracks in spindles and shafts are easily detected with such coils.

Most coils used for magnetizing are short, especially those wound on fixed frames. The relationship of the length of the part being inspected to the width of the coil must be considered. For a simple part, the effective overall distance that can

be inspected is 150 to 230 mm (6 to 9 in.) on either side of the coil. Thus, a part 305 to 460 mm (12 to 18 in.) long can be inspected using a normal coil approximately 25 mm (1 in.) thick. In testing longer parts, either the part must be moved at regular intervals through the coil or the coil must be moved along the part.

The ease with which a part can be longitudinally magnetized in a coil is significantly related to the length-to-diameter (L/D) ratio of the part. This is due to the demagnetizing effect of the magnetic poles set up at the ends of the part. This demagnetizing effect is considerable for L/D ratios of less than 10 to 1 and is very significant for ratios of less than 3 to 1. Where the L/D ratio is extremely unfavorable, pole pieces of similar cross-sectional area can be introduced to increase the length of the part and thus improve the L/D ratio. The magnetization of rings, disks, and other parts with low L/D ratios is discussed and illustrated in the section "Induced Current" in this article.

The number of ampere-turns required to produce sufficient magnetizing force to magnetize a part adequately for inspection is given by:

$$NI = 45,000 (L/D) \quad (\text{Eq 1})$$

where N is the number of turns in the coil, I is the current in amperes, and L/D is the length-to-diameter ratio of the part. When the part is magnetized at this level by placing it on the bottom of the round magnetizing coil, adjacent to the coil winding, the flux density will be about 110 lines/mm² (70,000 lines/in.²). Experimental work has shown that a flux density of 110 lines/mm² is more than satisfactory for most applications of coil magnetization and that 54 lines/mm² (35,000 lines/in.²) is acceptable for all but the most critical applications.

When it is desirable to magnetize the part by centering it in the coil, Eq 1 becomes:

$$NI = \frac{43\,000r}{\mu_{\text{eff}}} \quad (\text{Eq 2})$$

where r is the radius of the coil in inches and $\mu_{\text{eff}} = (6L/D) - 5$. Equation 2 is applicable to parts that are centered in the coil (coincident with the coil axis) and that have cross sections constituting a low fill factor, that is, with a cross-sectional area less than 10% of the area encircled by the coil.

When using a coil for magnetizing a bar-like part, strong polarity at the ends of the part could mask transverse defects. An advantageous field in this area is assured on full wave, three phase, direct current units by special circuitry known as "quick" or "fast" break. A "controlled" break feature on alternating current, half wave, and on single-phase full wave direct current units provides a similar advantageous field.

Central Conductors

For many tubular or ring-shaped parts, it is advantageous to use a separate conductor to carry the magnetizing current rather than the part itself. Such a conductor, commonly referred to as a central conductor, is threaded through the inside of the part (Fig. 7) and is a convenient means of circularly magnetizing a part without the need for making direct contact to the part itself. Central conductors are made of solid and tubular nonmagnetic and ferromagnetic materials that are good conductors of electricity.

Fig. 7 Use of central conductors for the circular magnetization of long, hollow cylindrical parts (a) and short, hollow cylindrical or ringlike parts (b) for the detection of discontinuities on inside and outside surfaces

The basic rules regarding magnetic fields around a circular conductor carrying direct current are as follows:

- The magnetic field outside a conductor of uniform cross section is uniform along the length of the conductor
- The magnetic field is 90° to the path of the current through the conductor
- The flux density outside the conductor varies inversely with the radial distance from the center of the conductor

Solid Nonmagnetic Conductor Carrying Direct Current. The distribution of the magnetic field inside a nonmagnetic conductor, such as a copper bar, when carrying direct current is different from the distribution external to the bar. At any point inside the bar, the flux density is the result of only that portion of the current that is flowing in the metal between the point and the center of the bar. Therefore, the flux density increases linearly, from zero at the center of the bar to a maximum value at the surface. Outside the bar, the flux density decreases along a curve, as shown in Fig. 8(a). In calculating flux densities outside the bar, the current can be considered to be concentrated at the center of the bar. If the radius of the bar is R and the flux density, B , at the surface of the bar is equal to the magnetizing force, H , then the flux density at a distance $2R$ from the center of the bar will be $H/2$; at $3R$, $H/3$; and so on.

Fig. 8 Flux density in and around solid conductors of the same diameter. (a) Nonmagnetic conductor ($\mu = 1.0$) carrying direct current. (b) Ferromagnetic conductor ($\mu > 1.0$) carrying direct current. (c) Ferromagnetic conductor ($\mu > 1.0$) carrying alternating current. See text for discussion.

Solid Ferromagnetic Conductor Carrying Direct Current. If the conductor carrying direct current is a solid bar of steel or other ferromagnetic material, the same distribution of magnetic field exists as in a similar nonmagnetic conductor, but the flux density is much greater. Figure 8(b) shows a conductor of the same diameter as that shown in Fig. 8(a). The flux density at the center is zero, but at the surface it is μH , where μ is the material permeability of the magnetic material. (Permeability is the ease with which a material accepts magnetism.) The actual flux density, therefore, may be many times that in a nonmagnetic bar. Just outside the surface, however, the flux density drops to exactly the same value as that for the nonmagnetic conductor, and the decrease in flux density with increasing distance follows the same curve.

Solid Ferromagnetic Conductor Carrying Alternating Current. The distribution of the magnetic field in a solid ferromagnetic conductor carrying alternating current is shown in Fig. 8(c). Outside the conductor, the flux density decreases along the same curve as if direct current produced the magnetizing force; however, while the alternating current is flowing, the field is constantly varying in strength and direction. Inside the conductor, the flux density is zero at the center and increases toward the outside surface--slowly at first, then accelerating to a high maximum at the surface. The flux density at the surface is proportional to the permeability of the conductor material.

Central Conductor Enclosed Within Hollow Ferromagnetic Cylinder. When a central conductor is used to magnetize a hollow cylindrical part made of a ferromagnetic material, the flux density is maximum at the inside surface of the part (Fig. 9). The flux density produced by the current in the central conductor is maximum at the surface of the conductor (H , in Fig. 9) and then decreases along the same curve outside the conductor, as shown in Fig. 8, through the space between the conductor and the inside surface of the part. At this surface, however, the flux density is immediately increased by the permeability factor, μ , of the material of the part and then decreases to the outer surface. Here the flux density again drops to the same decreasing curve it was following inside the part.

Fig. 9 Flux density in and around a hollow cylinder made of magnetic material with direct current flowing through a nonmagnetic central conductor

This method, then, produces maximum flux density at the inside surface and therefore gives strong indications of discontinuities on that surface. Sometimes these indications may even appear on the outside surface of the part. The flux density in the wall of the cylindrical part is the same whether the central conductor is of magnetic or nonmagnetic material, because it is the field external to the conductor that constitutes the magnetizing force for the part.

If the axis of a central conductor is placed along the axis of a hollow cylindrical part, the magnetic field in the part will be concentric with its cylindrical wall. However, if the central conductor is placed near one point on the inside circumference of the part, the flux density of the field in the cylindrical wall will be much stronger at this point and will be weaker at the diametrically opposite point.

In small hollow cylinders, it is desirable that the conductor be centrally placed so that a uniform field for the detection of discontinuities will exist at all points on the cylindrical surface. In larger-diameter tubes, rings, or pressure vessels, however, the current necessary in the centrally placed conductor to produce fields of adequate strength for proper inspection over the entire circumference becomes excessively large.

An offset central conductor should then be used (Fig. 10). When the conductor passing through the inside of the part is placed against an inside wall of the part, the current levels given in the section "Magnitude of Applied Current" in this article apply except that the diameter will be considered the sum of the diameter of the central conductor and twice the wall thickness. The distance along the part circumference (interior or exterior) that is effectively magnetized will be taken as four times the diameter of the central conductor, as illustrated in Fig. 10. The entire circumference will be inspected by rotating the part on the conductor, allowing for approximately a 10% magnetic field overlap.

Fig. 10 Schematic showing that the effective region of inspection when using an offset central conductor is equal to four times the diameter of the conductor

The diameter of a central conductor is not related to the inside diameter or the wall thickness of the cylindrical part. Conductor size is usually based on its current-carrying capacity and ease of handling. In some applications, conductors larger than that required for current-carrying capacity can be used to facilitate centralizing the conductor within the part.

Residual magnetization is usually employed whenever practicable because the background is minimized and contrast is therefore enhanced. Also, residual magnetization is faster and less critical than continuous magnetization.

The central-conductor type of inspection is sometimes required on components having parallel multiple openings, such as engine blocks. The cylinders can be processed with a single central conductor in the normal manner. However, a multiple central-conductor fixture can be designed that enables the operator to process two or more adjacent cylinders at one time with the same degree of sensitivity as if processed individually. In fact, in the areas between the central conductors, the circular fields reinforce one another to enhance sensitivity.

Direct-Contact Method

For small parts having no openings through the interior, circular magnetic fields are produced by direct contact to the part. This is done by clamping the parts between contact heads (head shot), generally on a bench unit (Fig. 11) that incorporates the source of the current. A similar unit can be used to supply the magnetizing current to a central conductor (Fig. 7).

Fig. 11 Bench unit for the circular magnetization of workpieces that are clamped between contact heads (direct-contact, head-shot method). The coil on the unit can be used for longitudinal magnetization.

The contact heads must be constructed so that the surfaces of the part are not damaged--either physically by pressure or structurally by heat from arcing or from high resistance at the points of contact. Heat can be especially damaging to hardened surfaces such as bearing races.

For the complete inspection of a complex part, it may be necessary to attach clamps at several points on the part or to wrap cables around the part to orient fields in the proper directions at all points on the surface. This often necessitates several magnetizations. Multiple magnetizations can be minimized by using the overall magnetization method, multidirectional magnetization, or induced-current magnetization.

Prod Contacts

For the inspection of large and massive parts too bulky to be put into a unit having clamping contact heads, magnetization is often done by using prod contacts (Fig. 12) to pass the current directly through the part or through a local portion of it. Such local contacts do not always produce true circular fields, but they are very convenient and practical for many purposes. Prod contacts are often used in the magnetic particle inspection of large castings and weldments.

Fig. 12 Single and double prod contacts. Discontinuities are detected by the magnetic field generated between the prods.

Advantages. Prod contacts are widely used and have many advantages. Easy portability makes them convenient to use for the field inspection of large tanks and welded structures. Sensitivity to defects lying wholly below the surface is greater with this method of magnetization than with any other, especially when half-wave current is used in conjunction with dry powder and the continuous method of magnetization.

Limitations. The use of prod contacts involves some disadvantages:

- Suitable magnetic fields exist only between and near the prod contact points. These points are seldom

more than 305 mm (12 in.) apart and usually much less; therefore, it is sometimes necessary to relocate the prods so that the entire surface of a part can be inspected

- Interference of the external field that exists between the prods sometimes makes observation of pertinent indications difficult; the strength of the current that can be used is limited by this effect
- Great care must be taken to avoid burning of the part under the contact points. Burning may be caused by dirty contacts, insufficient contact pressure, or excessive currents. The likelihood of such damage is particularly great on steel with a carbon content of 0.3 to 0.4% or more. The heat under the contact points can produce local spots of very hard material that can interfere with later operations, such as machining. Actual cracks are sometimes produced by this heating effect. Contact heating is less likely to be damaging to low-carbon steel such as that used for structural purposes

Induced Current

Induced current provides a convenient method of generating circumferential magnetizing current in ring-shaped parts without making electrical contact. This is accomplished by properly orienting the ring within a magnetizing coil such that it links or encloses lines of magnetic flux (flux linkage), as shown in Fig. 13(a). As the level of magnetic flux changes (increases or decreases), a current flows around the ring in a direction opposing the change in flux level. The magnitude of this current depends on the total flux linkages, rate of flux linkage changes, and the electrical impedance associated with the current path within the ring. Increasing the flux linkages and the rate of change increases the magnitude of current induced in the ring. The circular field associated with this current takes the form of a toroidal magnetic field that encompasses all surface areas on the ring and that is conducive to the disclosure of circumferential types of discontinuities. This is shown schematically in Fig. 13(b). To enhance the total flux linkages, laminated soft iron pole pieces are usually inserted through the hole in the part as shown in Fig. 13(a).

Fig. 13 Induced-current method of magnetizing a ring-shaped part. (a) Ring being magnetized by induced current. Current direction corresponds to decreasing magnetizing current. (b) Resulting induced current and toroidal magnetic field in a ring

Direct Versus Alternating Current. The choice of magnetizing current for the induced-current method depends on the magnetic properties of the part to be inspected. In cases in which the residual method is applicable, such as for most bearing races or similar parts having high magnetic retentivity, direct current is used for magnetizing. The rapid interruption of this current, by quick-break circuitry, results in a rapid collapse of the magnetic flux and the generation of a high-amperage, circumferentially directed single pulse of current in the part. Therefore, the part is residually magnetized with a toroidal field, and the subsequent application of magnetic particles will produce indications of circumferentially oriented discontinuities.

Passing an alternating current through a conductor will set up a fluctuating magnetic field as the level of magnetic flux rapidly changes from a maximum value in one direction to an equal value in the opposite direction. This is similar to the current that would flow in a single-shortened-turn secondary of a transformer. The alternating induced current, in conjunction with the continuous method, renders the method applicable for processing magnetically soft, or less retentive, parts.

Applications. The induced-current method, in addition to eliminating the possibility of damaging the part, is capable of magnetizing in one operation parts that would otherwise require more than one head shot. Two examples of this type of

part are illustrated in Fig. 14 and 15. These parts cannot be completely processed by one head shot to disclose circumferential defects, because regions at the contact point are not properly magnetized. Therefore, a two-step inspection process would be required for full coverage, with the part rotated approximately 90° prior to the second step. On the other hand, the induced-current method provides full coverage in one processing step. The disk-shaped part shown in Fig. 15 presents an additional problem when the contact method is employed to disclose circumferential defects near the rim. Even when a two-step process is employed, as with the ring shown in Fig. 14, the primary current path through the disk may not develop a circular field of ample magnitude in the rim area. The induced current can be selectively concentrated in the rim area by proper pole piece selection to provide full coverage (rim area) in a single processing step. The pole pieces shown in Fig. 15(b) are hollow and cylindrical, with one on each side of the disk. These pole pieces direct the magnetic flux through the disk such that the rim is the only portion constituting a totally enclosing current path.

Fig. 14 Current and magnetic-field distribution in a ring being magnetized with a head shot. Because the regions at the contact points are not magnetized, two operations are required for full coverage. With the induced-current method, parts of this shape can be completely magnetized in one operation.

Fig. 15 Current paths in a rimmed disk-shaped part that has been magnetized by (a) head-shot magnetization and (b) induced-current magnetization

Pole pieces used in conjunction with this method are preferably constructed of laminated ferromagnetic material to minimize the flow of eddy currents within the pole pieces, which detract from the induced (eddy) current developed within the part being processed. Pole pieces can also be made of rods, wire-filled nonconductive tubes, or thick-wall pipe saw cut to break up the eddy-current path. In some cases, even a solid shaft protruding from one side of a gear or disk can be used as one of the pole pieces.

Inspection of Steel Balls. Direct contact is not permitted during the inspection of hardened, finished steel balls for heat treating or grinding cracks, because of the highly polished surface finish. The discontinuities may be oriented in any direction, and 100% inspection of the balls is required. The induced-current method can provide the required inspection without damaging the surface finish. The L/D ratio of 1:1 for spheres is unfavorable for magnetization with a coil; therefore, laminated pole pieces are used on each side of the balls to provide a more favorable configuration for magnetizing. Because of the highly retentive nature of the material, residual magnetization with direct current and quick-break circuitry is used for magnetizing the balls. The smallness of the heat-treating or grinding cracks and the high surface finish dictate that the inspection medium be a highly oil-suspendible material.

Balls are inspected along the x -, y -, and z -axes in three separate operations. The operation for each axis consists of:

- An induced-current shot
- Bathing the ball with the wet-particle solution
- Inspection while rotating the ball 360°

Rotation and reorientation can be accomplished in a simple manually operated fixture, or the entire operation can be automated.

Magnetic Particle Inspection

Permeability of Magnetic Materials

The term permeability is used to refer to the ease with which a magnetic field or flux can be set up in a magnetic circuit. For a given material, it is not a constant value but a ratio. At any given value of magnetizing force, permeability, μ , is B/H , the ratio of flux density, B , to magnetizing force, H . Several permeabilities have been defined, but material permeability, maximum permeability, effective (apparent) permeability, and initial permeability are used with magnetic particle testing.

Material permeability is of interest in magnetic particle inspection with circular magnetization. Material permeability is the ratio of the flux density, B , to the magnetizing force, H , where the flux density and magnetizing force are measured when the flux path is entirely within the material. The magnetizing force and the flux density produced by that force are measured point by point for the entire magnetization curve with a fluxmeter and a prepared specimen of material.

Maximum Permeability. For magnetic particle inspection, the level of magnetization is generally chosen to be just below the knee of a normal magnetization curve for the specific material; the maximum material permeability occurs near this point. For most engineering steels, the maximum material permeability ranges from 0.06 to 0.25 T/A · m⁻¹ (500 to 2000 G/Oe) or more. The 500 value is for 400-series stainless steels. Specific permeability values for the various engineering materials are not readily available, but even if they were, they could be misleading. To a large extent, the numerous rules of thumb consider the variations in permeability, so that knowledge of permeability values is not a prerequisite for magnetic particle inspection.

Effective (apparent) permeability is the ratio of the flux density in the part to the magnetizing force, when the magnetizing force is measured at the same point in the absence of the part. Effective permeability is not solely a property of the material, but is largely governed by the shape of the part and is of prime importance for longitudinal magnetization.

Initial permeability is exhibited when both the flux density, B , and the magnetizing force, H , approach zero (Fig. 16a). With increasing magnetizing force, the magnetic field in the part increases along the virgin curve of the hysteresis loop.

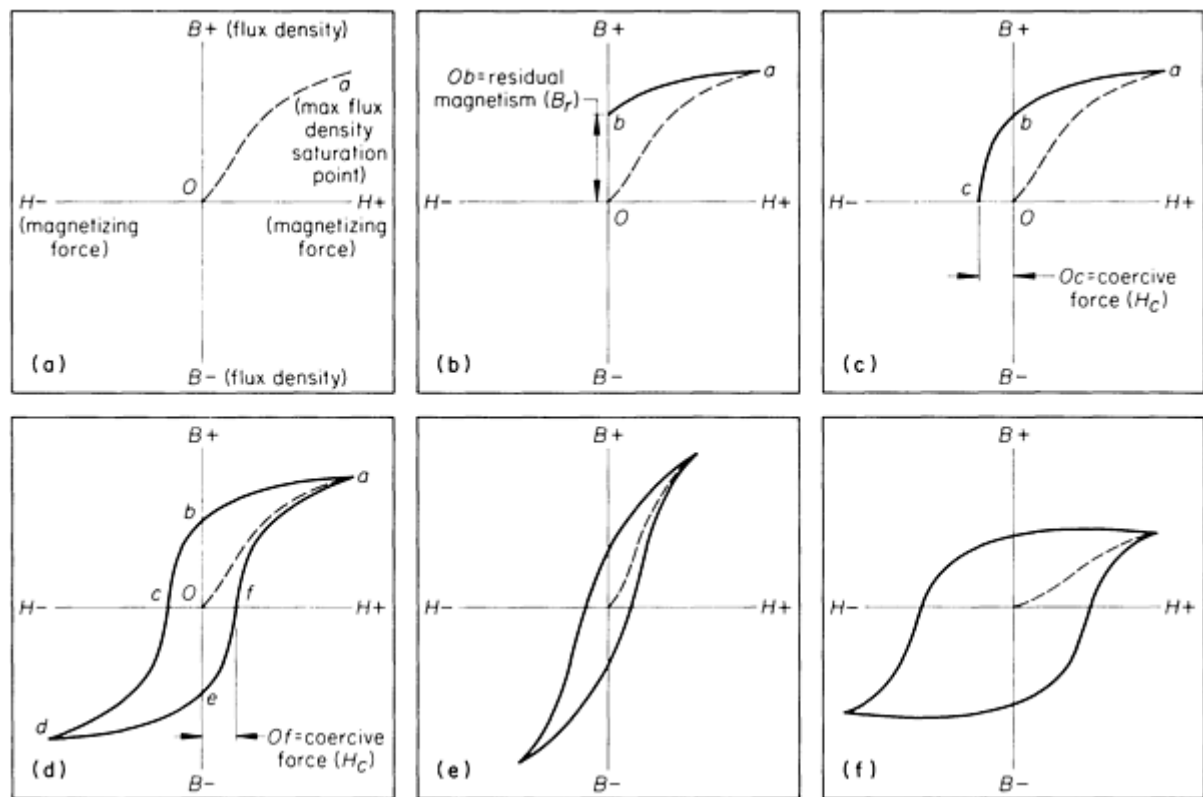

Fig. 16 Representative magnetization (hysteresis) curve for a ferromagnetic material. Dashed line in each of the charts is the virgin hysteresis curve. See text for discussion.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Magnetic Hysteresis

Some ferromagnetic materials, when magnetized by being introduced into an external field, do not return to a completely unmagnetized state when removed from that field. In fact, these materials must be subjected to a reversed field of a certain strength to demagnetize them (discounting heating the material to a characteristic temperature, called the Curie point, above which the ferromagnetic ordering of atomic moments is thermally destroyed, or mechanically working the material to reduce the magnetization). If an external field that can be varied in a controlled manner is applied to a completely demagnetized (virgin) specimen and if instrumentation for measuring the magnetic induction within the specimen is at hand, the magnetization curve of the material can be determined. A representative magnetization (hysteresis) curve for a ferromagnetic material is shown in Fig. 16.

As shown in Fig. 16(a), starting at the origin (O) with the specimen in the unmagnetized condition and increasing the magnetizing force in small increments, the flux in the material increases quite rapidly at first, then more slowly until it reaches a point beyond which any increase in the magnetizing force does not increase the flux density. This is shown by the dashed (virgin) curve Oa . In this condition, the specimen is said to be magnetically saturated.

When the magnetizing force is gradually reduced to zero, curve ab results (Fig. 16b). The amount of magnetism that the steel retains at point b is called residual magnetism, B_r .

When the magnetizing current is reversed and gradually increased in value, the flux continues to diminish. The flux does not become zero until point c is reached, at which time the magnetizing force is represented by Oc (Fig. 16c), which

graphically designates the coercive force, H_c , in the material. Ferromagnetic materials retain a certain amount of residual magnetism after being subjected to a magnetizing force. When the magnetic domains of a ferromagnetic material have been oriented by a magnetizing force, some domains remain so oriented until an additional force in the opposite direction causes them to return to their original random orientation. This force is commonly referred to as coercive force.

As the reversed field is increased beyond c , point d is reached (Fig. 16d). At this point, the specimen is again magnetically saturated. The magnetizing force is now decreased to zero, and the de line is formed and retains reversed-polarity residual magnetism, B_r , in the specimen. Further increasing the magnetizing force in the original direction completes the curve efa . The cycle is now complete, and the area within the loop $abcdefa$ is called the hysteresis curve.

The definite lag throughout the cycle between the magnetization force and the flux is called hysteresis. If the hysteresis loop is slender (Fig. 16e), the indication usually means that the material has low retentivity (low residual field) and is easy to magnetize (has low reluctance). A wide loop (Fig. 16f) indicates that the material has high reluctance and is difficult to magnetize.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Magnetic Particles and Suspending Liquids

Magnetic particles are classified according to the medium used to carry the particles to the part. The medium can be air (dry-particle method) or a liquid (wet-particle method). Magnetic particles can be made of any low-retentivity ferromagnetic material that is finely subdivided. The characteristics of this material, including magnetic properties, size, shape, density, mobility, and degree of visibility and contrast, vary over wide ranges for different applications.

Magnetic Properties. The particles used for magnetic particle inspection should have high magnetic permeability so that they can be readily magnetized by the low-level leakage fields that occur around discontinuities and can be drawn by these fields to the discontinuities themselves to form readable indications. The fields at very fine discontinuities are sometimes extremely weak.

Low coercive force and low retentivity are desirable for magnetic particles. If high in coercive force, wet particles become strongly magnetized and form an objectionable background. In addition, the particles will adhere to any steel in the tank or piping of the unit and cause heavy settling-out losses. Highly retentive wet particles tend to clump together quickly in large aggregates on the test surface. Excessively large clumps of particles have low mobility, and indications are distorted or obscured by the heavy, coarse-grain backgrounds.

Dry particles having coercive force and high retentivity would become magnetized during manufacture or in first use and would therefore become small, strong permanent magnets. Once magnetized, their control by the weak fields at discontinuities would be subdued by their tendency to stick magnetically to the test surface wherever they first touch. This would reduce the mobility of the powder and would form a high level of background, which would reduce contrast and make indications difficult to see.

Effect of Particle Size. Large, heavy particles are not likely to be arrested and held by weak fields when such particles are moving over a part surface, but fine particles will be held by very weak fields. However, extremely fine particles may also adhere to surface areas where there are no discontinuities (especially if the surface is rough) and form confusing backgrounds. Coarse dry particles fall too fast and are likely to bounce off the part surface without being attracted by the weak leakage fields at imperfections. Finer particles can adhere to fingerprints, rough surfaces, and soiled or damp areas, thus obscuring indications.

Magnetic particles for the wet method are applied as a suspension in some liquid medium, and particles much smaller than those for the dry method can be used. When such a suspension is applied over a surface, the liquid drains away, and the film remaining on the surface becomes thinner. Coarse particles would quickly become stranded and immobilized. The stranding of finer particles as a result of the draining away of the liquid occurs much later, giving these particles mobility for a sufficient period of time to be attracted by leakage fields and to accumulate and thus form true indications.

Effect of Particle Shape. Long, slender particles develop stronger polarity than globular particles. Because of the attraction exhibited by opposite poles, these tiny, slender particles, which have pronounced north and south poles, arrange themselves into strings more readily than globular particles. The ability of dry particles to flow freely and to form uniformly dispersed clouds of powder that will spread evenly over a surface is a necessary characteristic for rapid and effective dry-powder testing. Elongated particles tend to mat in the container and to be ejected in uneven clumps, but globular particles flow freely and smoothly under similar conditions. The greatest sensitivity for the formation of strong indications is provided by a blend of elongated and globular shapes.

Wet particles, because they are suspended in a liquid, move more slowly than do dry particles to accumulate in leakage fields. Although the wet particles themselves may be of any shape, they are fine and tend to agglomerate, or clump, into unfavorable shapes. These unfavorable shapes will line up into magnetically held elongated aggregates even when the leakage field is weak. This effect contributes to the relatively high sensitivity of fine wet particles.

Visibility and contrast are promoted by choosing particles with colors that are easy to see against the color of the surface of the part being inspected. The natural color of the metallic powders used in the dry method is silver-gray, but pigments are used to color the particles. The colors of particles for the wet method are limited to the black and red of the iron oxides commonly used as the base for wet particles.

For increased visibility, particles are coated with fluorescent pigment by the manufacturer. The search for indications is conducted in total or partial darkness, using ultraviolet light to activate the fluorescent dyes. Fluorescent magnetic particles are available for both the wet and dry methods, but fluorescent particles are more commonly used with the wet method.

Types of Magnetic Particles. The two primary types of particles for magnetic particle inspection are dry particles and wet particles, and each type is available in various colors and as fluorescent particles. Particle selection is principally influenced by:

- Location of the discontinuity, that is, on the surface or beneath the surface
- Size of the discontinuity, if on the surface
- Which type (wet or dry particles) is easier to apply

Dry particles, when used with direct current for magnetization, are superior for detecting discontinuities lying wholly below the surface. The use of alternating current with dry particles is excellent for revealing surface cracks that are not exceedingly fine, but is of little value for discontinuities even slightly beneath the surface (Fig. 17).

Fig. 17 Comparison of sensitivity of alternating current, direct current, direct current with surge, and half-wave current for locating defects at various distances below a surface by means of the dry-particle continuous magnetizing method. See text for description of test conditions.

Wet particles are better than dry particles for detecting very fine surface discontinuities regardless of which form of magnetizing current is used. Wet particles are often used with direct current to detect discontinuities that lie just beneath the surface. The surface of a part can easily be covered with a wet bath because the bath flows over and around surface contours. This is not easily accomplished with dry powders.

Colored particles are used to obtain maximum contrast with the surface of the part being inspected. Black stands out against most light-colored surfaces (Fig. 18), and gray against dark-colored surfaces. Red particles are more visible than black or gray particles against silvery and polished surfaces. Fluorescent particles, viewed under ultraviolet light, provide the highest contrast and visibility.

Fig. 18 Black magnetic-powder indications of a cold shut in a casting when seen under black light. Courtesy of Magnaflux Corporation

Dry particles are available with yellow, red, black, and gray pigmented coloring and with fluorescent coatings. The magnetic properties and particle sizes are similar in all colors, making them equally efficient. Dry particles are most sensitive for use on very rough surfaces and for detecting flaws beneath the surface. They are ordinarily used with portable equipment. The reclamation and reuse of dry particles is not recommended.

Air is used to carry the particles to the surface of the part, and care must be taken to apply the particles correctly. Dry powders should be applied in such a way that they reach the magnetized surface in a uniform cloud with a minimum of motion. When this is done, the particles come under the influence of the leakage fields while suspended in air and have three-dimensional mobility. This condition can be best achieved when the magnetized surface is vertical or overhead. When particles are applied to a horizontal or sloping surface, they settle directly to the surface and do not have the same degree of mobility.

Dry powders can be applied with small rubber spray bulbs or specially designed mechanical powder blowers. The air stream of such a blower is of low velocity so that a cloud of powder is applied to the test area. Mechanical blowers can also deliver a light stream of air for the gentle removal of excess powder. Powder that is forcibly applied is not free to be

attracted by leakage fields. Neither rolling a magnetized part in powder nor pouring the powder on the part is recommended.

Wet particles are best suited for the detection of fine discontinuities such as fatigue cracks. Wet particles are commonly used in stationary equipment where the bath can remain in use until contaminated. They are also used in field operations with portable equipment, but care must be taken to agitate the bath constantly.

Wet particles are available in red and black colors or as fluorescent particles that fluoresce a blue-green or a bright yellow-green color. The particles are supplied in the form of a paste or other type of concentrate that is suspended in a liquid to produce the coating bath.

The liquid bath may be either water or a light petroleum distillate having specific properties. Both require conditioners to maintain proper dispersion of the particles and to allow the particles the freedom of movement to form indications on the surfaces of parts. These conditioners are usually incorporated in the powder concentrates.

Oil Suspending Liquid. The oil used as a suspending liquid for magnetic particles should be an odorless, well-refined light petroleum distillate of low viscosity having a low sulfur content and a high flash point. The viscosity of the oil should not exceed $3 \times 10^{-6} \text{ m}^2/\text{s}$ (3 cSt) as tested at 40 °C (100 °F) and must not exceed $5 \times 10^{-6} \text{ m}^2/\text{s}$ (5 cSt) when tested at the bath temperature. Above $5 \times 10^{-6} \text{ m}^2/\text{s}$ (5 cSt), the movement of the magnetic particles in the bath is sufficiently retarded to have a definite effect in reducing buildup, and therefore the visibility, of an indication of a small discontinuity. Parts should be precleaned to remove oil and grease because oil from the surface accumulates in the bath and increases its viscosity.

Water Suspending Liquid. The use of water instead of oil for magnetic particle wet-method baths reduces costs and eliminates bath flammability. Figures 19, 20, 21, and 22 illustrate the effectiveness of water-base magnetic particle testing. Water-suspendible particle concentrates include the necessary wetting agents, dispersing agents, rust inhibitors, and antifoam agents.

Fig. 22 Defects in the leading edge and fillet areas of a hydroplane propeller as revealed by water-base

magnetic particle testing. (a) Overall view. (b) Close-up of fillet area. Courtesy of Circle Chemical Company

Water baths ordinarily should not be used where the temperature is below freezing. However, ethylene glycol can be employed to protect against reasonably low temperatures. Care must be exercised, however, because a high percentage of ethylene glycol can impede particle mobility. For the inspection of large billets, a solution containing three parts water and one part anti-freeze has been successfully used.

Because water is a conductor of electricity, units in which water is to be used must be designed to isolate all high-voltage circuits so as to avoid all possibility of operator shock, and the equipment must be thoroughly and positively grounded. Also, electrolysis of parts of the unit can occur if preventive measures are not taken. Units specifically designed to be used with water as a suspensoid are safe for the operator and minimize electrolytic corrosion.

The strength of the bath is a major factor in determining the quality of the indications obtained. The proportion of magnetic particles in the bath must be maintained at a uniform level. If the concentration varies, the strength of the indications will also vary, and the indications may be misinterpreted. Fine indications may be missed entirely with a weak bath. Too heavy a concentration of particles gives a confusing background and excessive adherence of particles at external poles, thus interfering with clean-cut indications of extremely fine discontinuities.

The best method for ensuring optimum bath concentration for any given combination of equipment, bath application, type of part, and discontinuities sought is to test the bath using parts with known discontinuities. Bath strength can be adjusted until satisfactory indications are obtained. This bath concentration can then be adopted as standard for those conditions.

The concentration of the bath can be measured with reasonable accuracy with the settling test. In this test, 100 mL (3.4 oz) of well-agitated bath is placed in a pear-shaped centrifuge tube. The volume of solid material that settles out after a predetermined interval (usually 30 min) is read on the graduated cylindrical part of the tube. Dirt in the bath will also settle and usually shows as a separate layer on top of the oxide. The layer of dirt is usually easily discernible because it is different in color from the magnetic particles.

Magnetic Particle Inspection

Ultraviolet Light

A mercury-arc lamp is a convenient source of ultraviolet light. This type of lamp emits light whose spectrum has several intensity peaks within a wide band of wave-lengths. When used for a specific purpose, emitted light is passed through a suitable filter so that only a relatively narrow band of ultraviolet wavelengths is available. For example, a band in the long-wave ultraviolet spectrum is used for fluorescent liquid penetrant or magnetic particle inspection.

Fluorescence is the characteristic of an element or combination of elements to absorb the energy of light at one frequency and emit light of a different frequency. The fluorescent materials used in liquid penetrant and magnetic particle inspection are combinations of elements chosen to absorb light in the peak energy band of the mercury-arc lamp fitted with a Kopp glass filter. This peak occurs at about 365 nm (3650 Å). The ability of fluorescent materials to emit light in the greenish-yellow wavelengths of the visible spectrum depends on the intensity of ultraviolet light at the workpiece surface. In contrast to the harmful ultraviolet light of shorter wavelengths, which damages organs such as the eyes and the skin, the black light of 365 nm (3650 Å) wavelengths poses no such hazards to the operator and provides visible evidence of defects in materials, as shown in Fig. 23, 24, 25, 26, 27, and 28.

Early specifications required 970 lx (90 ftc) of illumination at the workpiece surface measured with a photographic-type light meter, which responds to white light as well as ultraviolet light. Because the ultraviolet output of a mercury-arc lamp decreases with age and with hours of service, the required intensity of the desired wavelength is often absent, although the light meter indicates otherwise. Meters have been developed that measure the overall intensity of long-wave ultraviolet light only in a band between 300 to 400 nm (3000 to 4000 Å) and that are most sensitive near the peak energy band of the mercury-arc lamp used for fluorescent inspection. These meters read the intensity level in microwatts per square centimeter ($\mu\text{W}/\text{cm}^2$). For aircraft-quality fluorescent inspection, the minimum intensity level of ultraviolet illumination is $1000 \mu\text{W}/\text{cm}^2$. High-intensity 125-W ultraviolet bulbs are available that provide up to $5000 \mu\text{W}/\text{cm}^2$ at 380 mm (15 in.).

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Nomenclature Used in Magnetic Particle Inspection

An indication is an accumulation of magnetic particles on the surface of the part that forms during inspection.

Relevant indications are the result of errors made during or after metal processing. They may or may not be considered defects.

A nonrelevant indication is one that is caused by flux leakage. This type of indication is usually weak and has no relation to a discontinuity that is considered to be a defect. Examples are magnetic writing, change in section due to part design, or a heat affected zone line in welding.

False indications are those in which the particle patterns are held by gravity or surface roughness. No magnetic attraction is involved.

A discontinuity is any interruption in the normal physical configuration or composition of a part. It may not be a defect.

A defect is any discontinuity that interferes with the utility or service of a part.

Interpretation consists of determining the probable cause of an indication, and assigning it a discontinuity name or label.

Evaluation involves determining whether an indication will be detrimental to the service of a part. It is a judgement based on a well-defined accept/reject standard that may be either written or verbal.

Magnetic Particle Inspection

Detectable Discontinuities

The usefulness of magnetic particle inspection in the search for discontinuities or imperfections depends on the types of discontinuities the method is capable of finding. Of importance are the size, shape, orientation, and location of the discontinuity with respect to its ability to produce leakage fields.

Surface Discontinuities. The largest and most important category of discontinuity consists of those that are exposed to the surface. Surface cracks or discontinuities are effectively located with magnetic particles. Surface cracks are also more detrimental to the service life of a component than are subsurface discontinuities, and as a result they are more frequently the object of inspection.

Magnetic particle inspection is capable of locating seams, laps, quenching and grinding cracks, and surface ruptures in castings, forgings, and weldments. The method will also detect surface fatigue cracks developed during service. Magnetizing and particle application methods may be critical in certain cases, but in most applications the requirements are relatively easily met because leakage fields are usually strong and highly localized.

For the successful detection of a discontinuity, there must be a field of sufficient strength oriented in a generally favorable direction to produce strong leakage fields. For maximum detectability, the field set up in the part should be at right angles to the length of a suspected discontinuity (Fig. 3 and 4). This is especially true if the discontinuity is small and fine. The characteristics of a discontinuity that enhance its detection are:

- Its depth is at right angles to the surface
- Its width at the surface is small, so that the air gap it creates is small
- Its length at the surface is large with respect to its width
- It is comparatively deep in proportion to the width of its surface opening

Many incipient fatigue cracks and fine grinding cracks are less than 0.025 mm (0.001 in.) deep and have surface openings of perhaps one-tenth that or less. Such cracks are readily located using wet-method magnetic particle inspection. The depth of the crack has a pronounced effect on its detectability; the deeper the crack, the stronger the indication for a given level of magnetization. This is because the stronger leakage flux causes greater distortion of the field in the part.

However, this effect is not particularly noticeable beyond perhaps 6.4 mm ($\frac{1}{4}$ in.) in depth. If the crack is not close-lipped but wide open at the surface, the reluctance (opposition to the establishment of magnetic flux in a magnetic circuit) of the resulting longer air gap reduces the strength of the leakage field. This, combined with the inability of the particles to bridge the gap, usually results in a weaker indication.

Detectability generally involves a relationship between surface opening and depth. A surface scratch, which may be as wide at the surface as it is deep, usually does not produce a magnetic particle pattern, although it may do so at high levels of magnetization. Because of many variables, it is not possible to establish any exact values for this relationship, but in general a surface discontinuity whose depth is at least five times its opening at the surface will be detectable.

There are also limitations at the other extreme. For example, if the faces of a crack are tightly forced together by compressive stresses, the almost complete absence of an air gap may produce so little leakage field that no particle indication is formed. Shallow cracks produced in grinding or heat treating and subsequently subjected to strong compression by thermal or other stresses usually produce no magnetic particle indications. Sometimes, with careful, maximum-sensitivity techniques, faint indications of such cracks can be produced.

One other type of discontinuity that sometimes approaches the lower limit of detectability is a forging or rolling lap that, although open to the surface, emerges at an acute angle. In this case, the leakage field produced may be quite weak because of the small angle of emergence and the resultant relatively high reluctance of the actual air gap; consequently, very little leakage flux takes the path out through the surface lip of the lap to cross this high reluctance gap. When laps are being sought (usually when newly forged parts are being inspected), high-sensitivity, such as combining dc magnetizing with the wet fluorescent method, is desirable. Figure 29 shows two indications of forging laps in a 1045 steel crane hook.

Fig. 29 1045 steel crane hook showing indications of forging laps of the type revealed by magnetic particle inspection. Dimensions given in inches

A seam that was found during the magnetic particle inspection of a forged crane hook is shown in Fig. 30. The seam was present in the material before the hook was forged. The cold shut shown in Fig. 31 was found in the flange of a cast drum after machining. A faint indication was noted in the rough casting, but the size of the cold shut was not known until after machining of the drum.

Fig. 30 Magnetic particle indications of a seam (at arrow) in the shank of a forged crane hook

Fig. 31 Cold shut (at arrow) in the flange of a machined cast drum. Magnetic particle inspection revealed faint indications of the cold shut in the rough casting.

The magnetic particle inspection of a 460 mm (18 in.) diam internally splined coupling revealed the indications shown in Fig. 32, one of which was along the fusion zone of a repair weld. Routine magnetic particle inspection of a 1.2 m (4 ft) diam weldment revealed cracks in the weld between the rim and web, as shown in Fig. 33.

Fig. 32 Magnetic particle indications of cracks in a large cast splined coupling. Indication (at arrow) in photo at right is along the fusion zone of a repair weld.

Fig. 33 Indications of cracks (at arrows) in the weld between the web and rim of a 1.2 m (4 ft) diam weldment

Internal Discontinuities. The magnetic particle method is capable of indicating the presence of many discontinuities that do not break the surface. Although radiography and ultrasonic methods are inherently better for locating internal

discontinuities, sometimes the shape of the part, the location of the discontinuity, or the cost or availability of the equipment needed makes the magnetic particle method more suitable. The internal discontinuities that can be detected by magnetic particle inspection can be divided into two groups:

- Subsurface discontinuities (those lying just beneath the surface of the part)
- Deep-lying discontinuities

Subsurface discontinuities comprise those voids or nonmetallic inclusions that lie just beneath the surface. Nonmetallic inclusions are present in all steel products to some degree. They occur as scattered individual inclusions, or they may be aligned in long stringers. These discontinuities are usually very small and cannot be detected unless they lie very close to the surface, because they produce highly localized but rather weak fields.

Deep-lying discontinuities in weldments may be caused by inadequate joint penetration, subsurface incomplete fusion, or cracks in weld beads beneath the last weld bead applied. In castings, they result from internal shrinkage cavities, slag inclusions, or gas pockets. The depth to which magnetic particle testing can reach in locating internal discontinuities cannot be established in millimeters, because the size and shape of the discontinuity itself in relation to the size of the part in which it occurs is a controlling factor. Therefore, the deeper the discontinuity lies within a section, the larger it must be to be detected by magnetic particle inspection.

In considering the detectability of a discontinuity lying below the surface, of primary concern are the projected area presented as an obstruction to the lines of force and the sharpness of the distortion of the field produced. It is helpful to think of the magnetic field as flowing through the specimen like a stream of water. A coin, on edge below the surface and at right angles to the surface and flow, would cause a sharp disturbance in the movement of the water, but a straight round stick placed at a similar depth and parallel to the direction of flow would have very little effect. A ball or marble of the same size as the coin would present the same projected area, but would be much less likely to be detected than the coin because the flow lines would be streamlines around the sphere and the disturbance created in the field would be much less sharp.

The orientation of the discontinuity is another factor in detection. The coin-shaped obstruction discussed above was considered to be 90° to the direction of the flux. If the same discontinuity were inclined, either vertically or horizontally, at an angle of only 60 or 70°, there would be a noticeable difference in the amount of leakage field and therefore in the strength of the indication. This difference would result not only because the projected area would be reduced but also because of a streamlining effect, as with the sphere.

The strength and direction of the magnetic field are also important in the detection of deep-lying discontinuities. Direct current yokes are effective if the discontinuity is close to the surface. Prod magnetization using direct current or half-wave current is more effective for discontinuities deeper in the part.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Nonrelevant Indications

Nonrelevant indications are true patterns caused by leakage fields that do not result from the presence of flaws. Nonrelevant indications have several possible causes and therefore require evaluation, but they should not be interpreted as flaws.

Sources of Nonrelevant Indications

Particle patterns that yield nonrelevant indications can be the result of design, fabrication, or other causes and do not imply a condition that reduces the strength or utility of the part. Because nonrelevant indications are true particle buildups, they are difficult to distinguish from buildups caused by flaws. Therefore, the investigator must be aware of design and fabrication conditions that would contribute to or cause nonrelevant indications.

Particle Adherence Due to Excessive Magnetizing Force. One type of nonrelevant indication is that caused by particle adherence at leakage fields around sharp corners, ridges, or other surface irregularities when magnetized longitudinally with too strong a magnetizing force. The use of too strong a current with circular magnetization can produce indications of the flux lines of the external field. Both of the above phenomena (excessive magnetizing force or excessive current) are clearly recognized by experienced operators and can be eliminated by a reduction in the applied magnetizing force.

Mill Scale. Tightly adhering mill scale will cause particle buildup, not only because of mechanical adherence but also because of the difference in magnetic permeability between the steel and the scale. In most cases, this can be detected visually, and additional cleaning followed by retesting will confirm the absence of a true discontinuity.

Configurations that result in a restriction of the magnetic field are a cause of nonrelevant indications. Typical restrictive configurations are internal notches such as splines, threads, grooves for indexing, or keyways.

Abrupt changes in magnetic properties, such as those between weld metal and base metal or between dissimilar base metals, result in nonrelevant indications. Depending on the degree of change in the magnetic property, the particle pattern may consist of loosely adhering particles or may be strong and well defined. Again, it is necessary for the investigator to be aware of such conditions.

Magnetized writing is another form of nonrelevant indication. Magnetic writing is usually associated with parts displaying good residual characteristics in the magnetized state. If such a part is contacted with a sharp edge of another (preferably magnetically soft) part, the residual field is locally reoriented, giving rise to a leakage field and consequently a magnetic particle indication. For example, the point of a common nail can be used to write on a part susceptible to magnetic writing. Magnetic writing is not always easy to interpret, because the particles are loosely held and are fuzzy or intermittent in appearance. If magnetic writing is suspected, it is only necessary to demagnetize the parts and retest. If the indication was magnetic writing, it will not reappear.

Additional Sources. Some other conditions that cause nonrelevant indications are brazed joints, voids in fitted parts, and large grains.

Distinguishing Relevant From Nonrelevant Indications

There are several techniques for differentiating between relevant and nonrelevant indications:

- Where mill scale or surface roughness is the probable cause, close visual inspection of the surface in the area of the discontinuity and use of magnification up to ten diameters
- Study of a sketch or drawing of the part being tested to assist in locating welds, changes in section, or shape constrictions
- Demagnetization and retesting
- Careful analysis of the particle pattern. The particle pattern typical of nonrelevant indications is usually wide, loose, and lightly adhering and is easily removable even during continuous magnetization
- Use of another method of nondestructive inspection, such as ultrasonic testing or radiography, to verify the presence of a subsurface defect

The following two examples illustrate how nonrelevant indications are used in nondestructive testing to verify product quality.

Example 1: Nonrelevant Indications in Electric Motor Rotors.

An instance where nonrelevant indications are used to advantage is in the inspection of rotors for squirrel cage electric motors. These rotors are usually fabricated from laminations made of magnetic material. The conductor-bar holes are aligned during assembly of the laminations. The end rings and conductor bars are cast from an aluminum alloy in a single operation. The integrity of the internal cast aluminum alloy conductor bars must be checked to ensure that each is capable of carrying the required electrical current; voids and internal porosity would impair their electrical properties.

These rotors are tested by clamping them between the heads of a horizontal unit and processing them by the continuous method using wet magnetic particles. The end rings distribute the magnetizing current through each of the conductor bars, which constitute parallel paths. All conductor bars that are sound and continuous produce broad, pronounced, subsurface-type indications on the outside surface of the rotor. The absence of such indications is evidence that the conductor bar is discontinuous or that its current-carrying capacity is greatly impaired. This is a direct departure from the customary inspection logic in that negative results, or the absence of indications, are indicative of defects.

Example 2: Nonrelevant Indications Present in Welding A537 Grade 2 Carbon Steel With E8018-C1 Weld Wire.

Linear magnetic particle indications have frequently been observed in the heat-affected zone of A537 grade 2 (quenched-and-tempered) materials joined with E8018-C1 ($2\frac{1}{2}\%$ Ni) weld wire. However, when liquid penetrant examinations of these areas are performed, no indications are apparent.

Four types of welds were used in the investigation:

- *Weld A*: a T-joint with fillet welds on both sides (Fig. 34)
- *Weld B*: a butt weld (Fig. 35)
- *Weld C*: a pickup simulating a repair where a fit-up device had been torn off (Fig. 36)
- *Weld D*: a T-joint with fillet welds on both sides, one of which contained a longitudinal crack (Fig. 37)

The fourth sample was made in such a manner that it would contain a linear discontinuity in or near the heat-affected zone. Examination with magnetic particle and liquid penetrant inspection methods yielded the following results:

- *Weld A*: Magnetic particle inspection showed loosely held, slightly fuzzy linear indications at the toes of the fillet, with the bottom edge showing the strongest pattern due to gravity and the configuration. The liquid penetrant examination produced no relevant indications. The etched cross section revealed no discontinuities
- *Weld B*: Magnetic particle inspection showed loosely held, slightly fuzzy linear indications along both edges of the butt weld. The liquid penetrant examination produced no relevant indications. The etched cross section revealed no discontinuities
- *Weld C*: Magnetic particle inspection showed a very loosely held, fuzzy pattern over the entire pickup weld. The liquid penetrant examination produced no relevant indications. The etched cross section revealed only a minor slag inclusion, which had no bearing on the magnetic particle pattern produced
- *Weld D*: Magnetic particle inspection showed a tightly held, sharply defined linear indication along one edge of the fillet with connecting small, transverse linear indications at various locations. The liquid penetrant examination in this case produced the same pattern of indications. The etched cross section revealed a crack completely through the toe of one leg of the fillet

Weld C, shown in cross section (a), was checked using both the (b) liquid penetrant inspection method and the (c) magnetic particle inspection method. See text for discussion. Courtesy of Chicago Bridge & Iron Company

Fig. 37 T-joint weld of A537 grade 2 (quenched and tempered) material joined with E8018-C1 (2.5% Ni) weld wire showing a longitudinal crack in one of the fillet welds (arrow in cross section) made visible by linear magnetic particle indications. Weld D, shown in cross section (a), was checked using both the (b) liquid penetrant inspection method and the (c) magnetic particle inspection method. See text for discussion. Courtesy

The difference in magnetic properties between this parent material and the weld metal creates magnetic leakage fields in the heat-affected zone or metallic interface of these materials during a magnetic particle inspection. This can result in magnetic particle indications in the heat-affected zone along the toe of the fillets, along the edges of butt welds, or over entire shallow pickup welds. The magnetic particle indications produced by metallic interface leakage fields are readily distinguished from indications caused by real discontinuities by their characteristic of being loosely held and slightly fuzzy in appearance and by their location in or at the edge of the heat-affected zone.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

General Procedures for Magnetic Particle Inspection

In magnetic particle inspection, there are many variations in procedure that critically affect the results obtained. These variations are necessary because of the many types of discontinuities that are sought and the many types of ferromagnetic materials in which these discontinuities must be detected.

Establishing a set of procedures for the magnetic particle inspection of a specific part requires that the part be carefully analyzed to determine how its size and shape will affect the test results. The magnetic characteristics of the material and the size, shape, location, and direction of the expected discontinuity also affect the possible variations in the procedure. The items that must be considered in establishing a set of procedures for the magnetic particle inspection of a specific part include:

- Type of current
- Type of magnetic particles
- Method of magnetization
- Direction of magnetization
- Magnitude of applied current
- Equipment

Type of Current

The electric current used can be either alternating current or some form of direct current. This choice depends on whether the discontinuities are surface or subsurface and, if subsurface, on the distance below the surface.

Alternating Current. The skin effect of alternating current at 50 or 60 Hz limits its use to the detection of discontinuities that are open to the surface or that are only a few thousandths of an inch below the surface. With alternating current at lower frequencies, the skin effect is less pronounced, resulting in deeper penetration of the lines of force.

The rapid reversal of the magnetic field set up by alternating current imparts mobility to dry particles. Agitation of the powder helps it move to the area of leakage fields and to form stronger indications.

The strength of magnetization, which is determined by the value of the peak current at the top of the sine wave of the cycle, is 1.41 times that of the current indicated on the meter. Alternating current meters indicate more nearly the average current for the cycle than the peak value. Obtaining an equivalent magnetizing effect from straight direct current requires more power and heavier equipment.

Direct current, on the other hand, magnetizes the entire cross section more or less uniformly in a longitudinal direction, and with a straight-line gradient of strength from a maximum at the surface to zero at the center of a bar in the case of circular magnetization. This effect is demonstrated in Fig. 8(a) and 8(b).

Alternating Current Versus Direct Current. In an experiment designed to compare the effectiveness of 60-Hz alternating current and three types of direct current, 12 holes representing artificial defects were drilled in a 127 mm (5 in.) OD by 32 mm ($1\frac{1}{4}$ in.) ID by 22 mm ($\frac{7}{8}$ in.) thick ring made of unhardened O1 tool steel (0.40% C). The 12 holes, 1.8 mm (0.07 in.) in diameter and spaced 19 mm ($\frac{3}{4}$ in.) apart, were drilled through the ring parallel to the cylindrical surface at increasing distances from that surface. The centerline distances ranged from 1.8 to 21.3 mm (0.07 to 0.84 in.), in increments of 1.8 mm (0.07 in.). A central conductor, dry magnetic particles, and continuous magnetization were used for this test. The three types of direct current were straight direct current from batteries, three-phase rectified alternating current with surge, and half-wave rectified single-phase 60-Hz alternating current. The threshold values of current necessary to give readable indications of the holes in the ring are plotted in Fig. 17.

Current levels as read on the usual meters were varied from the minimum needed to indicate hole 1 (1.8 mm, or 0.07 in., below the surface) for each type of current, up to a maximum of over 1000 A. To produce an indication at hole 1 using alternating current, about 475 A was required, and at hole 2 (3.56 mm, or 0.14 in., below the surface), over 1000 A. Hole 3 (5.33 mm, or 0.21 in., below the surface) could not be revealed with alternating current at any current level available. Indications at hole 2 were produced using 450-A straight direct current, 320-A direct current preceded by a surge of twice that amperage, and 250-A half-wave current. Indications were produced at hole 12 (21.3 mm, or 0.84 in., below the surface) using 750-A half-wave current, while 975-A straight direct current was required for hole 10 (17.8 mm, or 0.70 in., below the surface).

The current levels needed to produce indications using wet particles were somewhat higher. For example, an indication for hole 1 using direct current and wet particles required approximately 440 A, and for hole 3, approximately 910 A. Over 625 A was required to detect hole 1 using alternating current and wet particles.

The hardness of the testpiece also had an effect on the current level needed to produce indications. At a hardness of 63 HRC, to produce an indication at hole 1, approximately 200 A of half-wave current, 300 A of direct current with surge, and 450 A of direct current were needed. For hole 3, the current levels needed for the three types of current were approximately 1300, 1875, and 2700 A, respectively. Tests similar to the one described above have been performed on ring specimens made of 1020 and 4130 steels (Ref 1).

For the inspection of finished parts such as machined and ground shafts, cams, and gears of precision machinery, direct current is frequently used. Alternating current is used for detecting fine cracks that actually break the surface, but direct current is better for locating very fine nonmetallic stringers lying just beneath the surface.

Method of Magnetization

The method of magnetization refers to whether residual magnetism in the part provides a leakage field strong enough to produce readable indications when particles are applied or if the part must be continuously magnetized while the particles are applied.

Residual Magnetism. The procedure for magnetic particle inspection with residual magnetism, using either wet or dry particles, basically consists of two steps: establishing a magnetic field in the part and subsequently applying the magnetic particles. The method can be used only on parts made of metals having sufficient retentivity. The residual magnetic field must be strong enough to produce leakage fields at discontinuities that in turn produce readable indications. This method is reliable only for detecting surface discontinuities.

Either the dry or the wet method of applying particles can be used with residual magnetization. With the wet method, the magnetized parts can either be immersed in a gently agitated bath of suspended metallic particles or flooded by a curtain spray. The time of immersion of the part in the bath can affect the strength of the indications. By leaving the magnetized part in the bath or under the spray for a considerable time, the leakage fields, even at fine discontinuities, can have time to attract and hold the maximum number of particles. The location of the discontinuity on the part as it is immersed has an effect on particle buildup. Buildup will be greatest on horizontal upper surfaces and will be less on vertical surfaces and horizontal lower surfaces. Parts should be removed from the bath slowly because rapid removal can wash off indications held by weak leakage fields.

Continuous Magnetism. In the continuous method, parts are continuously magnetized while magnetic particles are applied to the surfaces being inspected. In the dry-particle continuous method, care must be taken not to blow away

indications held by weak leakage fields. For this reason, the magnetizing current is left on during the removal of excess particles.

In the wet-particle continuous method, the liquid suspension containing the magnetic particles is applied to the part, and the magnetizing current is applied simultaneously with completion of particle application. This prevents washing away of indications held by weak leakage fields. For reliability of results, the wet continuous method requires more attention to timing and greater alertness on the part of the operator than the wet residual method.

The continuous method can be used on any metal that can be magnetized because in this method residual magnetism and retentivity are not as important in producing a leakage field at a discontinuity. This method is mandatory for inspection of low-carbon steels or iron having little or no retentivity. It is frequently used with alternating current on such metals because the ac field produces excellent mobility of dry magnetic particles. Maximum sensitivity for the detection of very fine discontinuities is achieved by immersing the part in a wet-particle bath, passing the magnetizing current through the part for a short time during immersion, and leaving the current on as the part is removed and while the bath drains from the surface.

Direction of Magnetization

The shape and orientation of the suspected discontinuity in relation to the shape and principal axis of the part have a bearing on whether the part should be magnetized in a circular or a longitudinal direction or in both directions. The rule of thumb is that the current must be passed in a direction parallel to the discontinuity. If the principal direction of the discontinuities is unknown, to detect all discontinuities, both circular and longitudinal magnetization must be used; with the prod and yoke methods, the prods or yoke must be repositioned at 90° from the first magnetizing position. The magnetic particle background held on a part by extraneous leakage fields is minimized when using the circular method of magnetizing because the field generally is self-contained within the part.

Magnitude of Applied Current

The amount of magnetized current or the number of ampere-turns needed for optimum results is governed by the types and minimum dimensions of the discontinuities that must be located or by the types and sizes of discontinuities that can be tolerated.

The amount of current for longitudinal magnetization with a coil is initially determined by Eq 1 and 2. For circular magnetization, when magnetizing by passing current directly through a part, the current should range from 12 to 31 A/mm (300 to 800 A/in.) of the diameter of the part. The diameter is defined as the largest distance between any two points on the outside circumference of the part. Normally, the current used should be 20 A/mm (500 A/in.) or lower, with the higher current values of up to 31 A/mm (800 A/in.) used to inspect for inclusions or to inspect alloys such as precipitation-hardened steels. The prod method of magnetization usually requires 4 to 4.92 A/mm (100 to 125 A/in.) of prod spacing. Prod spacing should not be less than 50 mm (2 in.) nor more than 203 mm (8 in.).

Equipment

Selection of equipment for magnetic particle inspection depends on the size, shape, number, and variety of parts to be tested.

Bench Units. For the production inspection of numerous parts that are relatively small but not necessarily identical in shape, a bench unit with contact heads for circular magnetization, as well as a built-in coil for longitudinal magnetization, is commonly used (Fig. 11).

Portable units using prods, yokes, or hand-wrapped coils may be most convenient for large parts. Half-wave current and dry particles are often used with portable equipment. Wet particles can be used with portable equipment, but the bath is usually not recovered.

Mass Production Machinery. For large lots of identical or closely similar parts, single-purpose magnetization-and-inspection units or fixtures on multiple-purpose units can be used.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Inspection of Hollow Cylindrical Parts

Some hollow cylindrical parts requiring magnetic particle inspection present difficulties in processing because of configuration, extraneous leakage field interference, requirements for noncontact of magnetizing units, the overall time required, or low L/D ratio. Techniques for inspecting long pieces of seamless tubing (oil well tubing), butt-welded and longitudinally welded carbon steel pipe or tubing, and a cylinder with a closed end are described in the following sections.

Oil well tubing is made of high-strength steel using hot finishing operations and has upset ends for special threading. The discontinuities most expected are longitudinally oriented on the main body of the tube and transversely oriented on the upset ends. For these reasons, the entire length of the tube is circularly magnetized and inspected for longitudinal-type discontinuities. Also, the upset ends are longitudinally magnetized and inspected for transverse-type discontinuities. Tube sections are usually more than 6 m (20 ft) long.

An insulated central conductor is used to introduce circular magnetism instead of passing the current through the material by head contacts. The central conductor facilitates inspection of the inside surface of the upset ends; the direct-contact method would not provide the required field.

The central-conductor technique used for circumferential magnetization of the tube body is illustrated in Fig. 38(a). The magnetic particles are applied to the outside surface of the tube. The residual-magnetism technique is used. The current density for this test is usually 31 to 39 A/mm (800 to 1000 A/in.) of tube diameter.

Fig. 38 Magnetic particle inspection of oil well tubing for longitudinal (a) and circumferential (b) discontinuities

The encircling-coil technique used to magnetize the upset ends in the longitudinal direction is shown in Fig. 38(b). The residual-magnetism technique is used. Both the inside and outside surfaces are inspected for discontinuities.

Welds in Carbon Steel Pipe. Magnetic particle inspection using the prod technique is a reliable method of detecting discontinuities in consumable-insert root welds and final welds in carbon steel pipe up to 75 mm (3 in.) in nominal diameter. (For larger-diameter pipe, less time-consuming magnetic particle techniques can be used.) The types of discontinuities found in root welds are shown in Fig. 39(a), and those found in final welds are shown in Fig. 39(b).

Fig. 39 Magnetic particle inspection for detection of discontinuities in consumable-insert root welds and final welds in carbon steel pipe. Dimensions given in inches

Placement of the prods is important to ensure reliable inspection of the welds. Circular magnetization, used to check for longitudinal discontinuities, is accomplished by placing the prods at 90° intervals (four prod placements) around the pipe, as shown in Fig. 39(c). For pipes larger than 25 mm (1 in.) in nominal diameter, prods should be spaced around the pipe at approximately 50 mm (2 in.) intervals, as shown in Fig. 39(e). Circumferentially oriented discontinuities are revealed by placing the prods as shown in Fig. 39(d). The prods are placed adjacent to and on opposite sides of the weld bead to ensure flux flow across the weld metal. If the circumferential distance between the prods is greater than 75 mm (3 in.) when positioned as shown in Fig. 39(d), the prods should be positioned as shown in Fig. 39(f). To ensure proper magnetization, the areas inspected should overlap approximately 25 mm (1 in.). Magnetic particles are applied to the weld area while the current is on because of the low retentivity of carbon steel.

A buildup of magnetic particles in the fusion-line crevice of the weld is indicative of either a subsurface discontinuity or a nonrelevant indication because of the abrupt change in material thickness and/or the crevelike depression between the weld metal and the base metal. However, a true indication, as from incomplete fusion between the weld metal and the base metal, would be a sharply defined particle pattern. This pattern would be difficult if not impossible to remove by blowing with a hand-held powder blower while the magnetizing current is being applied. If the indication at the fusion zone can be blown away with a hand-held powder blower, the indication is nonrelevant. The current used is approximately 3.9 A/mm (100 A/in.) of prod spacing.

Hollow cylinders closed at one end, such as drawn shells or forged fluid-power cylinders, can be magnetized circumferentially for the inspection of longitudinal discontinuities using a head shot end-to-end. However, this technique does not provide sensitivity for discontinuities on the inside surface.

As shown in Fig. 40, a central conductor can be used in such a manner that the closed end of the cylinder completes the current path. Also, the open end of the cylinder is accessible for the application of a wet-particle bath to the inside surface, which can then be inspected directly. For thin-wall cylinders, discontinuities on the inside surface produce subsurface-type indications on the outside surface. The central-conductor method for magnetization is advantageous when the inside diameter is too small to permit direct internal viewing.

Fig. 40 Use of a central conductor for the magnetic particle testing of a cylinder with one end closed

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Inspection of Castings and Forgings

Castings and forgings may be difficult to inspect because of their size and shape. External surfaces can usually be inspected with prods; however, on large parts this can be time consuming, and inspection of interior surfaces may not be adequate.

High-amperage power supplies, in conjunction with flexible cable used with clamps (as contact heads), central conductors, or wrapping, can effectively reduce inspection time because relatively large areas can be inspected with each processing cycle. Figure 41 illustrates the direct-contact, cable-wrap, and central-conductor techniques that can be used to inspect two relatively large parts. The three circuits for each part can be applied on a single-shot basis or, if high-output multidirectional equipment is available, can be combined into a single inspection cycle.

Fig. 41 Methods of using cable for applying magnetizing circuits to large forgings and castings. For the forging in (a), circuits 1 and 3 are head shots and circuit 2 is a cable wrap. For the casting in (b), circuits 1 and 3 are central conductors and circuit 2 is a cable wrap.

Generally, the higher-amperage power supplies are of the dc type. Alternating current and half-wave current supplies are limited to outputs of approximately 5000 to 6000 A because of the reactive impedance component associated with these types of current. Wet particles are generally preferred as the inspection medium in the presence of strong dc fields because wet particles exhibit much more mobility on the surface of a part than dry particles. Wet particles also readily permit full coverage of large surface areas and are easy to apply to internal surfaces.

Crane Hooks. The inspection of crane hooks, as required by the Occupational Safety and Health Act, has focused attention on cracks and other discontinuities in these components. Crane hooks are generally magnetic particle inspected with electromagnetic yokes having flexible legs. Power supplies are 115-V, 60-Hz alternating current and half-wave current. Stress areas in a crane hook are:

- The bight (in tension) on both sides and in the throat (area A, Fig. 42)
- The area below the shank (in compression and tension) on four sides (area B, Fig. 42)
- The shank (in tension), mainly in threads and fillet (area C, Fig. 42)

Fig. 42 Forged crane hook showing stress areas subject to inspection

The steps involved in the magnetic particle inspection of crane hooks are as follows:

1. Remove dirt and oil from hook
2. Magnetize and apply particles to areas A and B in Fig. 42, using a yoke and an ac field parallel to the axis of the hook
3. For hooks out of service, inspect the shank (area C, Fig. 42), using a yoke and an ac field parallel to the axis of the hook
4. For hooks in service, inspect the shank ultrasonically
5. Repeat steps 2 and 3 using a dc field for subsurface indications

The 50 kN (6 tonf) crane hook shown in Fig. 43 was removed from a jib crane after an indication was found during magnetic particle inspection. The discontinuity was found to be a deep forging lap. Sectioning the hook through the lap revealed a discontinuity about 19 mm ($\frac{3}{4}$ in.) deep in a 50 mm (2 in.) square section (section A-A, in Fig. 43). All inspections of the hook were made with the magnetic field parallel to the hook axis, thus inspecting for transverse cracks and other discontinuities. Because of the depth of the lap, the defect was detected even though the field was parallel to its major dimension. A sufficient flux-leakage field occurred at the surface to attract the magnetic particles.

Fig. 43 50 kN (6 tonf) crane hook showing magnetic particle indication of a forging lap and section through hook showing depth of lap

Inspection of a 90 kN (10 tonf) crane hook revealed a forging lap in the area below the shank. The lap was transverse and was located in the fillet below the keeper hole. A fatigue crack had initiated in the lap.

Drive-Pinion Shaft. An annual preventive maintenance inspection was performed on the large forged drive-pinion shaft shown in Fig. 44(a), and detection of a large crack (arrows, Fig. 44b) in the fillet between the shaft and coupling flange prevented a costly breakdown. Three areas were magnetic particle inspected for cracks:

- Along the shaft
- The fillet between the shaft and the coupling flange (cracked area, Fig. 44b)
- At each fillet in the wobbler coupling half (arrows, Fig. 44a)

Fig. 44 Forged drive-pinion shaft and coupling in which the detection of a crack during preventive maintenance magnetic particle inspection prevented a costly breakdown. (a) Drive-pinion shaft and coupler assembly; arrows show locations of fillets on wobbler coupling half that were inspected. (b) Fillet between shaft and coupling flange showing crack (at arrows) found during inspection

Inspection was conducted using a portable power source capable of up to 1500-A output in alternating current or half-wave direct current. Double prod contacts and a 4/0 cable were used to introduce the magnetic fields in the shaft. The fillets in the wobbler coupling half were inspected for discontinuities with double prod contacts.

The steps involved in inspecting the shaft were as follows:

1. Clean all areas to be tested
2. Wrap cable around shaft and apply current providing 2900 ampere-turns. Inspect for transverse cracks in the shaft portion
3. Place prods across fillet at coupling flange (Fig. 44b) at spacing of 152 to 203 mm (6 to 8 in.); apply 500-A current, producing a circular field perpendicular to fillet. Inspect for discontinuities parallel to fillet
4. Place prods across fillet at flange on wobbler coupling half and across fillets in shaft portion (arrows, Fig. 44a) at spacing of 152 to 203 mm (6 to 8 in.); apply 500-A current, producing a circular field perpendicular to the fillets. Inspect for discontinuities parallel to the fillets

Disk or Gear on Shaft. A forged or cast disk or gear on a heavy through shaft can be wrapped with a cable to form two opposing coils, as shown for the disk in Fig. 45. The two opposing coils produce radial magnetic fields on each side of the disk. This type of field reveals circumferential discontinuities on the sides of the disk and transverse discontinuities in the shaft. Also, the shaft can be used as a central conductor for the purpose of locating radial discontinuities in the disk and longitudinal discontinuities in the shaft.

Fig. 45 Disk on a through shaft in which the shaft was cable wrapped to produce a longitudinal magnetic field in the shaft and a radial field in the disk. Using the shaft as a central conductor produced a circular magnetic field in both the shaft and the disk.

In parts where the shaft extends from one side only, a pole piece can be used to simulate a through shaft. The pole piece should have approximately the same diameter as the shaft.

Y-shaped parts may not be processed on a horizontal wet-particle unit in such a manner that only one shot will be required for complete inspection. This is true even though steps are taken to ensure that the current is divided equally through the two upper legs of the Y. With equally divided current, an area of no magnetization will exist at the junction of the two legs. A Y-shaped part can be processed in two steps using a conventional horizontal wet-particle unit, or it can be processed in one operation using a modified unit having a double headstock and special current assurance magnetizing circuit.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Inspection of Weldments

Many weld defects are open to the surface and are readily detectable by magnetic particle inspection with prods or yokes. For the detection of subsurface discontinuities, such as slag inclusions, voids, and inadequate joint penetration at the root of the weld, prod magnetization is best, using half-wave current and dry powder. Yokes, using alternating current, direct current, or half-wave current, are suitable for detecting surface discontinuities in weldments.

The positioning of a yoke with respect to the direction of the discontinuity sought is different from the corresponding positioning of prods. Because the field traverses a path between the poles of the yoke, the poles must be placed on opposite sides of the weld bead to locate cracks parallel to the bead (Fig. 6), and adjacent to the bead to locate transverse cracks. Prods are spaced adjacent to the weld bead for parallel cracks and on opposite sides of the bead for transverse cracks.

For applications in which holding the prod contacts by hand is difficult or tiring, prods incorporating magnetic clamps, or leeches, that magnetically hold the prods to the work are available. The prods carrying the magnetizing current are held firmly to the work by an electromagnet. Both prods can be attached by the magnets, or one of the prods can be held magnetically and the other by hand.

There is one type of weld on which the penetrating power of half-wave current results in nonrelevant indications: a T-joint welded from one or both sides for which complete joint penetration is not specified and in which an open root is permissible and almost always present. When half-wave current is used with prods, this open root will probably be indicated on the weld surface. This nonrelevant indication can be eliminated by using alternating current instead of half-wave current.

A case in which nonrelevant magnetic particle indications were found occurred at the welded T-joints between six tubes and the end plates of a complicated assembly (Fig. 46). The welds were made from the outside of the tubes only. Liquid penetrant and radiographic inspections and metallographic examination disclosed that the integrity of the welds was good. Investigations revealed that the depth of penetration of the field produced by dc magnetization was sufficient to reveal the joint along the inside wall of the cylinder. Inspection by ac magnetization, which had less depth of penetration of the field, eliminated these indications.

Fig. 46 Assembly in which T-joints between tubes and end plates that were welded (as specified) with partial penetration produced nonrelevant magnetic particle indications when inspected using dc magnetization

The detectability of subsurface discontinuities in butt welds between relatively thin plates can often be improved by positioning a dc yoke on the side opposite the weld bead, as shown in Fig. 47. Magnetic particles are applied along the weld bead. Improvement is achieved because of the absence of extraneous leakage flux that normally emanates from the

yoke pole pieces. Techniques developed and used for the magnetic particle inspection of weldments are described in the two examples that follow.

Fig. 47 Method of using a yoke for detecting subsurface discontinuities in butt welds joining thin plates

Example 3: Magnetic Particle Inspection of Shielded Metal-Arc Welds in the Outer Hull of a Deep-Submergence-Vessel Float Structure.

The outer hull of the float structure of a deep-submergence vessel was made of 3.2 mm ($\frac{1}{8}$ in.) thick steel plate and was butt welded using the shielded metal-arc process. For magnetic particle inspection, the weld areas were magnetized with prods, using a half-wave current of 3.9 A/mm (100 A/in.) of prod spacing. Dry, red magnetic particles provided adequate sensitivity and color contrast for inspection.

The crowns on the surfaces of the welds were removed with a flat chisel. Neither grinding of the welds nor the use of pneumatic needle guns was permitted. The surfaces were cleaned of paint, scale, and slag by sand or vapor blasting.

The area to be inspected was shielded from air currents to prevent disturbing the magnetic particle indications. Magnetic particles were applied with a powder dispenser hand-held 305 to 381 mm (12 to 15 in.) from the weld at an angle of 30 to 45° to the surface of the plate along the axis of the weld. The powder dispenser was held stationary once it was positioned for each prod placement. The powder was allowed to float to the weld surface so that a very light dustlike coating of particles settled on the surface being tested. Excessive application of magnetic particles required removal of all particles and reapplication.

Longitudinal discontinuities were detected by placing the prods at a 152 mm (6 in.) spacing parallel to the longitudinal axis of the weld and on the surface of the weld. Successive prod spacings overlapped approximately 25 mm (1 in.) to ensure complete coverage. For the detection of transverse discontinuities, prods were positioned at right angles to the weld axis, 75 to 152 mm (3 to 6 in.) apart on each side of the weld, and at intervals not exceeding one-fourth the prod spacing.

Magnetic particle inspection was used instead of radiography. Following are the maximum radiographic acceptance standards from which the magnetic particle procedures were developed:

- A linear or linearly disposed indication 1.6 mm ($\frac{1}{16}$ in.) or more in length, with its length at least four times greater than its width
- A single slag (subsurface) indication longer than 0.8 mm ($\frac{1}{32}$ in.), and multiple slag indications closer together than 4.8 mm ($\frac{3}{16}$ in.) or totaling more than 3.2 mm ($\frac{1}{8}$ in.) in any 152 mm (6 in.) of weld length
- A cluster of four or more indications of any size spaced within 3.2 mm ($\frac{1}{8}$ in.) of each other

Example 4: Magnetic Particle Inspection of a Girder Weldment for an Overhead Crane

The girder weldment for an overhead crane (Fig. 48a) was magnetic particle inspected in the presence of the customer's representative. Fabrication of the weldment was complete, and the weldment had been sandblasted in preparation for painting.

Fig. 48 Magnetic particle inspection of a girder weldment for an overhead crane. (a) Girder weldment, with section showing welds and detail showing prod locations. (b) Magnetograph of magnetic field used to check for discontinuities in the welds. (c) Magnetograph of field used to check for discontinuities in top plate. Note different prod placement in (b) and (c). Dimensions given in inches

The dry-powder, continuous-magnetization method was used with half-wave current. The current used was 3.9 to 5.9 A/mm (100 to 150 A/in.) of prod contact spacing, which was 152 mm (6 in.). Inspected were the fillet welds joining the top and bottom plates to the web plate (section A-A in Fig. 48), and all butt seam welds of the top, bottom, and web plates. The edges of the top and bottom plates were also inspected for discontinuities. All prod-contact points on the girder were ground to ensure good contact; prod locations are shown in detail B in Fig. 48.

During magnetic particle testing of the welds, the prods were alternated on either side of the welds. A magnetograph of the magnetic flux during inspection of a weld joining the top plate to the web plate is shown in Fig. 48(b). Inspection of the edges of the top and bottom plates was performed by placing the prods parallel to the weld with contacts on the edge of the plate; a magnetograph of this test is shown in Fig. 48(c). Longitudinal indications were observed in both the plate and the weld.

Nonrelevant indications that the process was capable of detecting were established prior to inspecting the girder. All the indications detected were verified as either false or nonrelevant, signifying an absence of defects.

Magnetic Particle Inspection

Inspection of Billets

A billet is the last semifinished intermediate step between the ingot and the finished shape. Steel billets are rectangular or square and range from 2600 to 32,000 mm² (4 to 49 in.²) in cross-sectional area. The magnetic particle inspection of billets requires a large unit equipped to handle billets 50 to 184 mm (2 to 7 $\frac{1}{4}$ in.) square and 2.4 to 12 m (8 to 40 ft) long. The amperage setting on the testing unit should be 1200 to 4000 A. The discontinuities shown in Fig. 49 would appear as bright fluorescent indications under ultraviolet light.

Fig. 49 Discontinuities on the surfaces of steel billets that can be detected by magnetic particle inspection. (a) Arrowhead cracks. (b) Longitudinal cracks. (c) Normal seams. (d) Brush seams. (e) Laps. (f) Scabs. See text for discussion.

Cracks in billets appear as deep vertical breaks or separations in the surface of the steel. Arrowhead cracks (Fig. 49a) occur early in processing, usually as the result of primary mill elongation of an ingot containing a transverse crack. Longitudinal cracks (Fig. 49b) appear as relatively straight lines in the direction of rolling. They are 0.3 m (1 ft) or more in length and usually occur singly or in small numbers.

Seams are longitudinal discontinuities that appear as light lines in the surface of the steel.

Normal seams (Fig. 49c) are similar to longitudinal cracks, but produce lighter indications. Seams are normally closed tight enough that no actual opening can be visually detected without magnetic particle inspection. Seams have a large number of possible origins, some mechanical and some metallurgical.

Brush seams (Fig. 49d) are clusters of short (<102 mm, or 4 in., long) seams that appear as though they had been painted or brushed onto the surface. These defects are usually the result of the removal of metal from the steel surface by scarfing or scaling, exposing ingot blowholes and subsurface porosity. They may range in depth from 0.13 to 7.6 mm (0.005 to 0.300 in.) and may occur either in zones or across the entire surface of the billet.

Laps (Fig. 49e) are longitudinal discontinuities of varying severity that are caused by the formation of ribs or extensions of metal during hot rolling and the subsequent folding over of these protrusions. Laps usually run at acute angles to the surface. They often occur at opposite sides of the billet and frequently span the entire length of the billet.

Scabs (Fig. 49f) appear as extraneous pieces of metal partially welded to the surface of a steel billet. Two major sources of scabs are the splashing of metal against the mold wall during teeming and the adherence of scarfing wash or fins to blooms after conditioning.

Magnetic Particle Inspection

Inspection of Welded Chain Links

Magnetic particle inspection is commonly used for maintenance repair, preventive maintenance, and safety programs. The following procedure for the inspection of welded chain links is a proven method and is suitable for safety programs in which periodic inspection is required. In this procedure, a longitudinal field transverse to the weld will detect discontinuities in the weld and in the link itself. The continuous method, with wet fluorescent particles and ultraviolet light, is used.

The chain is suspended from the hook of a crane or hoist and pulled up through a magnetizing coil. Just below the coil, the wet fluorescent magnetic particles are sprayed onto the chain. Above the coil is the ultraviolet light that renders the indications readable. The chain is inspected in sections using the following steps:

1. Remove all oil or grease from chain links
2. Turn on current in coil
3. Apply the wet fluorescent magnetic particle suspension to each section while the section is in the magnetic field of the coil
4. Turn the current off after the suspension stops flowing and while the section to be inspected is still in the magnetic field of the coil
5. Inspect the section under ultraviolet light for transverse discontinuities in both the weld and the link itself
6. Continue until all sections have passed through the coil in an upward direction and have been inspected

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Automated Equipment for Specific Applications

The automation of magnetic particle inspection is often necessary to permit inspection at the required production rate. Loading, processing, conveying, rotating or manipulating, demagnetization, and discharge can all be automated, which results in consistent and effortless processing. The inspector can devote all of his time to actual visual inspection while the machine performs the other functions. Production rates are achieved by having the various functions performed simultaneously at different stations. Where applicable, the cost of automatic equipment can be justified when compared to the number of manual units needed for similar production rates.

The cost and time required for manual inspection can be a factor in automating the process. For example, in billet inspection, everything is automated except the actual visual inspection and marking of imperfections. Manual processing, inspection, and handling of such a product would be extremely costly and would not satisfy the production requirements. The use of automated magnetic particle inspection for bearing rollers, bearing rings, small parts, small castings, large couplings, crankshafts, and steel mill billets is discussed in the following sections.

Bearing rollers are produced at substantial rates, and when magnetic particle inspection is required, it must be conducted at a rate compatible with production. This usually requires automation of the process in such a manner that the various stages are performed simultaneously at individual stations.

The contact method is commonly used for inspecting finished rollers for seams, quench cracks, and grinding cracks. This may involve either the continuous or the residual method, depending on roller material and inspection requirements.

One design of automated equipment for inspecting bearing rollers by the continuous magnetization method incorporates an indexing-turntable arrangement and utilizes two inspectors. The various functions--magnetization, bath application, inspection and demagnetization--are performed simultaneously at the various stations. Each inspector visually inspects the previously processed roller in the fixture, and the roller is removed and placed on the demagnetizing cradle (if acceptable) or disposed of (if defective). The inspector then places a new roller in the fixture for subsequent processing and inspection by the other inspector. Acceptable rollers are automatically stripped from the cradle in tandem, demagnetized, and unloaded into or onto a suitable container.

The production rate of the unit described above is approximately 1000 parts per hour. A similarly designed unit, based on the residual method, utilizes four inspectors and has a capacity of 2000 parts per hour. The residual method permits the use of a magnetizing-current shot of very short duration (approximately 50 ms). This minimizes the heat generated at the points of contact by the flow of magnetizing current.

Where inspection requirements do not allow electrical contact with the rollers due to the fact that any heat generated at the points of contact is objectionable, production units based on the induced current method can be used.

Bearing rings can be completely inspected by a two-step process involving both a central conductor and induced current. The noncontact nature of both magnetizing techniques can be very desirable when highly polished surfaces are present.

This process utilizes automatic equipment for bearing-ring inspection on a high-volume basis. The design is based on a multiple-station, fixturized, indexing conveyor. The fixtures are combination laminated poles and central conductors. In both magnetizing methods, magnetizing current is direct current with quick break, and the wet-particle residual method is employed.

A bearing ring progresses through the unit in the following sequence:

1. Load
2. Magnetize using a central-conductor shot
3. Apply bath
4. Visually inspect for transverse indications
5. Replace on fixture
6. Magnetize using induced current
7. Apply bath
8. Visually inspect for circumferential indications
9. Place on gravity chute for final roll through ac demagnetizing coil and discharge

Those parts that are judged defective at one of the two inspection stations are immediately removed from the system.

Small parts can often be inspected on general-purpose equipment at production rates by separating the processing and inspection functions and providing a convenient means for transporting the parts from one station to the other. A typical arrangement comprises a horizontal wet-particle unit and a conveyORIZED unit integrated into a complete inspection system. Combinations of this type are available for handling a wide variety of parts. Variations such as automatic magnetization, automatic bath application, and controls for magnetizing a part in several directions at virtually the same time are also available. Special fixturing may or may not be required, depending on production rate and part configuration. Rates of up to 900 parts per hour can be achieved by such arrangements.

Small castings may warrant special consideration because of high-volume inspection techniques as well as manpower requirements. For example, the inspection of disk brake caliper castings could have been accomplished using general-purpose two-step production equipment manned by a loader-operator and four inspectors, but the use of a special-purpose unit for these castings not only reduced manpower requirements from five to three but also reduced the required floor space.

The automated special-purpose unit incorporated an indexing-type conveyor with special fixtures, a half-wave automatic three-circuit processing station, a two-man ultraviolet light inspection booth, and dual demagnetizing coils. The special fixtures properly oriented the casting for processing in addition to conveying the casting through the system. Longitudinal plus circular magnetization was provided by combining coil-wound laminated poles and contact heads. In operation, a casting was loaded onto the fixture, automatically processed, and inspected. Defective castings were discharged into containers; acceptable parts were placed on gravity chutes that carried them through demagnetizing coils into tote boxes.

Large couplings used in conjunction with oil well tubing and casing require circular magnetization for the disclosure of longitudinal defects. In one automated installation, a twin-line unit performs the required processing automatically using central conductors. Special roller-type fixtures facilitate manual rotation during visual inspection. When a defective coupling is encountered, the inspector merely depresses a reject button to direct that coupling into a reject bin when it reaches the unloading station.

Crankshafts. Various types of automatic equipment are available for inspecting crankshafts on a production basis. Design varies with crankshaft size and weight, inspection process and rate, and facilities available for loading and unloading. Most of this equipment incorporates completely automatic processing and handling based on a fixturized indexing conveyor. Some units use power-free fixtures to convey the crankshaft from the loading station to the processing station by gravity rails. This permits loading to be done independently of the processing and inspection cycles and the banking of uninspected crankshafts. The inspector can draw crankshafts from the bank as required. Empty fixtures are automatically returned to the loading area after the unloading operation has been completed.

Connecting Rods (Ref 2). Prior to machining, ferromagnetic parts such as connecting rods usually have rough surfaces with granular texture and sharp edges. The granular surface retains fluorescent magnetic particles that are a source of high visual background noise and degrade the contrast of the crack indication. A small crack indication concealed by high background noise is extremely hard to detect (Fig. 50).

Fig. 50 A small crack indication in a connecting rod that is masked by excessive visual background noise. Courtesy of Y.F. Cheu, General Motors Technical Center

The edges of a part attract magnetic particles that fluoresce brilliantly. The edge indication is bright, long, and thin, similar to a crack indication (Fig. 51). It is consequently very hard to distinguish a crack indication from an edge indication. One may say that edge location is a known parameter: an edge indication can be sorted out because its location is known. However, this would require that parts be precisely positioned with tolerance less than the thickness of a crack indication. This is very difficult to achieve in a high-volume production environment. In addition, because it is possible that a crack may occur on the edge, excluding edge indication based on location would leave cracks undetected on the edges.

Fig. 51 Crack indication and edge-indication uncertainty in a connecting rod. Courtesy of Y.F. Cheu, General Motors Technical Center

Thus, the low contrast and the uncertainty in distinguishing edge indications from crack indications make automation of fluorescent magnetic particle inspection difficult. To alleviate these problems, a new preimage-processing technique was developed to rinse the part immediately after it is processed with magnetic particles and before it is imaged. Figure 52(a) shows a part processed through magnetic particles without rinsing; Fig. 52(b) shows the same part after it is rinsed. Note that rinsing has removed the edge indications while simultaneously enhancing the crack indication.

Fig. 52 A connecting rod processed with magnetic particles and imaged. (a) Before rinsing. (b) After rinsing. Courtesy of Y.F. Cheu, General Motors Technical Center

The intensity of the fluorescent crack indication varies significantly because of the wide range of crack depth, the change of concentration of the magnetic particle solution, and the uneven sensitivity of the sensor. To accommodate these inevitable variations, a local adaptive-thresholding technique was developed and used in the crack-detection algorithm.

The algorithm demarcates an image into regional locales with 16 by 16 pixels in each locale. The average gray level of 16 by 16 pixels is calculated. The locale is then thresholded by twice this average. This locale adaptive-thresholding technique simplifies a gray-level image into a binary image based on relative intensity. The technique thereby minimizes the intensity variation problem and results in a less noisy binary image. Gray-scale digitization and binary image are discussed in the article "Machine Vision and Robotic Evaluation" in this Volume.

Figure 53(a) shows a digital image of a connecting rod with 256 levels of gray; the left half of the image is brighter than the right half. If the image is thresholded by a global-constant gray value, the resulting image (a crack indication and bright background noise) is shown in Fig. 53(b). On the other hand, Fig. 53(c) shows a binary image resulting from local adaptive thresholding of Fig. 53(a) as described in the previous paragraph. It is noted that local adaptive thresholding yields a more accurate binary image.

Fig. 53 Digital image processing of a magnetic particle inspected connecting rod. (a) Nonuniform brightness (256 gray-level image). (b) Result of constant global thresholding. (c) Result of local adaptive thresholding. (d) Result of shape discrimination. Courtesy of Y.F. Cheu, General Motors Technical Center

The algorithm to detect a crack from a binary image is based on the length and the aspect ratio (width-to-length ratio) of a crack. If both the length and the aspect ratio meet the specified criteria, a crack is detected. Figure 53(d) shows that a crack is detected and that background noise is ignored.

Example 5: A Ten-Station Rotary Table Integrated With a Machine Vision System to Detect Cracks in Connecting Rods

(Ref 2). The basic block diagram of the vision subsystem is shown in Fig. 54. It consists of multiple ultraviolet strobe lamps, an optical filter, a lens, a charge-coupled device (CCD) matrix camera, a frame grabber, and a microcomputer.

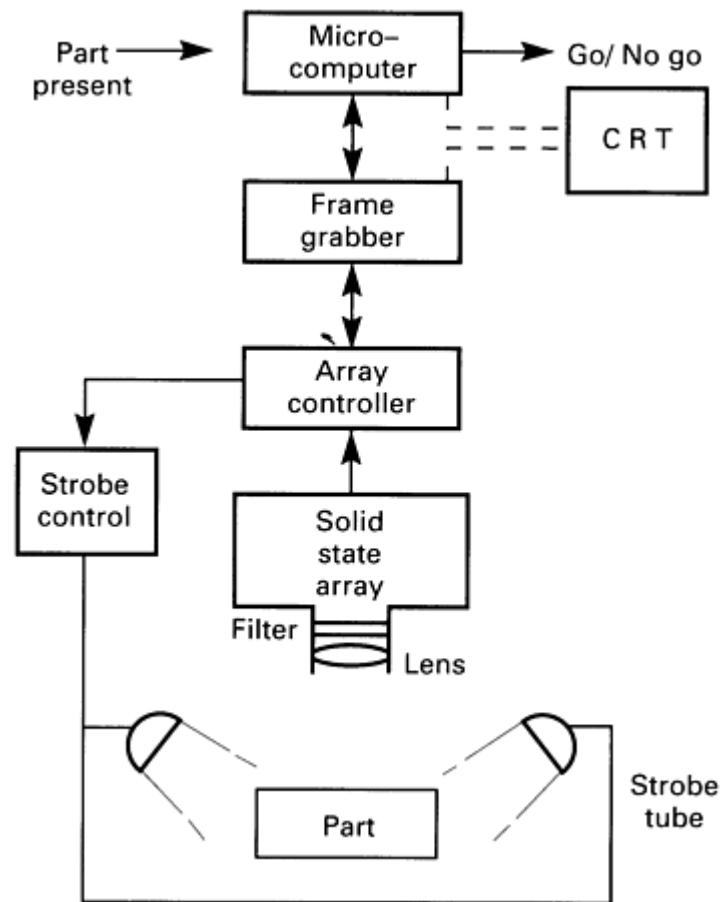

Fig. 54 Block diagram of machine vision subsystem for automated connecting-rod crack detection system.
Source: Y.F. Cheu, General Motors Technical Center

The strobe lamp is a xenon flash tube coupled with a band-pass ultraviolet filter to provide near-ultraviolet light. The near-ultraviolet light energizes fluorescent magnetic particles to emit visible light at a wavelength of 525 nm (5250 Å), which serves as a crack indication. The optical filter mounted behind the camera lens is a band-pass green filter to pass the crack indication and to filter out near-ultraviolet and ambient light. Multiple lamps are used to provide uniform and intensified lighting.

The CCD camera is a matrix array with 404 by 256 pixels. The frame grabber is a video digitizer and an image buffer. The digitizer is an 8-bit analog-to-digital (A/D) converter that converts the video into 256 levels of gray at a speed of 30 frames per second. The image buffer has a capacity of storing 512 by 512 pixels.

The microcomputer is a 16-bit machine that analyzes the digital image using the digital image processing technique described previously to make an inspection decision. An accept/reject decision resulting from the inspection is fed into a programmable controller. The programmable controller controls the material handling subsystem, which will unload the connecting rod at either the good rod station or the reject rod station.

The mechanical subsystem is a ten-station rotary index table (Fig. 55). Each station on the table has a gripper. Every 3 s, the table indexes 36°, drops 305 mm (12.0 in.), dwells, and rises 305 mm (12.0 in.). The sequence of operations for inspecting the connecting rods is as follows:

- *Load station:* A magazine loader lifts a connecting rod from the accumulation conveyor into a gripper
- *Magnetizing station:* The rod is magnetized while immersed in the magnetic particle solution
- *Rinse station:* The rod is rinsed with water to remove residual magnetic particles
- *Drain station:* Rinse water from the previous station is allowed to drip away to prevent interference by water droplets with the vision inspection

- *Camera station:* The connecting rod is inspected by the vision subsystem
- *Wrist-pin inspection station:* The wrist-pin hole is checked by an optical sensor to ascertain its opening
- *Rust inhibitor station:* The connecting rod is dipped into a bath of rust inhibitor to prevent rust formation on connecting rods
- *Paint identification station:* Color codes the defect-free rods
- *Unload and demagnetize station:* All defect-free rods are demagnetized and unloaded in a shipping container
- *Unload reject station:* All rejected rods are unloaded onto a table for final inspection and disposition

Fig. 55 Schematic of ten-station rotary table material-handling subsystem for automated connecting-rod crack detection system. Source: Y.F. Cheu, General Motors Technical Center

The sequencing functions of the process are controlled by a programmable controller. To ensure a reliable inspection, the programmable controller also monitors the magnetizing current, the pressure of the rinsing water, and the concentration level of the magnetic particle solution. The machine is capable of inspecting 1200 connecting rods per hour.

Typical examples of the system inspection results are shown in Fig. 56. Figure 56(a) shows a crack of average size, and Fig. 56(b) shows that it is detected.

Fig. 56 An average-sized crack in a connecting rod before (a) and after (b) detection by the automated inspection system. Courtesy of Y.F. Cheu, General Motors Technical Center

Steel-mill billets are magnetic particle inspected to locate and mark discontinuities that become elongated by the rolling process. Once located, discontinuities are removed by various means to improve the quality of the subsequently rolled final product.

Usual practice is to circularly magnetize the billet by passing the current end to end and to test by the wet-particle continuous method. The equipment required for performing the handling and processing functions is somewhat different from the normal inspection equipment.

A typical billet inspection unit is capable of handling billets up to 12 m (40 ft) long and weighing as much as 1.8 Mg (4000 lb). Every aspect of handling and processing is automatic. The inspector is required only to view and mark discernible indications. When the inspection has been completed, the inspector depresses a button to initiate processing of the next billet. One design incorporates a ferris wheel to rotate the billets at the inspection station. Two sides of the billet are viewed while it is in the upper position, and the remaining two sides become accessible when the billet is rotated to the lower position. Chain-sling billet turners are employed in other designs to perform billet rotation.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Demagnetization After Inspection

All ferromagnetic materials, after having been magnetized, will retain a residual magnetic field to some degree. This field may be negligible in magnetically soft metals, but in harder metals it may be comparable to the intense fields associated with the special alloys used for permanent magnets.

Although it is time consuming and represents an additional expense, the demagnetization of parts after magnetic particle inspection is necessary in many cases. Demagnetization may be easy or difficult, depending on the type of metal. Metals having high coercive force are the most difficult to demagnetize. High retentivity is not necessarily related directly to high coercive force, so that the strength of the retained magnetic field is not always an accurate indicator of the ease of demagnetizing.

Reasons for Demagnetizing. There are many reasons for demagnetizing a part after magnetic particle inspection (or, for that matter, after magnetization for any other reason). Demagnetization may be necessary for the following reasons:

- The part will be used in an area where a residual magnetic field will interfere with the operation of instruments that are sensitive to magnetic fields or may affect the accuracy of instrumentation incorporated in an assembly that contains the magnetized part
- During subsequent machining, chips may adhere to the surface being machined and adversely affect surface finish, dimensions, and tool life
- During cleaning operations, chips may adhere to the surface and interfere with subsequent operations such as painting or plating
- Abrasive particles may be attracted to magnetized parts such as bearing surfaces, bearing raceways, or gear teeth, resulting in abrasion or galling, or may obstruct oil holes and grooves
- During some electric arc-welding operations, strong residual magnetic fields may deflect the arc away from the point at which it should be applied
- A residual magnetic field in a part may interfere with remagnetization of the part at a field intensity too low to overcome the remanent field in the part

Reasons for Not Demagnetizing. Demagnetization may not be necessary if:

- Parts are made of magnetically soft steel having low retentivity; such parts will usually become demagnetized as soon as they are removed from the magnetizing source
- The parts are subsequently heated above their Curie point and consequently lose their magnetic properties
- The magnetic field is such that it will not affect the function of the part in service
- The part is to be remagnetized for further magnetic particle inspection or for some secondary operation in which a magnetic plate or chuck may be used to hold the part

This last reason may appear to conflict with the last item in the section "Reasons for Demagnetizing." The establishment of a longitudinal field after circular magnetization negates the circular field, because two fields in different directions cannot exist in the same part at the same time. If the magnetizing force is not of sufficient strength to establish the longitudinal field, it should be increased, or other steps should be taken to ensure that the longitudinal field actually has been established. The same is true in changing from longitudinal to circular magnetization. If the two fields (longitudinal and circular) are applied simultaneously, a field will be established that is a vector combination of the two in both strength and direction. However, if the fields are impressed successively, the last field applied, if it is strong enough to establish itself in the part, will destroy the remanent field from the previous magnetization. If the magnetizing force last applied does not equal or exceed the preceding one, the latter may remain as the dominant field.

The limits of demagnetization can be considered to be either the maximum extent to which a part can be demagnetized by available procedures or the level to which the terrestrial field will permit it to become demagnetized. These limits can be further modified by the practical degree or limit of demagnetization that is actually desired or necessary.

There are a number of ways of demagnetizing a part, all based on the principle of subjecting the part to a field continually reversing its direction and at the same time gradually decreasing in strength to zero (Fig. 57). The sine wave or curve of a reversing current at the bottom of Fig. 57 is used to generate the hysteresis loops. As the current diminishes in value with each reversal, the loop traces a smaller and smaller path. The curve at the upper right of Fig. 57 represents the flux density in the part as indicated on the diminishing hysteresis loops. Both current and flux density curves are plotted against time, and when the current reaches zero, the field remaining in the part will also have approached zero.

Fig. 57 Current and flux density curves during demagnetization, projected from the hysteresis loop. See text for discussion.

In using this principle, the magnetizing force must be high enough at the start to overcome the coercive force and to reverse the residual field initially in the part. Also, the incremental decrease between successive reductions in current must be small enough so that the reverse magnetizing force will be able, on each cycle, to reverse the field remaining in the part from the last previous reversal.

Demagnetization With Alternating Current. A common method of demagnetizing small to moderate-size parts is by passing them through a coil through which alternating current at line frequency is passing (usually 50 to 60 Hz). Alternatively, the 60-Hz alternating current is passed through a coil with the part inside the coil, and the current is gradually reduced to zero. In the first method, the strength of the reversing field is reduced by axially withdrawing the part from the coil (or the coil from the part) and for some distance beyond the end of the coil (or part) along that axial line. In the second method, gradual decay of the current in the coil accomplishes the same result. Passing a part through an ac coil is usually the faster, preferred method.

Small parts should not be loaded into baskets and the baskets passed through the coil as a unit, because alternating current will not penetrate into such a mass of parts and because only a few parts on the outside edges will be demagnetized (and these possibly only partially demagnetized). Small parts can be demagnetized in multiple lots only if they are placed in a single layer on a tray that holds them apart and in a fixed position with their long axes parallel to the axis of the coil.

Large parts are not effectively demagnetized with 60-Hz alternating current, because of its inability to penetrate. Alternating current with 25-Hz frequency is more effective.

Machines that provide decaying alternating current have a built-in means for automatically reducing the alternating current to zero by the use of step-down switches, variable transformers, or saturable-core reactors. When decaying alternating current is used, the current can be passed directly through the part instead of through a coil. Passing the current through the part is more effective on long, circularly magnetized parts than the coil method, but does not overcome the lack of penetration because of the skin effect, unless frequencies much lower than 60 Hz are used. High field strength ac demagnetizing coils are available with power factor correction, resulting in lower line current.

Demagnetization With Direct Current. Methods of demagnetizing with direct current are essentially identical in principle to the methods just described for alternating current. By using reversing and decreasing direct current, low-frequency reversals are possible, resulting in more complete penetration of even large cross sections.

A commonly used frequency is one reversal per second. It is a successful means of removing circular magnetic fields, especially when the current is passed directly through the part and can be used to demagnetize large parts. When a part in a coil is demagnetized using direct current at one reversal per second, the part remains in the coil for the duration of the entire cycle.

Oscillating circuits are a means of obtaining a reversing decaying current for demagnetizing purposes. By connecting a large capacitance of the correct value across the demagnetizing coil, the coil becomes part of an oscillatory circuit. The coil is energized with direct current; when the source of current is cut off, the resonant resistance-inductance-capacitance circuit oscillates at its own resonant frequency, and the current gradually diminishes to zero.

Yokes, either direct or alternating current, provide a portable means for demagnetizing parts. The space between the poles of the yoke should be such that the parts to be demagnetized will pass between them as snugly as possible. With alternating current flowing in the coil of the yoke, parts are passed between the poles and withdrawn. Yokes can be used on large parts for local demagnetization by placing the poles on the surface, moving them around the area, and then withdrawing the yoke while it is still energized. Yokes using low-frequency reversing direct current, instead of alternating current, are more effective in penetrating larger cross sections. The applicability of demagnetizing methods, based on part size, metal hardness, and production rate, is given in Table 2.

Table 2 Applicability of demagnetizing methods on the basis of part size, metal hardness, and production rate

Method	Part size ^(a)			Metal hardness ^(a)			Production rate ^(a)		
	Small	Medium	Large	Soft	Medium	Hard	Low	Medium	High
Coil, 60-Hz ac	A	A	N	A	A	N	A	A	A
Coil, dc, 30-point reversing step down	N	A	A	A	A	A	A	N	N
Through current, ac, 30-point step down	N	A	A	A	A	A	A	A	N
Through current, ac, reactor decay	N	A	A	A	A	A	A	A	N
Through current, dc, 30-point reversing step down	N	A	A	A	A	A	A	N	N
Yoke, ac	A	^(b)	N	A	A	N	A	N	N
Yoke, reversing dc	A	^(b)	N	A	A	A	A	N	N

Magnetic Rubber Inspection

Henry J. Weltman, Jack D. Reynolds, John E. Halkias, and William T. Kaarlela, General Dynamics Corporation

Several proprietary methods of magnetic particle inspection have been developed for specific applications. Three of these methods, which are described in this section, are magnetic rubber inspection, magnetic printing, and magnetic painting.

Magnetic rubber inspection is a nondestructive inspection method for detecting discontinuities on or near the surfaces of parts made of ferromagnetic metals. In this method, finely divided magnetic particles, dispersed in specially formulated room temperature curing rubber, are applied to a test surface, which is subsequently magnetized. The particles are attracted to the flux fields associated with discontinuities. Following cure of the rubber (about 1 h), the solid replica casting is removed from the part and examined, either visually or with a low-power microscope, for concentrations of magnetic particles that are indications of discontinuities on or just below the surface of the testpiece.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Method Advantages and Limitations

Advantages. Magnetic rubber inspection extends and complements the capabilities of other nondestructive inspection methods in certain problem areas. These include:

- Regions with limited visual accessibility
- Coated surfaces
- Regions having difficult-to-inspect shapes and sizes
- Indications requiring magnification for detection or interpretation

The replica castings furnish evidence of machining quality, physical dimensions, and surface conditions. The replicas can also be used to detect and record the initiation and growth of fatigue cracks at selected intervals during a fatigue test. The replicas provide a permanent record of the inspection; however, because the replicas shrink slightly during storage, critical measurements should be made within 72 h of casting. Replicas stored for extended periods may require a light wipe with solvent to remove any secreted fluid.

Limitations. The process is limited to the detection of discontinuities on or near the surfaces of parts made of ferromagnetic metals. It can be used on nonmagnetic metals for surface topography testing only. In this application, surface conditions, tool marks, and physical dimensions will be recorded, but there will be no migration of magnetic particles.

Magnetic rubber inspection is not as fast as other inspection methods, because of the time required to cure the rubber. This is of little disadvantage, however, when a large number of parts are being inspected. By the time all the regions being inspected have been prepared, poured, and magnetized, the first replicas are usually cured and ready for removal and examination.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Procedure

The conventional procedure used in magnetic rubber inspection can be divided into three steps:

- Preinspection preparation of parts
- Catalyzing, pouring, and magnetizing
- Review and interpretation of cured replicas

Preinspection preparation consists of cleaning the part of loose dirt or other contamination. It is often unnecessary to remove paint, plating, or flame-sprayed metal coating, but the removal of such coatings will often intensify any magnetic indications. Coatings thicker than 0.25 mm (0.01 in.) should always be removed. The next step is to prepare a reservoir to hold the liquid rubber on the inspection area. This is accomplished with the use of aluminum foil, aluminum or plastic tubing, and plastic tape and putty to seal the reservoirs against leakage.

Catalyzing and Pouring. The rubber inspection material must be thoroughly mixed before use to ensure a homogeneous dispersion. Black-oxide particles are included in the inspection material. A measured quantity of curing agents is stirred into the rubber, which is then transferred to the prepared reservoir.

Magnetizing. Continuous or residual magnetism is then induced into the part by using permanent magnets, direct current flowing through the part, or dc yokes, coils, prods, or central conductors. Direct current yokes are preferred for most applications. Because the magnetic particles in the suspension must migrate through the rubber, the duration of magnetism is usually longer than that of the standard magnetic particle method.

The minimum flux density along the surface of the test specimen is 2 mT (20 G); the higher the flux density, the shorter the required duration. Optimum durations of magnetization vary with each inspection task. Some typical examples of flux densities and durations of magnetization are given in Table 3.

Table 3 Flux density and duration of magnetization for various applications of magnetic rubber inspection

Type of area inspected	Flux density		Duration of magnetization, min
	mT	G	
Uncoated holes	5-10	50-100	$\frac{1}{2}$
	2.5-5	25-50	1
Coated holes	10-60 ^(a)	100-600	$\frac{1}{2}$ - 1 $\frac{1}{2}$ ^(a)

Uncoated surfaces	15	150	1
	10	100	3
	5	50	10
	2	20	30
Coated surfaces	5-60	50-600	1-60 ^(a)

(a) Flux density and time depend on the thickness of the coating.

As in the standard magnetic particle method, cracks and other discontinuities are displayed more strongly when they lie perpendicular to the magnetic lines of force. Therefore, the magnetizing current should be applied from two directions to increase reliability. This is accomplished by magnetizing in one direction, then moving the magnetizing unit to change the field 90° and remagnetizing on the same replica. Experiments have shown that the second magnetization does not disturb particles drawn to discontinuities during the first magnetization.

Review and Interpretation. Following cure, the replicas are removed from the part and examined for concentration of magnetic particles, which indicates the presence of discontinuities. This examination is best conducted with a low-power microscope (about seven to ten diameters) and a high-intensity light. During this examination, the topography of the replica is noted; tool marks, scratches, or gouges in the testpiece are revealed. Indications on a replica removed from a 16 mm (⁵/₈ in.) diam through hole in 24 mm (¹⁵/₁₆ in.) thick D-6ac low-alloy ultrahigh-strength steel plate are shown in Fig. 58.

Fig. 58 Indications of discontinuities (arrows) on a magnetic rubber replica removed from a 16 mm (⁵/₈ in.) diam through hole in 24 mm (¹⁵/₁₆ in.) thick D-6ac steel plate

Alternative Procedure. Another procedure used in magnetic rubber inspection involves placing a thin plastic film between the test surface and the rubber. This can be accomplished by stretching a sheet of polyvinylidene chloride over

the test area and painting a thin layer of catalyzed or uncatalyzed rubber over it. The film can then be removed and examined for indications immediately following magnetization, eliminating the need to wait for the rubber to cure.

In addition to providing immediate inspection results, this technique has other advantages:

- No damming is required
- Postinspection cleanup is easier because the rubber never directly comes into contact with the part
- Uncatalyzed rubber can be reused
- Catalyzed rubber can be used if a permanent record is desired

The technique, however, is less sensitive than the conventional magnetic rubber inspection method and is difficult to apply to irregularly shaped surfaces.

Magnetic Particle Inspection

Use on Areas of Limited Visual Accessibility

Examples of areas of limited visual accessibility that can be magnetic rubber inspected are holes and the inside surfaces of tubular components. Holes with small diameters, especially if they are threaded, are very difficult to inspect by other nondestructive methods. The deeper the hole and the smaller the diameter, the greater the problem. Liquid penetrant and magnetic particle methods are each highly dependent on the visual accessibility of the part itself; therefore, they are limited in such applications. With the use of magnetic rubber inspection, however, the visibility restriction is removed because replica castings can be taken from the inaccessible areas and examined elsewhere under ideal conditions without any visual limitations.

An application for the inspection of small-diameter holes is illustrated in Fig. 59. The testpiece is a 4.0 mm ($\frac{5}{32}$ in.) thick D-6ac steel aircraft longeron containing several groups of three nutplate holes (Fig. 59a). Each group consisted of two rivet holes 2.4 mm ($\frac{3}{32}$ in.) in diameter and a main hole 6.4 mm ($\frac{1}{4}$ in.) in diameter. Examination of a replica of one group of nutplate holes (Fig. 59b) revealed indications of cracks in one of the rivet holes and in the main hole.

Fig. 59 Aircraft longeron (a), of 4.0 mm ($\frac{5}{32}$ in.) thick D-6ac steel, showing nutplate holes that were magnetic rubber inspected. (b) Cured magnetic rubber replica with indications (arrows) of cracks in the 6.4 mm ($\frac{1}{4}$ in.) diam main hole and a 2.4 mm ($\frac{3}{32}$ in.) diam rivet hole

Blind holes present a problem in conventional magnetic particle inspection or in liquid penetrant inspection. If the part is stationary, the inspection fluid will accumulate at the bottom of the hole, preventing inspection of that area. Another problem is directing adequate light into a blind hole for viewing.

Similar visibility problems restrict inspection of the inside surfaces of tubular components. The longer the component and the smaller its diameter, the more difficult it becomes to illuminate the inside surface and to see the area of interest. Magnetic particle, liquid penetrant, and borescope techniques have limited value in this type of application. Grooves, lands, and radical section changes also limit the use of ultrasonic and radiographic methods for the inspection of inside surfaces. The magnetic rubber technique, however, provides replica castings of such surfaces for examination after the replicas have been removed from the components. Some examples of this application include mortar and gun barrels, pipe, tubing, and other hollow shafts.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Use on Coated Surfaces

Coatings such as paint, plating, and flame- or plasma-sprayed metals have always presented difficulties in conventional nondestructive inspection. Liquid penetrants are unsuccessful unless discontinuities in the substrate have also broken the surface of the coating. Even then, it is difficult to determine whether a liquid penetrant indication resulted from cracks in the coating or cracks in the coating plus the substrate. Production ultrasonic techniques have been successfully used to locate discontinuities in coated flat surfaces; however, their ability to detect small cracks less than 2.54 mm (0.100 in.) long by 0.0025 mm (0.0001 in.) wide in bare or coated material is poor to marginal.

Because most coatings are nonmagnetic, it is possible to use magnetic particle and magnetic rubber techniques to inspect ferromagnetic materials through the coatings. Experience has shown that conventional magnetic particle techniques also become marginal if the coating is 0.10 mm (0.004 in.) thick or greater. However, magnetic rubber inspection has the capability of producing indications through much thicker coatings. Because of the weak leakage field at the surface, the particles used in the conventional magnetic particle method are lightly attracted to the region of the discontinuity. In the magnetic rubber technique, the reduced particle attraction is compensated for by increasing the time of magnetization, up to several minutes, to ensure sufficient particle accumulation. The attracted particles remain undisturbed until the rubber is cured.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Use on Difficult-to-Inspect Shapes or Sizes

Complex structures exhibiting varying contours, radical section changes, and surface roughness present conditions that make interpretation of data obtained by radiographic, magnetic particle, liquid penetrant, or ultrasonic inspection difficult because of changing film densities, accumulation of excess fluids, and high background levels. As a result, discontinuities in such structures frequently remain undetected. The magnetic rubber process minimizes background levels on the cured replicas with little change in the intensity of any crack indications. Typical items to which magnetic rubber inspection is applicable are multiple gears, internal and external threads, and rifling grooves in gun barrels.

When magnetic particle fluid is applied to a threaded area, some of the liquid is held by surface tension in the thread roots (the most likely area for cracks). This excess fluid masks defect indications, especially when the fluorescent method is used. With the magnetic rubber method, thread root cracks are displayed with little or no interfering background.

Example 6: Magnetic Rubber Inspection of Spline Teeth in an Aircraft-Flap Actuator.

The process applied to internal spline teeth is illustrated in Fig. 60(a), which shows an aircraft-flap actuator bracket with the magnetic rubber replica. A macroscopic view of this replica (Fig. 60b) reveals several cracks in the roots of the spline teeth. The bracket was made of 4330 steel. The spline teeth were 16 mm ($\frac{5}{8}$ in.) long, with 24/48 pitch.

Fig. 60 Magnetic rubber inspection of spline teeth in a 4330 steel bracket for an aircraft-flap actuator. (a) View of bracket with rubber replica removed. (b) Macrograph of replica showing crack indications in roots of teeth

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Magnification of Indications

The examination of cast replicas under magnification permits detection of cracks as short as 0.05 mm (0.002 in.). Detection of these small cracks is often important to permit easier rework of the part prior to crack propagation. These cracks are also of interest during fatigue test monitoring.

Discontinuity indications in magnetic particle inspection often result from deep scratches or tool marks on the part surface, and it is difficult to distinguish them from cracks. When the magnetic rubber replicas are viewed under magnification, the topography of the surface is easily seen, and indications from scratches and tool marks can be distinguished from crack indications. This distinction may prevent the unnecessary rejection of parts from service.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Surface Evaluation

Magnetic rubber replicas are reproductions of the test surface and therefore display surface conditions such as roughness, scratches, tool marks, or other machining or service damage. Some surface conditions in holes, such as circumferential tool marks, are usually not harmful. Discontinuous tool marks (from tool chatter) are stress raisers and potential sites of crack initiation and propagation. Axial tool marks, which may result from a fluted reamer, are often not permitted in areas of high stress. Surface studies by magnetic rubber inspection can be applied to areas other than holes, such as rifling lands and grooves.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Use for Fatigue Test Monitoring

Magnetic rubber inspection has been used in the structural laboratory for studies of crack initiation and propagation during fatigue testing. Because each replica casting is a permanent record of the inspection, it is convenient to compare the test results during various increments of a test program.

Example 7: Magnetic Rubber Inspection of Aircraft Structural Part to Monitor Steel Fatigue.

An example of the fatigue test monitoring of an aircraft structural part made of D-6ac steel is shown in Fig. 61. The test area was a 4.8 mm ($\frac{3}{16}$ in.) diam, 5.6 mm ($\frac{7}{32}$ in.) deep hole. A replica of the hole at the beginning of the test is shown in Fig. 61(a). A few tool marks were noted at this time. After 3500 cycles of fatigue loading, another replica of the hole was made (Fig. 61b). A comparison with the original replica showed some new discontinuity indications growing from the tool marks. After 4000 cycles (Fig. 61c), another replica showed that the indications in the hole were increasing and beginning to join together. This propagation continued until at 4500 cycles the crack extended through the entire hole (Fig. 61d). A few cycles later, the testpiece failed through the hole.

Fig. 61 Magnetic rubber replicas used to monitor crack growth in a hole during fatigue testing of a D-6ac steel aircraft part. Part fractured at 4545 cycles. (a) Initial replica of the hole showing a tool mark (arrow). (b) Replica made after 3500 fatigue cycles. Intensity of indication increased at tool mark (lower arrow), and a new indication was formed (upper arrow). (c) Replica made after 4000 cycles. Indications joined, and growth of crack (arrows) is evident. (d) Replica made after 4500 cycles. Mature fatigue crack (arrows), extending all along hole, is very evident.

Because the test hole described above was located in an area that was obstructed from view, nondestructive inspection methods requiring viewing the hole would have been very difficult to perform. Moreover, the hole was coated with flame-sprayed aluminum, which would have further limited the applicability of some nondestructive-inspection methods.

Magnetic Particle Inspection

Magnetic Printing (U.S. Patent 3,243,876)

Orlando G. Molina, Rockwell International

Magnetic printing employs a magnetizing coil (printer), magnetic particles, and a plastic coating of the surface of the testpiece for the detection of discontinuities and flaws. The process can be used on magnetic materials that have very low magnetic retentivity.

The magnetizing coil, or magnetic printer, consists of a flat coil made of an electrical conductor, and it is connected to a power supply capable of delivering 60-Hz alternating current of high amperage at low voltage. When the coil is energized, a strong, pulsating magnetic field is distributed along the axis of the coil and produces a vibratory effect on the testpiece and the magnetic particles. This vibratory effect causes the magnetic particles to stain or print the plastic coating

in regions where magnetic particles have been attracted by changes in magnetic permeability. The magnetic particles are made of ferromagnetic iron oxide (Fe_3O_4) and are similar to those used for conventional magnetic particle inspection.

Magnetically printed patterns are made visible by first spraying the surface of the testpiece with a white plastic coating. The coating provides a contrasting background and a surface on which the particles print. After a print has been obtained and the particles have been removed, the patterns can be fixed by spraying with a clear plastic coating. Because the two coatings are of the same composition, a single film is formed, within which the printed pattern is sandwiched. When dry, the coating can be stripped from the surface of the testpiece and used as a permanent record.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Procedure

The testpiece should be cleaned so that it is free of dirt, moisture, oil, paint, scale, and other materials that can obscure a discontinuity or flaw. The white plastic coating is sprayed onto the test surface in an amount to establish a white background to offset the color of the test surface. The coating should be free of puddles, runs, and signs of orange peel. The coating is dried before application of the magnetizing current and particles.

With the magnetizing current on and properly adjusted, the testpiece and magnetic printer are placed adjacent to each other, and dry printing particles are dusted on the test surface with a powder bulb applicator. The testpiece and printer can be moved relative to each other to obtain uniform printing. When a suitable print has formed, usually after 6 to 12 s, the magnetizing current is turned off. The excess magnetic printing particles can be removed with a gentle air blast or gentle tapping.

If a suitable print has not been obtained, the print can be erased with a damp sponge, and the application of magnetizing current and printing particles repeated. If a permanent record is needed, the printed surface is sprayed with two coats of clear plastic. To assist in removing the coating, a piece of pressure-sensitive clear plastic tape can be applied to the printed surface after the clear plastic coating has dried to the touch. Copies of magnetic printings can be made by conventional photographic contact printing methods, using the magnetic printed record as a negative. A transparency for projection purposes can be made by magnetic printing on the clear coating instead of the white coating. White or clear nitrocellulose lacquer can be used in place of the strippable coatings when a permanent, nonstrippable magnetic print is required.

On some occasions, the magnetic printing particles group together in certain areas of the part surface, reducing the printing capabilities of the particles. When an aluminum alloy plate, such as 2024, is placed beneath the magnetizing coil (with the coil between the aluminum alloy plate and the testpiece), the particles remain in constant dispersion, thus preventing grouping.

A similar inspection method (U.S. Patent 3,826,917) uses a coating, preferably an organic coating, containing fluorescent material and nonfluorescent particles, preferably suspended in a liquid medium. Magnetic-flux lines are established substantially perpendicular to the suspected discontinuities in the surface of the testpiece. The particles agglomerate and form indications on the coating adjacent to the discontinuities. The testpiece is inspected under ultra-violet light to locate and reveal the surface discontinuities. If a permanent record is needed, a clear strippable plastic coating is applied over the magnetic indications of imperfections, and the resulting coating is stripped from the surface.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Applications

Magnetic printing can be used for inspecting ferromagnetic materials of either high or low magnetic retentivity to detect any condition that affects magnetic permeability. Some typical applications of magnetic printing are illustrated in Fig. 62, and discussed in the following sections.

Fig. 62 Typical applications of magnetic printing for the detection of discontinuities and metallurgical flows. (a) PH 15-7 Mo stainless steel brazed honeycomb panel showing core pattern. (b) AM-350 steel tube showing Lüders lines (at A) and weld bead (at B). (c) AM-350 steel tube; upper region is a magnetic print showing white riverlike areas that are stringers of retained austenite, and lower region is a nonprinted area. (d) Weld bead in PH 15-7 Mo stainless steel sheet showing heat-affected zones (arrows). (e) Print of the machined surface of a PH 15-7 Mo stainless steel weldment showing ferrite stringers in an essentially austenitic matrix (area at A), weld metal (area at B) and the adjacent heat-affected zones (arrows at C's), and surface where the magnetic print had been removed (area at D).

Brazed Honeycomb Panels. Figure 62(a) shows a magnetic print of a brazed honeycomb panel made of PH 15-7 Mo stainless steel. Visible in the print is the core pattern otherwise invisible to the eye. Areas of lack of attachment between core cells and facing sheet, puddling of brazing alloy, and the face sheet seam weld have been observed in magnetic prints of honeycomb panels.

Elastic and Plastic Deformation. A response to certain degrees of elastic and plastic deformation in some ferromagnetic materials can be detected by magnetic printing. Indications of localized plastic deformation (Lüders lines) and the seam weld in an AM-350 steel tube are shown in Fig. 62(b). These patterns are obtainable even after the stress has been removed. However, magnetic printing patterns can be obtained when a testpiece is under elastic stress, but they are no longer obtainable when the stress is removed. These phenomena occur because of regions of different magnetic permeability within a given testpiece.

Crack Detection. The magnetic printing method is generally more sensitive in detecting cracks than liquid penetrants. No special orientation of the flux lines is needed to detect cracks at different angles to each other, as is required in conventional magnetic particle inspection. Crack growth in fatigue and tension tests can be monitored by making magnetic prints at intervals during the test. In a tensile test on an AM-350 steel tube specimen, changes were revealed in contained areas of retained austenite. Not only was gradual transformation noticed in the recorded appearance of the metallurgical detail but a distinct indication was recorded in the last print taken before fracture. Some of the magnetic prints showed stress patterns at the ends of cracks.

Metallurgical details not always obtainable by common macroetching methods are usually revealed by magnetic printing. These details include flow lines in extrusions and forgings, as well as stringers of retained austenite. The magnetic printing of an AM-350 steel tube is shown in Fig. 62(c). The white, riverlike areas are stringers of retained austenite; the presence of retained austenite was confirmed by x-ray diffraction and metallographic examination.

Heat-affected zones adjacent to welds can be detected by magnetic printing. The heat-affected zones adjacent to the weld bead in PH 15-7 Mo stainless steel are shown in Fig. 62(d). This weld was subsequently sectioned for magnetic printing and metallographic examination, which verified the presence of heat-affected zones. Figure 62(e) shows ferrite stringers in an essentially austenitic matrix, cast weld metal, heat-affected zones, and an area where the magnetic print had been removed. The print exhibits a three-dimensional effect as if the weld area had not been machined.

Magnetic Painting (U.S. Patent 3,786,346)

D.E. Lorenzi, Magnaflux Corporation

Magnetic painting uses a visually contrasting magnetic particle slurry for flaw detection. A slurry concentrate having a consistency of paint is brush applied to the surface being inspected. Brushing allows for the selective application of the material; the magnetic particles can be spread evenly and thoroughly over the test area of interest. When the testpiece is subjected to a suitable magnetizing force, flaws appear as contrasting black indications on a light-gray background, as illustrated by the cracks in the weld metal shown in Fig. 63. Wet fluorescent magnetic paint indications of minute grinding cracks in the faces of a small sprocket are shown in Fig. 64. These indications are semipermanent; that is, they remain intact for extended periods of time unless intentionally erased by rebrushing.

Fig. 63 Magnetic paint indications of cracks in weld metal

Fig. 64 Wet fluorescent magnetic paint indications of minute grinding cracks in the faces of a small sprocket

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Method Advantages

Magnetic paint slurry requires no special lighting aids and is compatible with both the continuous and the residual methods of magnetization. It is nondrying and, depending on the degree of cleanliness required, can be removed with dry rags, paper towels, or prepared cleaning solvents.

Magnetic paint covers dark- and light-colored test surfaces equally well. Consequently, the contrast between indication and background is independent of the test-surface color. In contrast to dry magnetic particles, high wind velocities and wet test surfaces do not constitute adverse inspection conditions with magnetic paint. Magnetic paint can be applied and processed on a testpiece completely immersed in water. The material requires minimal surface preparation of testpieces because it can be applied directly over oily, rusty, plated, or painted surfaces with little or no degradation of performance, provided the coatings are not excessively thick.

Because magnetic paint is a slurry having the consistency of ordinary paint, it can be selectively applied with a brush to any test surface, regardless of its spatial orientation. As a result, there is no material overspray, and any problems associated with airborne magnetic particles and/or liquid are completely eliminated. This becomes a very desirable feature when magnetic particle inspection must be performed on vertical and overhead surfaces.

For applications that require the continuous method of magnetization, the critical sequencing between the application of magnetic particles and the magnetization is eliminated because the magnetic paint is applied before the testpiece is magnetized. In addition, the material can be rebrushed to erase previous results, and the testpiece can be reprocessed without additional slurry.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Performance

Magnetic painting can be used with all standard magnetizing techniques--circular, coil, prods, and yokes, using ac or dc magnetization--and is applicable to the detection of surface as well as subsurface flaws. The material formulation utilizes

selective magnetic particles, in flake form, dispersed in a viscous, oily vehicle. The viscosity of the oil-type suspending medium is chosen to restrict substantial lateral mobility of the ferromagnetic flakes while permitting rotary movement of the flakes at the flaw site when acted upon by magnetic leakage fields (Fig. 65).

Fig. 65 Schematic of rotation of flakes of magnetic paint at the site of a discontinuity

Magnetic paint appears light gray in color when brush applied to a testpiece. This indicates that the flakes are oriented with their faces predominantly parallel to the surface and tend to reflect the ambient light. Because the flakes tend to align themselves with a magnetic leakage field, they virtually stand on end when subjected to the leakage field associated with a cracklike discontinuity. These edges, being relatively poor reflectors of light, appear as dark, contrasting lines against the light-gray background. Broad leakage fields result in correspondingly broad dark areas.

The nature of the indication depends, to a significant extent, on the ratio of oil-to-flake used in the slurry mix. The standard mixture provides good contrast between indications and background as well as relatively long permanence. However, the concentration can be diluted, by increasing the oil-to-flake ratio, to achieve greater indicating sensitivity (Fig. 66). Diluting the mixture results in some loss of contrast and indication permanence. Although the material is supplied having an oil-to-flake ratio of the order of 6:1, ratios as high as 20:1 can be used.

Fig. 66 Effect of oil-to-flake ratio in a magnetic paint slurry mix on the contrast between a flaw indication (dark vertical line near center) and background. (a) 6:1 ratio. (b) 10:1 ratio. Magnetic paint was applied over bare metal (upper band across indication) and over 0.15 mm (0.006 in.), 0.30 mm (0.012 in.), and 0.46 mm (0.018 in.) thicknesses of transparent plastic tape.

Magnetic Particle Inspection

Revised by Art Lindgren, Magnaflux Corporation

Applications

Because magnetic painting is a recent development, field applications have been limited. However, extensive laboratory testing has produced favorable results and suggests that improved testing capabilities can be realized in the following areas of application:

- Inspection of welds in pipelines, tank cars, shipbuilding, pressure vessels, and general structural steel construction
- Field inspection of used drill pipe and tubing
- Overhaul and routine field maintenance on aircraft, trucks, buses, and railroad equipment
- General industrial maintenance inspection of structural parts and equipment components

Magnetic Field Testing

R.E. Beissner, Southwest Research Institute

Introduction

MAGNETIC FIELD TESTING includes some of the older and more widely used methods for the nondestructive evaluation of materials. Historically, such methods have been in use for more than 50 years in the examination of magnetic materials for defects such as cracks, voids, or inclusions of foreign material. More recently, magnetic methods for assessing other material properties, such as grain size, texture, or hardness, have received increasing attention. Because of this diversion of applications, it is natural to divide the field of magnetic materials testing into two parts, one directed toward defect detection and characterization and the other aimed at material properties measurements.

This article is primarily concerned with the first class of applications, namely, the detection, classification, and sizing of material flaws. However, an attempt has also been made to provide at least an introductory description of materials characterization principles, along with a few examples of applications. This is supplemented by references to other review articles.

All magnetic methods of flaw detection rely in some way on the detection and measurement of the magnetic flux leakage field near the surface of the material, which is caused by the presence of the flaw. For this reason, magnetic testing techniques are often described as flux leakage field or magnetic perturbation methods. The magnetic particle inspection method is one such flux leakage method that derives its name from the particular method used to detect the leakage field. Because the magnetic particle method is described in the article "Magnetic Particle Inspection" in this Volume, the techniques discussed in this article will be limited to other forms of leakage field measurement.

Although it is conceivable that leakage field fluctuations associated with metallurgical microstructure might be used in the analysis of material properties, the characterization methods now in use rely on bulk measurements of the hysteretic properties of material magnetization or of some related phenomenon, such as Barkhausen noise. The principles and applications of magnetic characterization presented in this article are not intended to be exhaustive, but rather to serve as illustrations of this type of magnetic testing.

The principles and techniques of leakage field testing and magnetic characterization are described in the two sections that follow. These sections will discuss concepts and methods that are essential to an understanding of the applications described in later sections. The examples of applications presented in the third section will provide a brief overview of the variety of inspection methods that fall under the general heading of magnetic testing.

Magnetic Field Testing

R.E. Beissner, Southwest Research Institute

Principles of Magnetic Leakage Field Testing

Origin of Defect Leakage Fields. The origin of the flaw leakage field is illustrated in Fig. 1. Figure 1(a) shows a uniformly magnetized rod, which consists of a large number of elementary magnets aligned with the direction of magnetization. Inside the material, each magnetic pole is exactly compensated by the presence of an adjacent pole of opposite polarity, and the net result is that interior poles do not contribute to the magnetic field outside the material. At the surfaces, however, magnetic poles are uncompensated and therefore produce a magnetic field in the region surrounding the specimen. This is illustrated in Fig. 1(a) by flux lines connecting uncompensated elementary poles.

Fig. 1 Origin of defect leakage fields. (a) Magnetic flux lines of a magnet without a defect. (b) Magnetic flux lines of a magnet with a surface defect. Source: Ref 1

If a slot is cut in the rod, as illustrated in Fig. 1(b), the poles on the surface of this slot are now also uncompensated and therefore produce a localized magnetic field near the slot. This additional magnetic field, which is represented by the extra flux lines in Fig. 1(b), is the leakage field associated with the slot.

Figure 1, although adequate for a qualitative understanding of the origin of leakage fields, does not provide an exact quantitative description. The difficulty is the assumption that the magnetization remains uniform when the flaw is introduced. In general, this does not happen, because the presence of the flaw changes the magnetic field in the vicinity of the flaw, and this in turn leads to a change in magnetization near the flaw. With regard to Fig. 1, this means that the strengths and orientations of the elementary dipoles (magnets) actually vary from point to point in the vicinity of the flaw, and this variation also contributes to the flaw leakage field. The end result is that the accurate description of a flaw leakage field poses a difficult mathematical problem that usually requires a special-purpose computer code for its solution.

Experimental Techniques. One of the first considerations in the experimental application of magnetic leakage field methods is the generation of a suitable magnetic field within the material. In some ferromagnetic materials, the residual field (the field that remains after removal of an external magnetizing field) is often adequate for surface flaw detection. In practice, however, residual magnetization is rarely used because use of an applied magnetizing field ensures that the material is in a desired magnetic state (which should be known and well characterized) and because applied fields provide more flexibility (that is, one can produce a high or low flux density in the specimen as desired).

Experience has shown that control of the strength and direction of the magnetization can be useful in improving flaw detectability and in discriminating among different types of flaws (Ref 1, 2, 3, 4, 5, 6, 7, 8, and 9). In general, the magnitude of the magnetization should be chosen to maximize the flaw leakage field with respect to other field sources that might interfere with flaw detection; the optimum magnetization is usually difficult to determine in advance of a test and is often approached by trial-and-error experimentation. The direction of the field should be perpendicular to the largest flaw dimension to maximize the effect of the flaw on the leakage field.

It is possible to generate a magnetic field in a specimen either directly or indirectly (Ref 10, 11, 12). In direct magnetization, current is passed directly through the part. With the indirect approach, magnetization is induced by placing the part in a magnetic field that is generated by an adjacent current conductor or permanent magnet. This can be done, for example, by threading a conductor through a hollow part such as a tube or by passing an electric current through a cable wound around the part. Methods of magnetizing a part both directly and indirectly are illustrated schematically in Fig. 2.

Fig. 2 Methods of magnetization. (1) Head-shot method. (b) Magnetization with prods. (c) Magnetization with a central conductor. (d) Longitudinal magnetization. (e) Yoke magnetization

The flaw leakage field can be detected with one of several types of magnetic field sensors. Aside from the use of magnetic particles, the sensors most often used are the inductive coil and the Hall effect device.

The inductive coil sensor is based on Faraday's law of induction, which states that the voltage induced in the coil is proportional to the number of turns in the coil multiplied by the time rate of change of the flux threading the coil (Ref 13). It follows that detection of a magnetostatic field requires that the coil be in motion so that the flux through the coil changes with time.

The principle is illustrated in Fig. 3, in which the coil is oriented so as to sense the change in flux parallel to the surface of the specimen. If the direction of coil motion is taken as x , then the induced electromotive force, E , in volts is given by:

$$E = 10^{-8} N A \frac{dB}{dx} \frac{dx}{dt}$$

where N is the number of turns in the coil, A is its cross-sectional area, and B is the flux density, in Gauss, parallel to the surface of the part. Thus, the voltage induced in the coil is proportional to the gradient of the flux density along the direction of coil motion multiplied by the coil velocity. Figure 4 shows the flux density typical of the leakage field from a slot, along with the corresponding signal from a search coil oriented as in Fig. 3.

Fig. 3 Flux leakage measurement using a search coil. Source: Ref 13

Fig. 4 Leakage flux and search coil signal as a function of position. Source: Ref 13

Unlike the inductive coil, which provides a measure of the flux gradient, a Hall effect sensor directly measures the component of the flux itself in the direction perpendicular to the sensitive area of the device (Ref 1). Because the response of a Hall effect sensor does not depend on the motion of the probe, it can be scanned over the surface to be inspected at any rate that is mechanically convenient. In this respect, the Hall device has an advantage over the coil sensor because there is no need to maintain a constant scanning speed during the inspection. On the other hand, Hall effect sensors are more difficult to fabricate, are somewhat delicate compared to inductive coil sensors, and require more complex electronics.

Other magnetic field sensors that are used less often in leakage field applications include the flux gate magnetometer (Ref 14), magnetoresistive sensors (Ref 15), magnetic resonance sensors (Ref 16), and magnetographic sensors (Ref 17), in which the magnetic field at the surface of a part is registered on a magnetic tape pressed onto the surface.

Analysis of Leakage Field Data. In most applications of the leakage field method, there is a need not only to detect the presence of a flaw but also to estimate its severity. This leads to the problem of flaw characterization, that is, the determination of flaw dimensions from an analysis of leakage field data.

The most widely used method of flaw characterization is based on the assumptions that the leakage field signal amplitude is proportional to the size of the flaw (which usually means its depth into the material) and that the signal amplitude can therefore be taken as a direct measure of flaw severity. In situations where all flaws have approximately the same shape and where calibration experiments show that the signal amplitude is indeed proportional to the size parameter of concern, this empirical method of sizing works quite well (Ref 18).

There are, however, many situations of interest where flaw shapes vary considerably and where signal amplitude is not uniquely related to flaw depth, as is the case for corrosion pits in steel tubing (Ref 19). In addition, different types of flaws, such as cracks and pits, can occur in the same part, in which case it becomes necessary to determine the flaw types present as well as their severity. In such cases, a more careful analysis of the relationship between signal and flaw characteristics is required if serious errors in flaw characterization are to be avoided.

One of the earliest attempts to use a theoretical model in the analysis of leakage field data was based on the analytic solution for the field perturbed by a spherical inclusion (Ref 20, 21). Two conclusions were drawn from this analysis. First, when one measures the leakage flux component normal to the surface of the part, the center of the flaw is located below the scan plane at a distance equal to the peak-to-peak separation distance in the flux signal (Fig. 5), and second, the peak-to-peak signal amplitude is proportional to the flaw volume. A number of experimental tests of these sizing rules have confirmed the predicted relationships for nonmagnetic inclusions in steel parts (Ref 21).

Fig. 5 Dependence of magnetic signal peak separation (a) on the depth of a spherical inclusion (b)

Further theoretical and experimental data for spheroidal inclusions and surface pits have shown, however, that the simple characterization rules for spherical inclusions do not apply when the flaw shape differs significantly from the ideal sphere. In such cases, the signal amplitude depends on the lateral extent of the flaw and on its volume, and characterization on the basis of leakage field analysis becomes much more complicated (Ref 19, 22).

Finally, there has been at least one attempt to apply finite-element calculations of flaw leakage fields to the development of characterization rules for a more general class of flaws. Hwang and Lord (Ref 23) performed most of their computations for simple flaw shapes, such as rectangular and triangular slots and inclusions, and from the results devised a set of rules for estimating the depth, width, and angle of inclination of a flaw with respect to the surface of the part. One of their applications to a flaw of complex shape is shown in Fig. 6.

Fig. 6 Characterization of a ferrite-tail type of defect. The dashed line shows the flaw configuration estimated from the leakage field data.

The promising results obtained from the finite-element work of Hwang and Lord, as well as the analytically based work on spheroidal flaws, suggest that the estimation of flaw size and shape from leakage field data is feasible. Another numerical method potentially applicable to flux leakage problems is the boundary integral method, which may prove useful in flaw characterization. Unfortunately, much more work must be done on both the theoretical basis and on experimental testing before it will be possible to analyze experimental leakage field data with confidence in terms of flaw characteristics.

Magnetic Field Testing

R.E. Beissner, Southwest Research Institute

Principles of Magnetic Characterization of Materials

Metallurgical and Magnetic Properties. The use of magnetic measurements to monitor the metallurgical properties of ferromagnetic materials is based on the fact that variables such as crystallographic phase, chemical composition, and microstructure, which determine the physical properties of materials, also affect their magnetic characteristics (Ref 24, 25, 26). Some parameters, such as grain size and orientation, dislocation density, and the existence of precipitates, are closely related to measurable characteristics of magnetic hysteresis, that is, to the behavior of the flux density, B , induced in a material as a function of the magnetic field strength, H .

This relationship can be understood in principle from the physical theory of magnetic domains (Ref 27). Magnetization in a particular direction increases as the domains aligned in that direction grow at the expense of domains aligned in other

directions. Factors that impede domain growth also impede dislocation motion; hence the connection, at a very fundamental level, between magnetic and mechanical properties.

Other magnetic properties, such as the saturation magnetization, which is the maximum value B can achieve, or the Curie temperature at which there is a transition to a nonmagnetic state, are less dependent on microstructure, but are sensitive to such factors as crystal structure and chemical composition. Interest in the magnetic characterization of materials, principally steels, derives from many such relationships between measurable magnetic parameters and metallurgical properties. These relationships are, however, quite complicated in general, and it is often difficult to determine how or if a particular measurement or combination of measurements can be used to determine a property of interest. Nevertheless, the prospect of nondestructive monitoring and quality control is an attractive one, and for this reason research on magnetic materials characterization continues to be an active field.

It is not the purpose of this article to explore such magnetic methods in depth, but simply to point out that it is an active branch of nondestructive magnetic testing. The more fundamental aspects of the relationship between magnetism and metallurgy are discussed in Ref 26 and 28. Engineering considerations are reviewed in Ref 24. The proceedings of various symposia also contain several papers that provide a good overview of the current status of magnetic materials characterization (Ref 29, 30, 31).

Experimental Techniques. A typical setup for measuring the B - H characteristic of a rod specimen is shown in Fig. 7. The essential elements are an electromagnet for generating the magnetizing field, a coil wound around the specimen for measuring the time rate of change of the magnetic flux, B , in the material, and a magnetic field sensor, in this case a Hall effect probe, for measuring the magnetic field strength, H , parallel to the surface of the part. The signal generator provides a low-frequency magnetizing field, typically of the order of a few Hertz, and the output of the flux measuring coil is integrated over time to give the flux density in the material. In the arrangement shown in Fig. 7, an additional feature is the provision for applying a tensile load to the specimen for studies of the effects of stress on the hysteresis data. When using a rod specimen such as this, it is important that the length-to-diameter ratio of the specimen be large so as to minimize the effects of stray fields from the ends of the rod on the measurements of B and H .

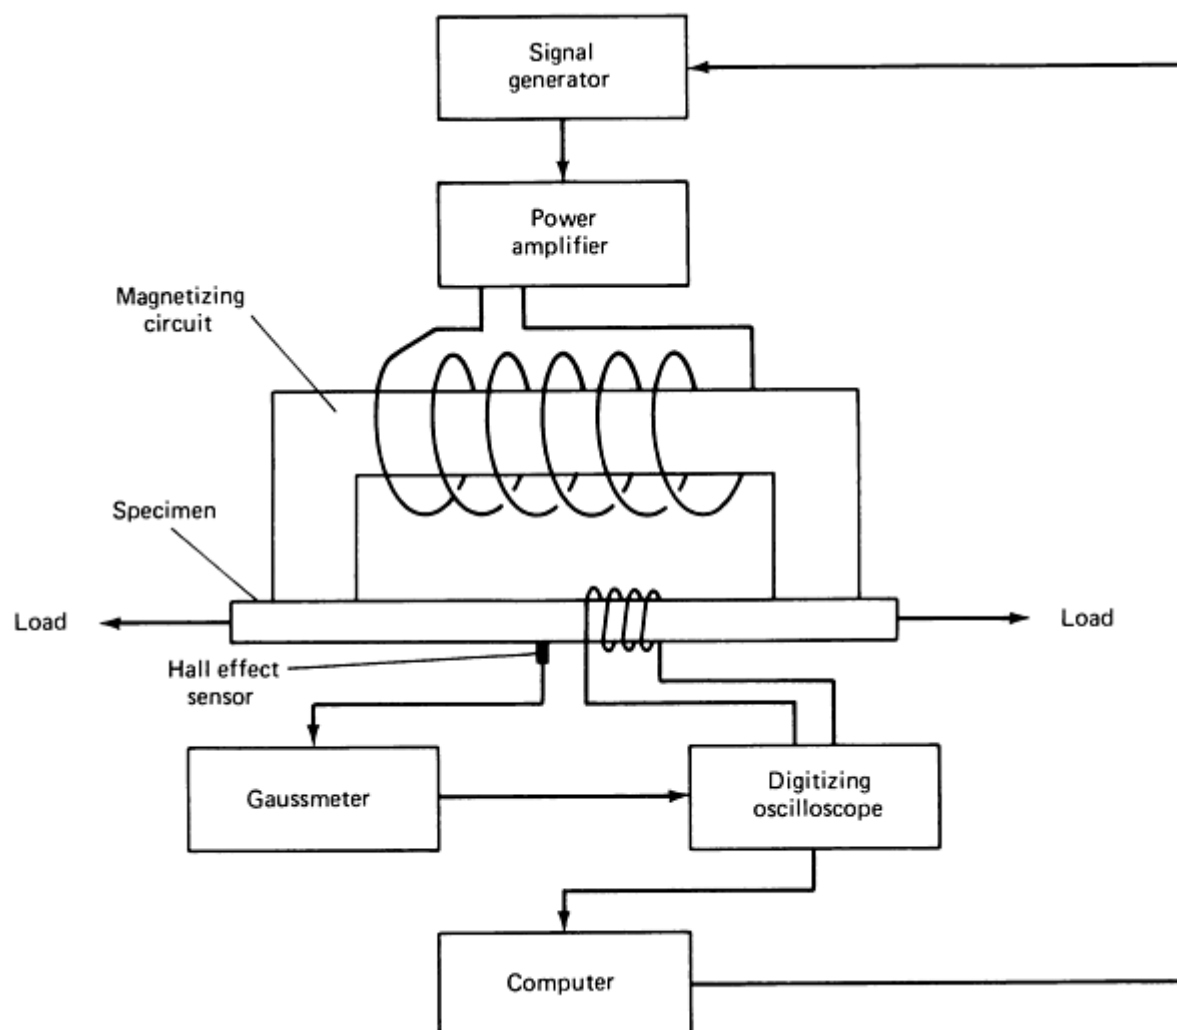

Fig. 7 Experimental arrangement for hysteresis loop measurements. Source: Ref 32

Another magnetic method that uses a similar arrangement is the measurement of Barkhausen noise (Ref 33, 34). As the magnetic field strength, H , is varied at a very slow rate, discontinuous jumps in the magnetization of the material can be observed during certain portions of the hysteresis cycle. These jumps are associated with the sudden growth of a series of magnetic domains that have been temporarily stopped from further growth by such obstacles as grain boundaries, precipitates, or dislocations. Barkhausen noise is therefore dependent on microstructure and can be used independently of hysteresis measurements, or in conjunction with such measurements, as another method of magnetic testing. The experimental arrangement differs from that shown in Fig. 7 in that a single sensor coil, oriented to measure the flux normal to the surface of the specimen, is used instead of the Hall probe and the flux winding.

The review articles and conference proceedings cited above contain additional detail on experimental technique and a wealth of information on the interpretation of hysteresis and Barkhausen data. However, it should be noted that test methods and data interpretation are often very specific to a particular class of alloy, and techniques that seem to work well for one type of material may be totally inappropriate for another. The analysis of magnetic characterization data is still largely empirical in nature, and controlled testing of a candidate technique with the specific alloy system of interest is advisable.

Magnetic Field Testing

R.E. Beissner, Southwest Research Institute

Applications

Flaw Detection by the Flux Leakage Method. Perhaps the most prevalent use of the flux leakage method is the inspection of ferromagnetic tubular goods, such as gas pipelines, down hole casing, and a variety of other forms of steel piping (Ref 35, 36). In applications in the petroleum industry, the technique is highly developed, but details on inspection devices and methods of data analysis are, for the most part, considered proprietary by the companies that provide inspection services. Still, the techniques currently in use have certain features in common, and these are exemplified by the typical system described below.

The device shown in Fig. 8 is an inspection tool for large-diameter pipelines. Magnetization is provided by a large electromagnet fitted with wire brushes to direct magnetic flux from the electromagnet into the pipe wall. To avoid spurious signals from hard spots in the material, the magnetization circuit is designed for maximum flux density in the pipe wall in an attempt to magnetically saturate the material. Leakage field sensors are mounted between the pole pieces of the magnet in a circle around the axis of the device to provide, as nearly as possible, full coverage of the pipe wall. In most such tools, the sensors are the inductive coil type, oriented to measure the axial component of the leakage field gradient. Data are usually recorded on magnetic tape as the system is propelled down a section of pipe. After the inspection, the recorded signals are compared with those from calibration standards in an attempt to interpret flaw indications in terms of flaw type and size.

Fig. 8 Typical gas pipeline inspection pig. The tool consists of a drive unit, an instrumentation unit, and a center section with an electromagnetic and flux leakage sensors.

In addition to systems for inspecting rotationally symmetric cylindrical parts, flux leakage inspection has been applied to very irregular components, such as helicopter rotor blade D-spars (Ref 37), gear teeth (Ref 38), and artillery projectiles (Ref 39). Several of these special-purpose applications have involved only laboratory investigations, but in some cases specialized instrumentation systems have been developed and fabricated for factory use. These systems are uniquely adapted to the particular application involved, and in most cases only one or at most several instrumentation systems have been built. Even in the case of laboratory investigations, special-purpose detection probe and magnetizing arrangements have been developed for specific applications.

One such system for automated thread inspection on drill pipe and collars is described in Ref 40. The device consists of an electromagnet and an array of sensors mounted outside a nonmagnetic cone that threads onto the tool joint. The assembly is driven in a helical path along the threads by a motor/clutch assembly. To minimize the leakage flux signal variations caused by the threads, signals from the sensor array are compared differentially. The system is capable of operating in a high field strength mode for the detection of cracks and corrosion pits and also in a residual field mode for the detection of other forms of damage. At last report, the system was undergoing field tests and was found to offer advantages, in terms of ease of application and defect detection, over the magnetic particle technique normally used for thread inspection.

The flux leakage method is also finding application in the inspection of ropes and cables made of strands of ferromagnetic material. One approach is to induce magnetization in the piece by means of an encircling coil energized by a direct current (dc). With this method, one measures the leakage field associated with broken strands using a Hall effect probe or an auxiliary sensor coil. A complementary method with alternating current (ac), which is actually an eddy current test rather than flux leakage, is to measure the ac impedance variations in an encircling coil caused by irregularities in the cross-sectional area of the specimen. Haynes and Underbakke (Ref 41) describe practical field tests of an instrumentation system that utilizes both the ac and dc methods. They conclude that instrumentation capable of a combination of inspection techniques offers the best possibility of detecting both localized flaws and overall loss of cross section caused by generalized corrosion and wear. They also present detailed information on the practical characteristics of a commercially available device that makes use of both the ac and dc methods.

Another area in which the flux leakage method has been successfully implemented is the inspection of rolling-element antifriction bearings (Ref 42, 43, 44, and 45). A schematic illustration of the method as applied to an inner bearing race is shown in Fig. 9. In this application, the part is magnetized by an electromagnet, as indicated in Fig. 9(a). The race is then rotated by a spindle, and the surface is scanned with an induction coil sensor. Typically, the race is rotated at a surface speed of about 2.3 m/s (7.5 ft/s), and the active portion of the raceway is inspected by incrementally indexing the sensor across the raceway. Magnetizing fields are applied in the radial and circumferential orientations. It has been shown that radial field inspection works best for surface flaws, while circumferential field inspection shows greater sensitivity to subsurface flaws (Ref 43). Data have been collected on a large number of bearing races to establish the correlation between leakage field signals and inclusion depths and dimensions determined by metallurgical sectioning (Ref 44, 45).

Fig. 9 Flux leakage inspection of a bearing race. (a) Magnetization of inner race. (b) Perturbation in the magnetic flux at the surface of the inner race. (c) Probe scanning the surface

Finally, the flux leakage method has also been adapted to the inspection of steel reinforcement in concrete beams (Ref 46, 47). The basic function of the magnetic field disturbance (MFD) inspection equipment is to provide maps of the magnetic field across the bottom and sides of the beam. An electromagnet on an inspection cart, which is suspended on tracks below the beam, provides a magnetic field that induces magnetization in permeable structures in its vicinity, such as steel rebars, cables, and stirrups. An array of Hall effect sensors distributed across the bottom and sides of the beam measures the field produced by magnetized structures within the beam. If a flaw is present in one of these magnetized structures, it will produce a disturbance of the normal magnetic field pattern associated with the unflawed beam. Thus, the idea behind the MFD system is to search the surface of the beam for field anomalies that indicate the presence of flaws in reinforcing steel within the structure.

A flaw, such as a broken wire in a cable or a fractured rebar, produces a distinctive magnetic field anomaly that depends on the size of the discontinuity and its distance from the sensor. Because the signal shape that results from such an anomaly is known, flaw detection is enhanced by searching magnetic field records for specific signal shapes, that is, those that are characteristic of discontinuities in magnetic materials. In the MFD system, this is accomplished by a computer program that compares signal shapes with typical flaw signal shapes. The program produces a correlation coefficient that

serves as a measure of similarity of the observed signal shape to a typical flaw signal shape. Flaw detection is therefore not only enhanced by signal shape discrimination but also automated by computer processing of the magnetic field data.

Laboratory tests have demonstrated the ability of the system to detect fracture in steel rebars and cables in a large prestressed concrete structure (Ref 47). Also planned are field tests of the equipment in the inspection of bridge decks for reinforcement corrosion damage.

Nondestructive Characterization of Materials. Only two examples of magnetic methods for monitoring material properties are given because the examples chosen should suffice to illustrate the types of tests that might be employed. Measurements of magnetic characteristics can, however, provide a wealth of data, and various features of such data can yield information on different material properties. For example, it has been demonstrated that different features of magnetic hysteresis data can be interpreted in terms of heat treatment and microstructure, plastic deformation, residual stress, and mechanical hardness (Ref 25).

An example of the effects of mechanical hardness on hysteresis data is shown in Fig. 10. These data were obtained in the absence of applied tensile stress with the experimental arrangement shown in Fig. 7. Specimens of different hardness were prepared by tempering at different temperatures. The grain size (ASTM No. 7) was the same for all four specimens used in these tests. Other data showed, however, that grain size has little effect on hysteretic behavior for the classes of alloys studied.

Fig. 10 Effect of mechanical hardness on hysteresis loop data. (a) AISI 410 stainless steel. (b) SAE 4340 steel. Source: Ref 32

The main point illustrated in Fig. 10 is that the mechanically harder specimens of the same alloy are also harder to magnetize; that is, the flux density, B , obtained at a large value of H is smaller for mechanically harder specimens than for softer specimens. For one alloy, AISI 410 stainless steel, the hysteresis loop intersects the $B = 0$ axis at larger values of H for the harder specimen than for the softer specimen; that is, the coercive force is greater for the harder material. However, for the other material, SAE 4340 steel, the coercive force does not change with hardness. This suggests that, for the two alloys considered here, the saturation flux density provides a more reliable measure of hardness than the coercive force.

Mayos *et al.* (Ref 48) used two quite different techniques to measure the depth of surface decarburization of steels. One method was a variation of a standard eddy current test, with the difference from standard practice being that eddy current probe response was measured in the presence of a low-frequency (~ 0.1 Hz) magnetic field. This arrangement provides a measure of incremental permeability, that is, the magnetic permeability corresponding to changes in the applied field about some quasistatic value. The second method employed was Barkhausen noise analysis.

Depth of decarburization was analyzed by varying the frequency of the excitation field, thus changing the skin depth in the material. Experiments were performed with both artificial samples containing two layers of different carbon content and industrial samples in which carbon concentration varied smoothly with distance from the surface.

It was shown that certain features of both Barkhausen noise and incremental permeability data can be correlated with depth of decarburization. The Barkhausen noise method showed a somewhat stronger sensitivity to depth, but was useful over a smaller range of depths than the incremental permeability method. It can be concluded that both methods are useful, with the optimum choice depending on accuracy requirements and the expected depth of decarburization.

Electric Current Perturbation NDE

Gary L. Burkhardt and R.E. Beissner, Southwest Research Institute

Introduction

ELECTRIC CURRENT PERTURBATION (ECP) is an electromagnetic nondestructive evaluation method for detecting and characterizing defects in nonferromagnetic material. Laboratory evaluations have shown that this method can detect very small surface and subsurface cracks in both low- and high-conductivity metals (for example, titanium and aluminum alloys). Results from experiments and an analytical ECP model confirm that linear relationships exist between the ECP signal amplitude and the crack interfacial area and between the signal peak-to-peak separation and the crack length. This article will discuss the principles of the ECP method, typical inspection results, and crack characterization results.

Electric Current Perturbation NDE

Gary L. Burkhardt and R.E. Beissner, Southwest Research Institute

Background

The principle by which ECP detects flaws is illustrated in Fig. 1. An electric current density, \mathbf{j}_0 , is introduced into the region to be inspected, thus producing an associated magnetic-flux density, \mathbf{B}_0 (Fig. 1a). A flaw perturbs the current flow, as shown in Fig. 1(b), and the flux density is changed by an amount $\Delta\mathbf{B}$. Flaw detection is accomplished by sensing this change in flux density, $\Delta\mathbf{B}$, with a magnetic-field sensing device (Fig. 2). The sensor coils are oriented to detect the x -axis component of the magnetic flux.

(a)

(b)

Fig. 1 Electric current density, j , and the associated magnetic flux density, B (a) with no surface flaw and (b) with a flaw (for example, a crack) perpendicular to the current flow

Fig. 2 ECP probe configuration and orientation with respect to a flaw in a part surface. The size difference between the sensor and the induction coil is much greater than shown.

In most applications, the ECP method makes use of an induction coil, much like that of a conventional eddy-current probe, to provide the unperturbed current density, \mathbf{j}_0 , in the region to be inspected. However, unlike conventional eddy-current methods, the use of a coil to induce an alternating current is not essential. Experiments have in fact used not only ac injection but also dc injection, with results similar to those obtained by induction. When direct current is injected, a Hall effect sensor is used instead of coils.

Another difference between ECP and conventional eddy-current methods lies in the orientation of the sensor. The exciter coil and the sensor coil axes in the ECP method are perpendicular (Fig. 2), which reduces or eliminates direct coupling with \mathbf{B}_0 . In addition, the use of differential sensors tends to cancel the effect of remaining coupling. These decoupling features allow the excitation to be much stronger in the ECP method, yielding gains in sensitivity. Probe-to-surface coupling is also minimized, and sensitivity to probe liftoff variations is greatly reduced (Ref 1). Liftoff is a major source of noise with probes using conventional eddy-current coil orientations. The end result is that ECP probes have excellent signal-to-noise characteristics, making them well suited to the detection of small flaws. The penalty for this geometry is directionality: The sensing coils select specific current perturbations and ignore others.

In practice, one noticeable difference between the ECP and conventional eddy-current method is that the frequencies employed with ECP are almost always much lower. The difference in operating frequencies results from the requirement for eddy-current probes to use higher frequencies to reduce liftoff noise by separating the liftoff component of the signal from the flaw component (Ref 2). This is not necessary with ECP because the probe design inherently reduces liftoff noise. Therefore, while many eddy-current probes designed for surface-flaw detection are configured for frequencies of several hundred kilohertz to several megahertz, ECP probes are normally used at frequencies below 100 kHz. Using lower frequencies allows the ECP electronics to be simplified.

A block diagram of a typical ECP system is shown in Fig. 3. A signal generator drives a current source to provide excitation current for the induction coil in the ECP probe. The sensor output is directed to an amplifier and a phase-sensitive detector. Devices such as a digitizing oscilloscope or chart recorder can also be used for recording and displaying ECP signals.

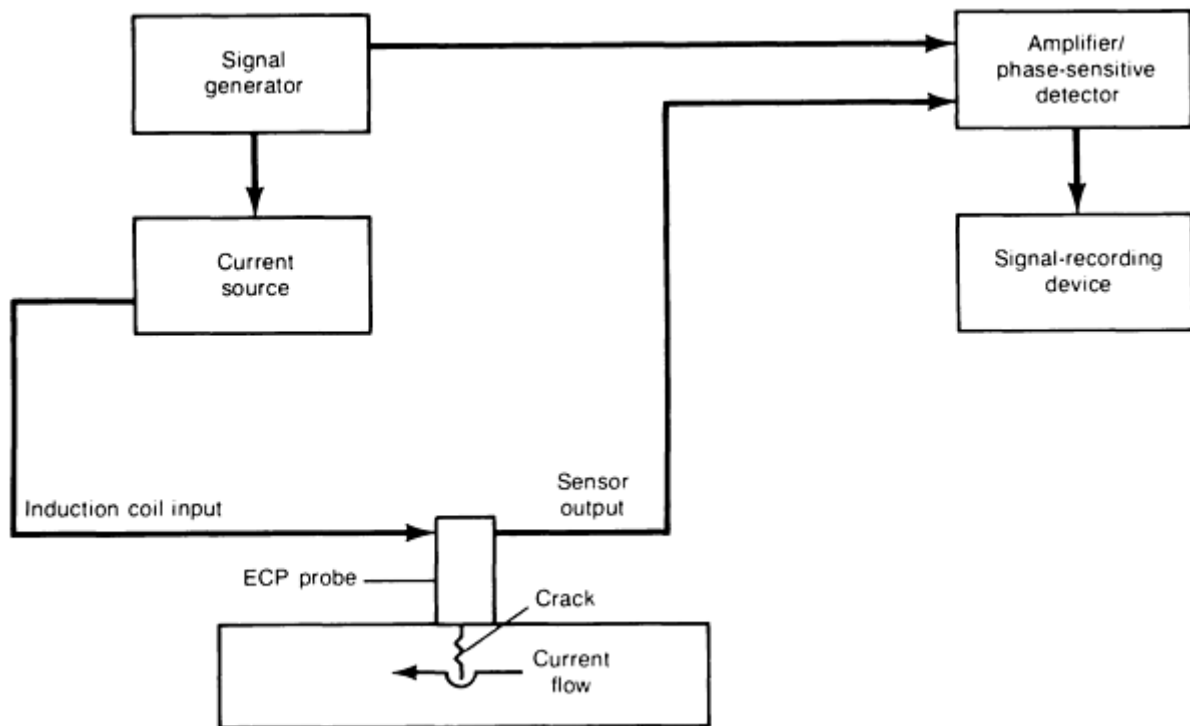

Fig. 3 Block diagram of a typical ECP system

Electric Current Perturbation NDE

Gary L. Burkhardt and R.E. Beissner, Southwest Research Institute

Typical Applications

The following examples describe the evaluation of the ECP method for detecting flaws in a variety of parts. In these examples, the evaluation first involved the machining of small notches in the surfaces of the parts. These notches served as test flaws.

In each of the examples, the induced current, j_0 , was perpendicular to the length of the notches. The ECP sensors scanned the surface to determine the ECP response to the test flaws. The scan direction was perpendicular to the flaw in Examples 1 and 5, but was parallel to the flaw in Examples 2, 3, and 4. When the scan direction is perpendicular, a unipolar ECP signal is produced, and when the scan direction is parallel to the flaw, a bipolar ECP signal is produced. The ECP signal shapes for perpendicular and parallel scans are shown in Fig. 4 and 5.

Fig. 4 Calculated ECP signals for scans perpendicular to a 0.46 mm (0.018 in.) long by 0.10 mm (0.004 in.) deep slot

Fig. 5 Calculated ECP signals for scans parallel to a 0.46 mm (0.018 in.) long by 0.10 mm (0.004 in.) deep slot

Example 1: Surface Flaws in a Flat Plate.

The sensitivity of the ECP method to very small surface flaws in a low-conductivity material was illustrated with flaws in a flat-bar Ti-6Al-4V specimen (Ref 3). The ECP signals obtained by scanning a probe linearly past three electrical discharge machined (EDM) notches are shown in Fig. 6. The 0.47 mm (0.0184 in.) long by 0.17 mm (0.0066 in.) deep notch in this specimen gave a very prominent ECP signal. More important, recognizable signals were also obtained from the two small notches--one 0.20 mm (0.0079 in.) long by 0.06 mm (0.0022 in.) deep and the other 0.22 mm (0.0085 in.) long by 0.05 mm (0.0020 in.) deep. The background signal in the region where no flaws were present was caused by the inhomogeneity of the specimen material. From these data, the inherent sensitivity of the ECP method for detection of very small surface flaws was established.

Fig. 6 ECP signals from EDM notches in a Ti-6Al-4V flat-bar specimen. Flaw dimensions are length by depth.

Example 2: Flaw Detection in Fan-Disk Blade Slots.

Evaluations of the ECP method were performed on blade slots in the first-stage fan disk of the F100 gas-turbine engine (Ref 3). Figure 7 shows a photograph of this disk, which was fabricated from Ti-6Al-2Sn-4Zr-6Mo material. The blade-slot configuration is illustrated in Fig. 8. An 8.89 mm (0.350 in.) radius on each side of the blade slot blended into a flat area on the bottom of the blade slot, and the primary area of interest for surface-flaw detection was at the tangency point of this radius. Notches were electrical discharge machined in two blade slots at the tangency point for use as target flaws. The ECP probe scan path was approximately in line with each EDM notch (Fig. 8). Figure 9 shows the ECP signals from two blade slots with surface EDM notches measuring 0.46 mm (0.0182 in.) long by 0.27 mm (0.0105 in.) deep and 0.27 mm (0.0105 in.) long by 0.15 mm (0.0058 in.) deep. Prominent signatures were obtained from both the larger EDM notch (Fig. 9a) and the smaller EDM notch (Fig. 9b); this demonstrated the sensitivity for detecting small flaws in this engine component.

Fig. 9 ECP signals from EDM notches in F100 first-stage fan-disk blade slots. (a) Signal from the 0.46 mm (0.0182 in.) long by 0.27 mm (0.0105 in.) deep notch. (b) Signal from the 0.27 mm (0.0105 in.) long by 0.15

mm (0.0058 in.) deep notch

Example 3: Surface Flaws in Thread Roots.

The ECP method was evaluated for the detection of flaws in the thread roots of a titanium helicopter rotary wing-head spindle (Ref 4). The threaded end of the spindle is illustrated in Fig. 10. Notches were electrical discharge machined into the thread roots, as shown in Fig. 10. The ECP probe was positioned on the crest of the threads, resulting in a liftoff of 1.22 mm (0.048 in.) from the root. For scanning, the probe was held stationary while the spindle was simultaneously rotated and translated axially so that the probe followed the threads.

Fig. 10 Threaded end of a helicopter spindle showing a flaw location

The ECP data were obtained on a spindle containing three rectangular notches designated A, B, and C (Fig. 11). These notches were spaced 120° apart around the circumference in the root of one thread. As shown in Fig. 11, prominent ECP signals were obtained from all three defects, including the smallest one, which measured 0.64 mm (0.025 in.) long by 0.43 mm (0.017 in.) deep. These data exhibit several important characteristics. First, the signal background was far above electronic noise and was highly reproducible for repeat scans. The ECP sensitivity was limited only by the signal background obtained from the spindle itself, not by electronic noise. Second, signals were obtained when the probe passed directly over the defects in a thread and when the probe was located at adjacent threads, as indicated by the satellite signals designated A', B', and C' in Fig. 11. Signal polarity reversals were obtained when the probe was positioned away from the flaws in the adjacent threads; the satellite signals can be distinguished from the primary flaw signals by this polarity reversal. These characteristics are typical of the ECP method and demonstrate that it is not adversely affected by the complex specimen geometry imposed by the spindle threads.

Fig. 11 ECP signals from flaws A, B, and C in a spindle thread root with a probe on the crest of the threads. Signals obtained when the probe was located over the adjacent thread are designated A', B', and C'. Flaw dimensions are length by depth.

Example 4: Flaw Detection through Spindle Wall Thickness.

The helicopter rotary wing-head spindle described in Example 3 was also inspected with an ECP probe located in the spindle bore. In this evaluation, flaws in the thread roots were detected through the 9.32 mm (0.367 in.) spindle wall thickness.

Data obtained from a spindle that contained a flaw 7.75 mm (0.305 in.) long by 2.21 mm (0.087 in.) deep in the root of the first thread are shown in Fig. 12; the flaw is identified as I. A flaw signal was obtained when the probe passed directly over the flaw, and satellite signals (I') were obtained when the probe was located at the adjacent threads. The flaw-to-sensor distance was large because the inspection was performed through the wall thickness. This resulted in the satellite signal polarity reversal (evident in Example 3) occurring outside the region shown in the plot.

Fig. 12 ECP signals from defect I (7.75 mm, or 0.305 in., long by 2.21 mm, or 0.087 in., deep) in the spindle thread root with a probe located in the spindle bore. The signals obtained when the probe was located at adjacent threads are designated I'.

Example 5: Second-Layer Fastener-Hole Cracks.

The ECP method was evaluated on a C-5A aircraft spanwise splice-joint specimen to demonstrate the detection of fastener-hole defects in the second layer with the probe positioned on the outer surface of the first layer (Ref 5). A cross section of the two-layer splice joint is illustrated in Fig. 13. The aluminum specimen had top and bottom layer thicknesses of 3.8 mm (0.15 in.) (in the joint region) and a single row of 4.77 mm (0.188 in.) diam tapered titanium fasteners with countersunk heads. The specimen contained 2.5 mm (0.10 in.) deep and 5.1 mm (0.20 in.) long through-thickness radial notches in the second layer.

Fig. 13 Schematic of a two-layer structural-fastener configuration

The ECP probe was positioned on the top layer of the specimen and was scanned linearly along the row of fasteners (Fig. 14), with the sensor scan track 13.5 mm (0.53 in.) from the edge of the fastener holes. Strong signatures were obtained from hole No. 11, with a 5.1 mm (0.20 in.) notch oriented toward the scan track side of the fastener hole, and from hole No. 8, with a notch of the same size oriented toward the opposite side of the fastener hole from the scan track. A prominent signal was also obtained from the 2.5 mm (0.10 in.) notch in hole No. 4. Signals from unflawed holes are very small and are not evident at the sensitivity used to obtain the data in Fig. 14. These results show the potential for a rapid, linear scan inspection of fastener holes.

Fig. 14 ECP signals from second-layer flaws in a C-5A wing-splice specimen with the probe on the top layer. Flaw dimensions are the radial length of EDM notches.

Flaw Characterization

Both experimental data and theoretical modeling results suggest the potential capability of the ECP method for flaw characterization (Ref 6). Signal features related to crack characterization are most apparent when the scan direction is parallel with the crack length (perpendicular to \mathbf{j}_0) and directly over it, although these features can be extracted from other scan orientations. When a defect is scanned perpendicular to \mathbf{j}_0 , a bipolar signal is obtained, as in the scan shown in Fig. 11. The peak-to-peak signal amplitude and the peak-to-peak spacing can be related to the flaw interfacial area and the flaw length, respectively. These relationships will be discussed in this section. The details of theoretical modeling are discussed in Ref 1.

Experimental results were obtained from a single, half-penny-shaped fatigue crack grown with a laboratory fatigue machine in a Ti-6Al-4V rod-type tensile specimen. Fracture of identical specimens containing cracks grown under similar conditions showed that true half-penny-shaped fatigue cracks (2:1 aspect ratio) were obtained.

Theory and experiment were compared for the peak-to-peak signal amplitude as a function of the interfacial area of the crack (the planar area exposed if the specimen were fractured) and for the peak-to-peak separation as a function of crack surface length. These data are shown in Fig. 15. In Fig. 15(a), it can be seen that the theory predicts an approximately linear relationship between signal amplitude and the interfacial area of the crack. Experimental results show very close agreement with theory, indicating that the crack interfacial area for cracks of this type can be estimated by measurement of the ECP signal amplitude.

Fig. 15 Flaw characterization of half-penny cracks with the ECP method. (a) Comparisons between the ECP signal amplitude and the crack interfacial area. (b) Comparisons between the ECP signal peak-to-peak separation and the crack length

A plot of the ECP peak-to-peak separation as a function of crack surface length is shown in Fig. 15(b) for both theory and experiment. The theoretical model again predicts an approximately linear relationship between the peak-to-peak separation and the crack surface length over the range of lengths shown in the plot. Experimental data show a similar relationship, although some departure from linearity is observed. In both cases, a direct relationship is apparent between the peak-to-peak separation and the crack surface length. This shows that the surface length of the defect can be estimated by measuring the peak-to-peak separation of the ECP signal.

These correlations between the signal amplitude and the interfacial area of the crack and between the peak-to-peak separation and the surface length demonstrate that crack parameters can be obtained from signal features, thus establishing the feasibility of crack characterization. The results were obtained with half-penny-shaped defects. However, flaw characterization has also been demonstrated with other aspect ratios (Ref 3).

Magabsorption NDE

William L. Rollwitz, Southwest Research Institute

Introduction

MAGABSORPTION TECHNIQUES were originated by the author at Southwest Research Institute in June 1957. During electron spin resonance (ESR) measurements on a rocket propellant, it was noticed that an entirely different ESR signal was obtained from the propellant with Fe_3O_4 than from the same propellant without the iron oxide. When the microwave power for the ESR was turned off but the modulation was left on, the different signal disappeared. When the modulation power was turned off, the different signal also disappeared. Therefore, the signal appeared to depend not only on the microwaves but also on the modulation. The frequency of the signal itself was predominantly a second harmonic of the modulation frequency. When the magnetic field was varied from 0 to 0.4 T (4000 G), the ESR-type signal was obscured by the different signal. The shape of the different signal did not change as the field varied from 0 to 0.4 T (4000 G), but the amplitude did. The amplitude decreased almost linearly from 0.4 T (4000 G). The signal had the same shape but at a much lower level as the field increased. The signal was obtained from the sample with iron oxide but not from the sample without the Fe_3O_4 . The same type of signal was obtained from a nuclear magnetic resonance (NMR) detector at 30 MHz and from the ESR detector at 9240 MHz. When the modulation was stopped with the NMR and ESR detectors, the signal disappeared.

It was concluded that the shape of this different signal was independent of the frequency used; it was a function of the presence of Fe_3O_4 , and it had a fundamental frequency that was twice the modulation frequency. When the signal was observed before the amplitude detection in the NMR detector, it was found to be a 30-MHz carrier amplitude and/or frequency modulated with the different signal whose fundamental frequency was twice the modulation frequency. The phenomenon was not a resonance function of frequency. It was a function of the modulation field and was an amplitude modulation of the radio-frequency (RF) signal used.

A schematic diagram of a system specifically made to detect the different signal is shown in Fig. 1. The sample of Fe_3O_4 in Fig. 1 is in two alternating magnetic fields. The first is an RF field at 30 or 9240 MHz, and the second is a lower-frequency field at 60 Hz. The peak value of the RF field, H_{RF} is much lower than 8 A/m (0.1 Oe). The peak value of the lower-frequency field is much higher at around 8000 A/m (100 Oe). The RF detection coil is resonated at the radio frequency by the tuning capacitor in the NMR detector. The output of the NMR or ESR amplifier is the special signal amplitude modulated on the RF voltage. The different signal is separated from the RF by an amplitude detector. Because the shape of the different signal was found to be independent of frequency, a much lower frequency was used. For the first detection system specifically made to detect the different signal, a frequency of 0.5 MHz was chosen as shown in Fig. 1. An NMR-type detector was used at 0.5 MHz to detect the different signal.

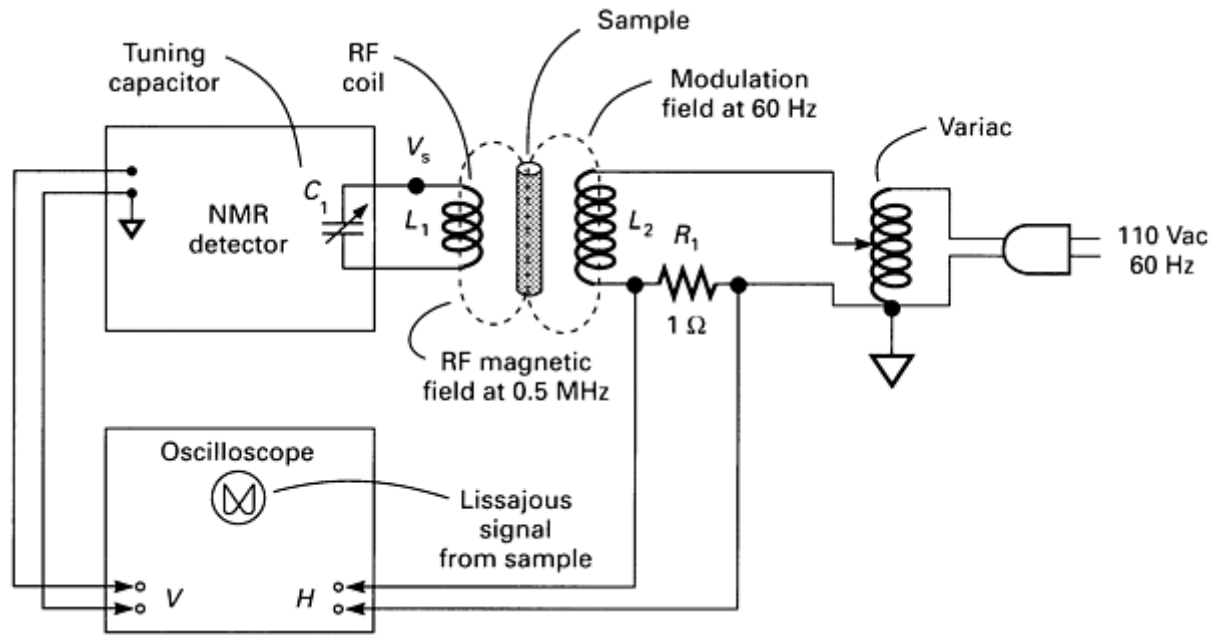

Fig. 1 Schematic of the special test system for the investigation of the detection of the different signal with an NMR-type detector

The resonant circuit of the NMR-type detector can be represented by the diagram in Fig. 2. It is possible to use the techniques used in nuclear magnetic resonance, which relate the very small changes in the energy absorbed by the nuclei from the RF magnetic field as an amplitude modulation of the RF voltage V_s across the RF coil in Fig. 2, where L is the inductance of the RF coil, R_L is the resistance representing the losses in the coil, and C is the capacitance required to tune the circuit to $\omega_0 = 2\pi \cdot 0.5 \cdot 10^6$ radians/s. The impedance, Z_0 , with no sample in the two fields, is:

$$Z_0 = \frac{L}{CR} \quad (\text{Eq 1})$$

Fig. 2 Resonant circuit showing the sample in the RF magnetic field

When there is a sample in the two magnetic fields, the impedance is changed to Z_s , which is:

$$Z_s = \frac{L}{CR} \frac{1}{1 + (4\pi FQP/\omega_o H_1^2)} \quad (\text{Eq 2})$$

where F is the filling factor of the sample in the RF magnetic field, P is the power absorbed by the resonated nuclei sample, Q is the figure of merit of the resonant circuit where $Q = \omega_o L/R$, and H_1 is the peak amplitude of the sinusoidal RF magnetic field. The change of impedance caused by the power absorption by the sample is:

$$\Delta Z = Z_o - Z_s = Z_o \frac{4\pi QFP}{\omega_o H_1^2} \quad (\text{Eq 3})$$

where

$$\frac{4\pi FQP}{\omega_o H_1^2} \ll 1$$

and

$$1 + \frac{4\pi QFP}{\omega_o H_1^2} \simeq 1$$

Equation 3 shows that the change in the resonant impedance of the detection circuit is directly proportional to the power absorption (the rate of energy absorption) by the sample from the RF magnetic field. The nuclear magnetic resonance signal is also directly proportional to the power absorbed by the chosen nuclei from an RF magnetic field. The RF power absorbed by the nuclei is proportional to the complex susceptibility of the sample, which is:

$$\chi = \chi' - \chi'' \quad (\text{Eq 4})$$

The power absorbed from the RF coil by the sample will therefore have two components--one in phase with the RF magnetic field proportional to χ'' and a second one 90° out of phase with the RF magnetic field proportional to χ' . The first is called the in-phase or absorption component of the NMR signal, and the second is called the quadrature-phase or dispersion component of the signal. The different signal also has in-phase and quadrature-phase components. Therefore, the different signal is directly proportional to the power absorbed by the susceptibility of the sample of iron oxide. The susceptibility has both an in-phase component and a quadrature-phase component.

In October 1957, the author received funding for a program to study the phenomenon in more detail. Just before the project was undertaken, it was found that W.E. Bell of Varian Associates had discovered a similar different signal. He had termed the phenomenon magnetoabsorption and had written a paper with that title in 1956 (Ref 1). Bell attributed the phenomenon to magnetoresistance and called it magnetoabsorption because the apparatus measures the RF absorption in the test specimen as a function of the applied magnetic field.

The magnetoresistance phenomenon is described by Bozorth as the change in the electrical resistivity of iron when it is magnetized (Ref 2). In most magnetic materials, this magnetoresistance is an increase of resistivity with magnetization when the current and magnetization are parallel and a decrease when they are at right angles to each other; the change in resistivity is independent of the sense of field or induction and, in this respect, is like magnetostriction (Ref 2). Reference 2 also gives the curve of $\Delta\rho/\rho$ as a function of the applied field strength; this magnetoresistance curve for nickel is shown in Fig. 3. The magnetoresistance curve has a butterfly shape and hysteresis. The magnetoresistance change is 10 to 15% of the resistivity at saturation, $\Delta\rho_s$. Reference 2 also states that the change in resistance (increase or decrease) is beyond the knee of the magnetization curve.

Fig. 3 Hysteresis of the magnetoresistance of nickel as plotted against applied field strength. Source: Ref 2

The effects of both tension and magnetic field on the resistivity of ferromagnetic materials are discussed in Ref 2 with the aid of the domain illustrations in Fig. 4. According to Ref 2, domains having an initially haphazard distribution of orientation (Fig. 4a) are aligned parallel by a strong (saturating) magnetic field (Fig. 4b). Tension applied to an unmagnetized material, with positive magnetostriction, orients the domains along the axis of tension with one-half of the domains antiparallel to the others (Fig. 4c). Because the resistivity depends on magnetization and increases with increasing magnetization, each domain will contribute to the resistivity an amount depending on its orientation. This contribution will be the same for parallel and antiparallel orientations; for the specimen as a whole, $\Delta\rho$ will be the same for Fig. 4(b) and 4(c) and will be $\Delta\rho_s$. When the magnetostriction is negative, tension orients the domains at right angles to the direction of tension, and the resistivity decreases (Fig. 4d). A magnetic field applied subsequently causes the domains to rotate so as to increase the resistivity (Fig. 4e). When a material having positive magnetostriction is subjected to strong tension, subsequent application of a magnetic field will cause 180° rotations (of the domains) almost exclusively, and these will have no effect on resistivity (going from Fig. 4c to e).

Fig. 4 Domain interpretation of the effects of field and tension on resistance. At right, domain vectors have been moved to a common origin. (a) Unmagnetized. (b) Saturated. (c) Tension applied (positive magnetostriction). (d) Tension applied (negative magnetostriction). (e) Tension and strong field. (f) Residual induction

Because of the above discussion from Ref 2, the term magnetoabsorption was adopted by the author for the phenomenon, and the internally sponsored work at Southwest Research Institute was undertaken using the title "Magnetoabsorption" (Ref 3). However, the term magabsorption is now being used because the techniques have developed differently from the magnetoabsorption described by Bell (Ref 1).

One of the magabsorption measurements described in Ref 3 involved measurements on iron carbonyl powders with a bridge-type NMR detector. The in-phase or the loss component and the quadrature or the reactive component of the magabsorption signal were separately detected and recorded. They were displayed as Lissajous figures where the

magabsorption signal (in-phase or quadrature-phase) was on the vertical axis of the oscilloscope and a voltage proportional to the 60-Hz modulation was fed to the horizontal axis. The in-phase (resistive) and the quadrature-phase (reactive) components of the magabsorption signals from a 3 μm (120 $\mu\text{in.}$) sample of carbonyl iron are shown in Fig. 5. The shapes of the quadrature-phase signals are quite different from the in-phase signals in Fig. 5. The resistivity or the in-phase signals have higher harmonic content than the quadrature-phase or reactive signals. Other results obtained during the research summarized in Ref 3 are discussed in the section "Measurements and Applications" in this article.

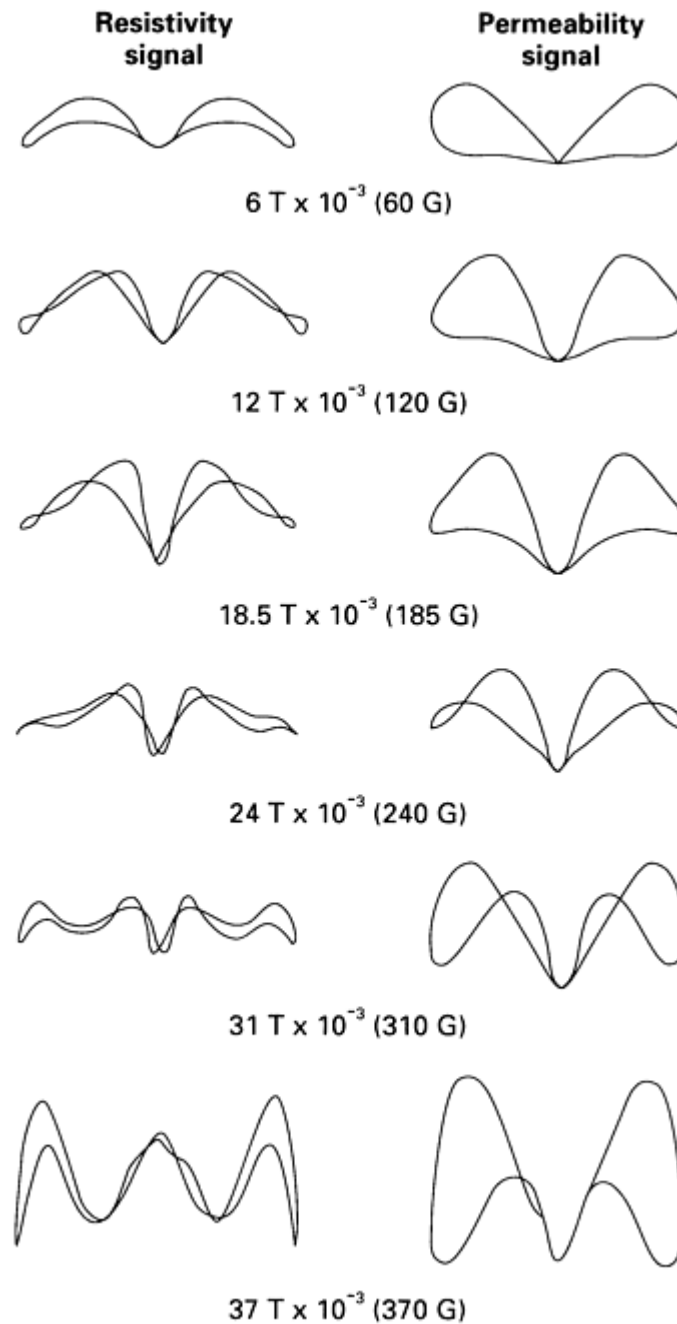

Fig. 5 Comparison of resistivity and permeability components for a 3 μm (120 $\mu\text{in.}$) sample of iron carbonyl

The above discussion of the effect on the magnetoresistance caused by an applied magnetic field and an applied stress on a piece of ferromagnetic material, coupled with the differences between the magabsorption signals from nickel powder and nickel plating on a brass screw, led to the belief that magabsorption could be used to measure the stress and material properties of ferromagnetic materials and nickel-plated nonferromagnetic materials. Research in this area was conducted, and it resulted in four final reports (Ref 4, 5, 6, 7). This work is briefly described in this article, along with information from Ref 8. Two patents have also been issued for this technology (Ref 9, 10).

Magabsorption NDE

William L. Rollwitz, Southwest Research Institute

Magabsorption Theory

Magabsorption involves the measurement of the change in the energy absorbed from the field of an RF coil, by a ferromagnetic material placed in the field of the coil, as a function of the strength of a magnetic bias field also applied to the materials. The general concept of magabsorption is shown in Fig. 6. The ferromagnetic material is in both the RF magnetic field of strength H_{RF} and the bias magnetic field of strength H_B . The value of H_{RF} is much smaller than H_B .

Fig. 6 General concept of magabsorption showing the RF field and the bias field in the material

A thorough understanding of the basic electrical and magnetic properties of ferromagnetic materials is essential to the theoretical treatment of magabsorption. With these properties, a solution can be obtained that has correlated very well with experimental measurements. However, because some of these properties are difficult to describe mathematically, an exact solution is difficult if not impossible. Therefore, simplifying approximations are required to obtain a useful solution.

B-H Characteristics. When a magnetic field is applied to any material, a resulting magnetic flux density, B , is induced. The intensity of the applied magnetic field is called the magnetic field intensity, H . The resulting flux density, B , is directly proportional to the magnetic field intensity, H .

This relationship is normally written in the following form:

$$B = \mu H \quad (\text{Eq 5})$$

The constant of proportionality, μ , is called the permeability, which may be nonlinear. When a ferromagnetic material is subjected to a magnetic field, the flux density, B , is not a linear function of the magnetic field intensity, H . In other words, the permeability, μ , is not a constant. In addition to this nonlinearity, the permeability depends on the past magnetic and stress history of the ferromagnetic material. This dependence on past magnetic and stress history is known as hysteresis.

The hysteresis loop is explained by the concept of magnetic domains. Each domain consists of a group of atoms acting as a small magnet. The group of atoms in a small region forms a small magnet because molecular interactions cause the molecular magnetic moments to be aligned parallel to one another. In other words, each domain is spontaneously magnetized to saturation even in the absence of an external magnetic field. Because the directions of magnetization in different domains are not necessarily parallel to one another, the resultant magnetic flux density may be zero. When the specimen is placed in a magnetic field, the resultant magnetic flux density can be changed by two different mechanisms. The first is movement of a domain wall, and the second is directional rotation of the magnetic field of the domain. These two domain processes must stop at a high magnetic field intensity because all the domains become aligned with the applied magnetic field. This limiting process causes the nonlinearity of the $B-H$ characteristics. Also, the stability of different domain orientations causes the hysteresis of the $B-H$ characteristics. Therefore, the shape of the hysteresis loop and the domain orientation are dependent on the type of material, its stress history, and its magnetic history.

Reversible Permeability. If at some point on the hysteresis loop the magnetic field intensity is reversed from its normal direction, the resulting magnetic flux density will not follow the original hysteresis loop. This deviation from the original hysteresis is explained by the concept of the domain. If the magnetic field intensity is decreased before it reaches the previous limit, the orientation stability of the domain will cause hysteresis.

If the deviation of the magnetic field intensity is a small cyclic field, ΔH , super-imposed on a large bias field, H_B then a smaller inner hysteresis loop will be formed, as shown in Fig. 7. Note that the magnetic biasing field, H_B , is the magnetic field that determines the larger external hysteresis loop. As the size of the small cyclic deviation in the magnetic field intensity, ΔH , is decreased, the resulting change in the magnetic flux density, ΔB , is decreased. As ΔH approaches zero, the ratio $\Delta B/\Delta H$ approaches a limiting value $\mu_o\mu_r$:

$$\lim_{\Delta H \rightarrow 0} \frac{\Delta B}{\Delta H} = \mu_o\mu_r = \mu \quad (\text{Eq 6})$$

where μ_o is the permeability of free space (in henries/meter), μ_r , is the relative reversible permeability (unitless), and μ is the reversible permeability (in henries/meter).

Fig. 7 Superimposed hysteresis loops

The reversible, or alternating current (ac), permeability is the property of great interest in the study of magabsorption. Reversible permeability is dependent on the reversible boundary displacement and reversible rotation of the domains in the ferromagnetic material. Therefore, the reversible permeability is dependent on the type of material and its magnetic and stress history. The relative reversible permeabilities for unannealed nickel, annealed nickel, and iron are shown in Fig. 8. For all the relative reversible permeability curves in Fig. 8, the upper portion of the curve is observed for an increasing bias field, and the lower portion of the curve is observed for a decreasing bias field. Assuming that the ferromagnetic material was originally demagnetized, the plot of μ_r versus H_B is symmetrical about $H_B = 0$.

Fig. 8 Relative reversible permeability curves for (a) unannealed nickel wire, (b) annealed nickel wire, and (c) iron thermocouple wire

A block diagram of an apparatus used to measure relative reversible permeability is shown in Fig. 9. A small cyclic deviation, ΔH , in the magnetic field intensity was generated with an exciting coil. The change in the magnetic flux density was detected with two identical pickup coils. The two pickup coils were connected so that the sum of their output voltages would be determined by the derivative of the difference in the magnetic flux in the two coils. If a sample is placed in one of the pickup coils, the output voltage is directly proportional to the derivative of the magnetic flux in the sample. Using an electronic integrator to integrate the output voltage of the two pick-up coils, a voltage is obtained that is directly proportional to the magnetic flux in the sample. The output voltage of the integrator was displayed versus the cyclic deviation in the magnetic field intensity on an oscilloscope. The resulting oscilloscope display is the smaller inner hysteresis loop shown in Fig. 7. A biasing magnetic field was applied with the use of larger field coils.

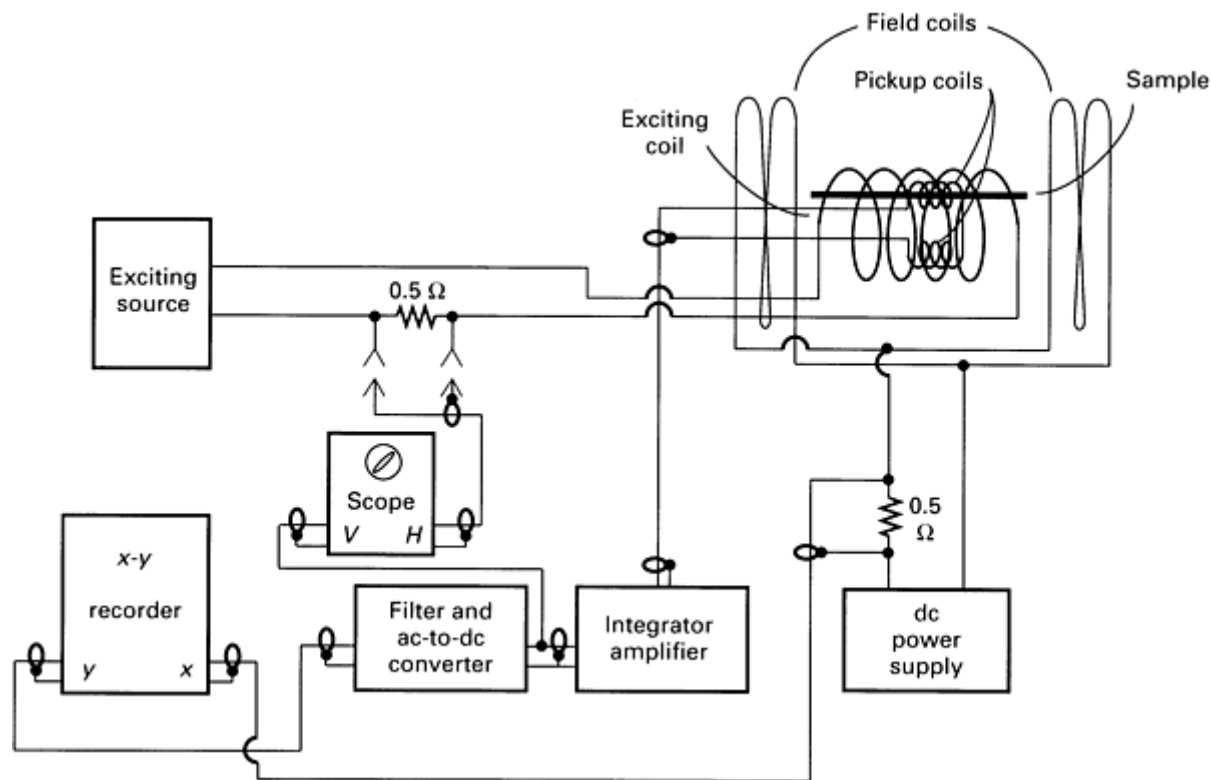

Fig. 9 Block diagram for relative reversible permeability apparatus

If the cyclic deviation in the magnetic field intensity, ΔH , is held constant in magnitude, the cyclic deviation in the magnetic flux density, ΔB , is directly proportional to the relative reversible permeability, μ_r . The output of the integrator can be converted to dc voltage with an ac-to-dc converter, which can be displayed on an x-y recorder versus the biasing magnetic field, H_B .

The Magabsorption Phenomenon. The basic arrangement of magabsorption measurements is shown in Fig. 6. When H_B varies slowly in the material and B is plotted as a function of H , the B/H hysteresis loop of Fig. 10 is obtained. If H_B is applied sinusoidally, the B/H curve will be repeated at the same rate, and B is not only distorted in the shape relative to the sinusoidal magnetomotive force but also shifted in phase. As the frequency of H_B increases, both the distortion in shape and the shift in phase increase. If another magnetomotive force, H_{RF} , of smaller magnitude and higher frequency is added to the material (Fig. 6), there will be a second B_{RF}/H_{RF} loop for the material. This second hysteresis loop is shown at one value of H_B in Fig. 10. As H_B varies through one sine wave, the magnitude and phase of B_{RF} also change. If the RF permeability, $B_{RF}/H_{RF} = \mu_{RF}$, is graphed as a function of H_B , the curve in Fig. 11 is obtained. This RF permeability hysteresis curve is also a function of the frequency and the amplitude of the magnetomotive force, H_B .

Fig. 10 Hysteresis loops of the material under two magnetomotive forces, H_B and H_{RF}

Fig. 11 RF permeability as a function of the alternating magnetomotive force, H_B , at a fixed value of the RF magnetomotive force, H_{RF} . The numbers on the curves correspond to numbers on the curve of H_B in Fig. 10.

The variation in μ_{RF} as a function of H_B is the basis for the magabsorption phenomenon. Because the RF permeability, μ_{RF} , changes as H_B is varied sinusoidally, the energy absorbed by the material from the RF coil also varies as a function of H_B . These variations in the absorption of RF energy by the material can also cause changes in the impedance of the RF coil. For example, if a cylindrical sample is placed in the coil as shown in Fig. 12, the change in coil impedance, ΔZ , is related to the energy absorbed, according to Eq 3.

Fig. 12 Basic magabsorption circuit composed of an inductance, L , with the sample core in a biasing field, H_B , and tuned to resonance with capacitance C . The circuit is fed from an RF voltage $e_i = E_i \cos(\omega t)$

The variations in coil impedance from magabsorption involve a resistive change, ΔR , and a change in inductance, ΔL . Both of these changes can be related to the RF permeability, μ_{RF} . Because the RF hysteresis loop has a shape other than a straight line (that is, an ellipse), if H_{RF} is $H_{RF} \exp i\omega t$, the RF induction is $B_{RF} \exp i(\omega t + \theta)$. Therefore, the RF permeability is a complex variable:

$$\mu_{RF} = \mu'_{RF} + i\mu''_{RF} \quad (\text{Eq 7})$$

where μ''_{RF} is the loss (ΔR) term and μ'_{RF} is the dispersion (ΔL) term. For a cylindrical sample of radius a and a coil of radius c as shown in Fig. 12, the solution of the Maxwell equations resulted in the following normalized values of ΔR and ΔL for a ferromagnetic material (Ref 4):

$$\Delta R = \frac{\omega_{RF} L_0}{c^2} (-0.18 \times 10^{-7} + 2.23 \times 10^{-4} \cdot a \cdot \sqrt{\mu''_{RF}}) \quad (\text{Eq 8})$$

$$\Delta L = \frac{\omega_{RF} L_0}{c^2} (0.08 \times 10^{-7} - a^2 + 2.22 \times 10^{-4} \cdot a \cdot \sqrt{\mu'_{RF}}) \quad (\text{Eq 9})$$

where c is larger than a and μ'_{RF} and μ''_{RF} are functions of the bias field H_B . Because there is no simple equation for μ_{RF} as a function of H_B (Fig. 11), the shape of ΔR and ΔL is most easily obtained graphically, as shown in Fig. 13. The resultant curve, in the top right-hand corner, is either the magabsorption amplitude signal of the loss (ΔR) component or the dispersive (ΔL) component.

Fig. 13 Graphical derivation of the magabsorption curve from the permeability and $F(R)$ and $F(L)$ curves

Therefore, the variations in the absorption of RF energy by the material produce a magabsorption signal, which causes the resistance and inductance of the RF coil to change. The basic or fundamental frequency of the magabsorption signal is twice that of the magnetic bias frequency. If H_B has a frequency of 60 Hz, the magabsorption signal has a basic frequency of 120 Hz. However, because the magabsorption signal is not a pure sinusoid (Fig. 14), the entire frequency content of the magabsorption signal has harmonics of the basic frequency. Therefore, the magabsorption signal, v_{MA} , is:

$$v_{MA} = v_o + v_n \sum_{n=0}^{\infty} \cos (2n\omega_B t + \phi_n) \quad (\text{Eq 10})$$

where ω_B is the magnetic bias angular frequency and ϕ_n is the phase angle of the harmonic order, n .

Fig. 14 Time plot of H_B and μ_{RF} . Although the shape of μ_{RF} is distorted relative to a sinusoid, the basic frequency of μ_{RF} is twice that of H_B .

A more extensive derivation of the magabsorption signal is discussed in a report of work done for the Air Force Materials Laboratory in Dayton, OH (Ref 4). It was from this report that Eq 8 and 9 were obtained.

Magabsorption Detection

The phenomenon of magabsorption changes the resistance and inductance of the RF coil, which causes the modulation of the RF voltages in the circuit shown in Fig. 6. The RF voltage across the resonant circuit is amplitude modulated by the change in resistance of the coil and is phase or frequency modulated by the change in inductance of the coil. Of course, there is a small additional amplitude modulation caused by the phase modulation. Therefore, if the voltage across the resonant circuit of Fig. 6 is demodulated through both an amplitude detector and a phase detector using a voltage, proportional to the bias current, as a reference signal, the magabsorption amplitude signal is obtained from the amplitude detector, and the magabsorption frequency signal is obtained from a phase or frequency detector.

If the voltage generator e_s and the resistance R_s are those of a self-sustained oscillator, the voltage across the resonant circuit is amplitude modulated by means of the magabsorption amplitude signal, and the frequency of oscillation will be modulated by the magabsorption frequency signal. If the oscillator is operated at a high level of output (A, Fig. 15), the detection sensitivity will be weak for the amplitude modulation. When the oscillator is operated at its marginal point or the point close to where oscillations cease (B, Fig. 15), the slope for the voltage change as a function of resistance change in the coil is very large, and the voltage across the resonant circuit is highly modulated by the magabsorption amplitude signal. Because the resonant circuit alone controls the frequency, the frequency modulation is relatively independent of the oscillation level. It will be true, however, that at the high levels of oscillation the effective Q of the RF coil will be low, and the amplitude modulation of the oscillator output by the magabsorption amplitude signal will be reduced. Under this condition, the amplitude modulation caused by the frequency modulation will be reduced.

Fig. 15 Oscillation voltage as a function of the resonant circuit conductance. A, operation point for low sensitivity; B, operation point for high sensitivity

The amplitude modulation of the RF signal by the magabsorption signal in Fig. 13 has a fundamental frequency and harmonic frequency components at twice the frequency of the bias field. If ω_B is the bias field frequency, the magabsorption signal frequencies are at $2\omega_B$, $4\omega_B$, $6\omega_B$, and so on. If ω_{RF} is the frequency of the RF field in Fig. 6, the equation for the modulated RF signal, v_s , across the resonant LC circuit in Fig. 6 is:

$$v_s = \sum_{n=0}^6 \left(1 + \frac{V_B}{V_{RF}} A_n \cos 2n\omega_B t \right) \cdot (V_{RF} \cos \omega_{RF} t) \quad (\text{Eq 11})$$

where V_B and V_{RF} are the peak amplitudes of the bias and RF fields and A_n is a multiplier to give the amplitude of the n^{th} harmonic of the magabsorption signal.

With a marginal oscillator as a magabsorption detector, the magabsorption amplitude signal can be obtained with an amplitude modulation detector. The magabsorption frequency signal, however, will be obtained with a frequency discriminator or similar frequency demodulator. Both of these voltages from the demodulators will be similar in shape to the magabsorption curve, and they will be nearly of equal amplitude for the same or similar demodulator constants. Further, each signal can be described by a Fourier series, as indicated in Eq 10.

General Detection Methods. The magabsorption signal as modulation on a carrier can be detected in three ways. First, the modulated carrier can be amplified and the modulation recovered by a diode detector, a coherent detector, or a mixer. This would yield the ΔR component of the magabsorption signal.

In the second method, a receiver or narrow-band amplifier is set to one or more of the sideband frequencies, and the amplitude of that sideband is detected by amplitude demodulation. For example, if the bias frequency, f_B , is 80 Hz and the RF frequency, f_{RF} , is 10 kHz, the magabsorption modulated carrier will have components at 10,160, 10,320, 10,480, 10,640, 9840, 9680, 9520, and 9360 Hz if the magabsorption signal contains only four harmonics. Therefore, the presence of a magabsorption signal could be detected by a narrow-band amplifier tuned to any one of the frequencies given above. Because the 10,160 Hz and 9840 Hz components are the strongest, they will provide the most sensitive detection.

The third method is to amplify the voltage across the resonance circuit and to detect the frequency modulation. This would give the ΔL component of the magabsorption signal. The amplitude demodulation (the first method) gives a mixture of both the ΔR and the ΔL components of the magabsorption signal. In most cases, however, the ΔR component is much larger than the ΔL component because the frequency modulation (ΔL) causes only a small amplitude modulation relative to that caused by ΔR .

The basic magabsorption circuit used with the cylindrical sample of radius a is shown in Fig. 12. The magabsorption phenomenon causes a change in both the resistance, ΔR , and the inductance, ΔL , of the magabsorption detection coil. These variations change the coil impedance, Z_c , by an amount ΔZ such that $Z_c = \Delta Z + Z_o$. The magnitude of the voltage across the parallel resonant circuit at resonance is $V_c = (L/RC)I_c$, where $I_c \cong (E_i/R_i) \cos(\omega t)$, because R_i is much larger than Z_c . For all magabsorption measurements, a high- Q coil is used. A high- Q coil is defined as one in which $Q = (\omega L/R) > 10$.

For magabsorption measurements on wire, the filling factor, F , which is the ratio of the volume of the wire sample to the volume inside of the RF coil, is less than 0.01. This value of the filling factor keeps the loaded Q of the coil also greater than 10. The theoretical derivation has shown that $\Delta R \cong \omega \Delta L$. Taking into account the above assumptions and because $R_i \cong 10 L_o/R_o C$ and ΔR is less than $0.1 R_o$, the voltage change, ΔV , can be approximated within 1% to be directly proportional to the ΔR from magabsorption. The change in resonant frequency can also be shown to be directly related to ΔL .

The Magabsorption Bridge Detector. The voltage across the resonant RF circuit in Fig. 12 is $V_c + \Delta V$. Although the actual value is approximately $0.1 E_i$, there may be problems in amplifying $V_c + \Delta V$ because of the dynamic range of many amplifiers. Therefore, the bridge circuit in Fig. 16 has been used to eliminate V_c and to give an output of only ΔV . The left resonant circuit contains the material sample, while the right resonant circuit contains no sample. The rectified voltages across each resonant circuit are detected, subtracted, filtered, and supplied to the output. With no magabsorption signal, the output is zero. With a magabsorption signal, the output of the bridge in Fig. 16 is:

$$V_o = \frac{V_c \cdot \Delta R}{11R_o} \quad (\text{Eq 12})$$

The magabsorption bridge is used when the variation rate for ΔR is very low (<0.1 Hz). At low variation rates, the output is very stable with changes in time, temperature, and input voltage. The use of the bridge reduces stringent requirements on the amplitude stability and the frequency stability of the source for the input to the bridge at 500 kHz. This bridge was used for all of the earliest magabsorption measurements.

Fig. 16 Magabsorption measurement RF bridge, in which the peak value of two similar simple circuits are subtracted to give the magabsorption signal

When the bias field is changed or varied, the bridge must be rebalanced for each sample unless a complicated automatic balancing circuit is used. The need to rebalance the bridge can be eliminated if the resonant circuit in Fig. 12 is the resonant circuit of an oscillator.

The Marginal Oscillator Magabsorption Detector. Figure 17 shows the schematic of the circuit when the RF coil is part of an active oscillator circuit. This type of circuit can also be used to detect the ΔR component of the magabsorption signal. This detection will occur only if the oscillator is made to operate as close to Class A or linear conditions as possible. As such, it will be an efficient magabsorption detector.

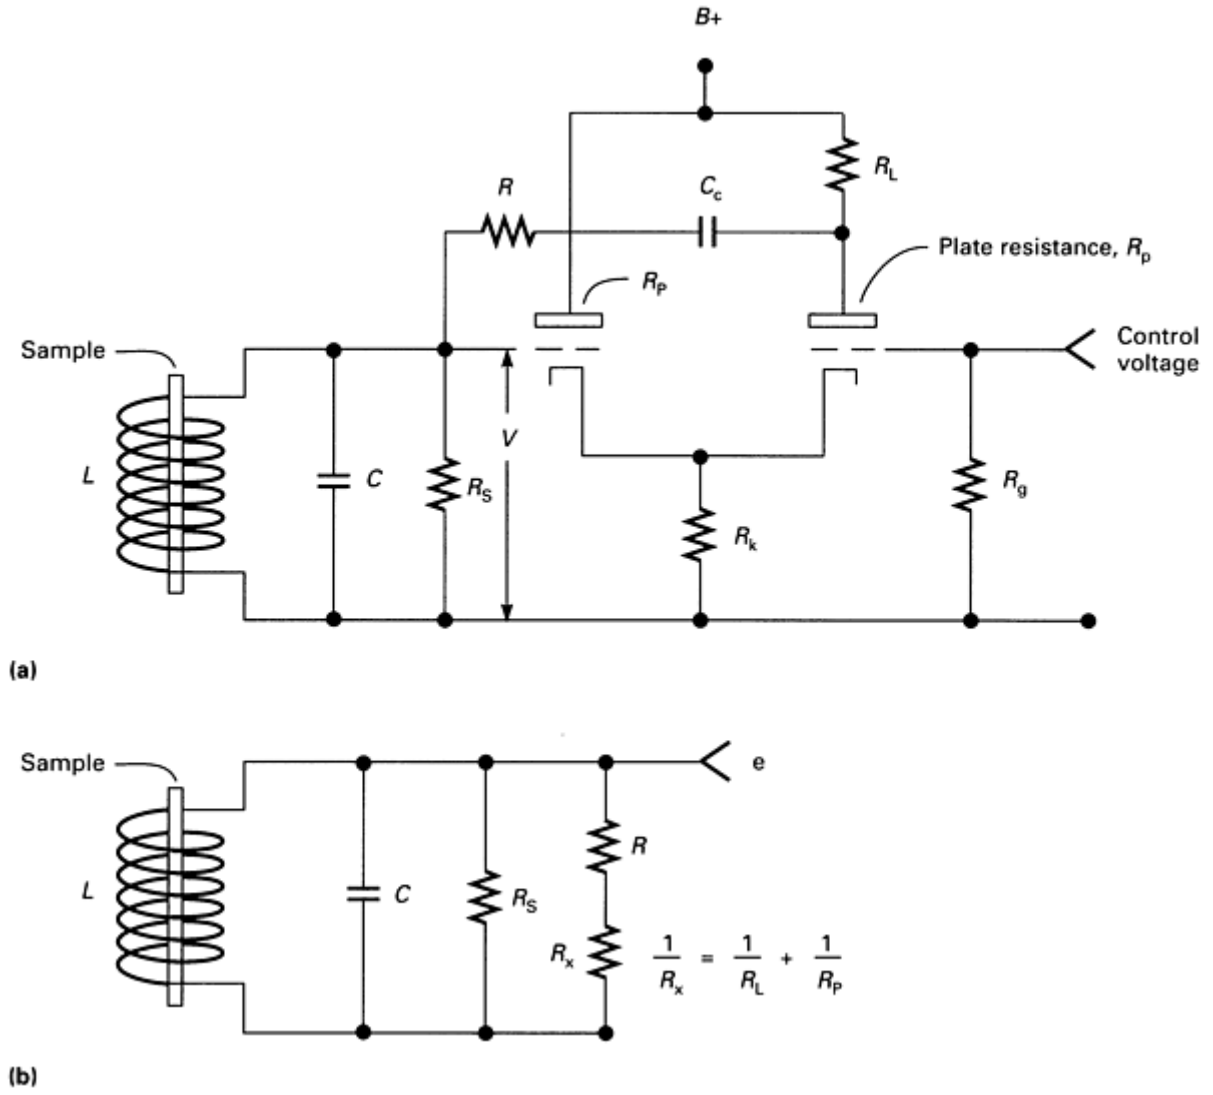

Fig. 17 Marginal oscillator basic circuit (a) and equivalent circuit (b)

The detector illustrated in Fig. 17 is called a marginal oscillator because it is operated on the edge of dropping out of oscillation. The presence of a magabsorption sample in the RF coil will change both the series resistance and the inductance of the coil. Instead of ΔL changing only the resonant frequency of the RF coil, ΔL changes both the driving frequency of the oscillator and the resonance frequency of the RF coil by the same amount. Therefore, the resonant frequency of the coil and the frequency fed to the RF coil are the same. They are locked together because the RF resonant circuit controls both. In this way, it is possible to measure the effect of the sample both on the losses from the coil and the inductance of the coil. As stated previously, the losses change the amplitude of the oscillation, while the dispersion changes the oscillation frequency.

For an analysis of the effects of the magabsorption phenomenon on a marginal oscillator, assume that the ratio of the radius of the sample to the radius of the RF coil is such that the effect of the sample is small compared to the magnitudes of the coil inductance and effective resistance. The sample effect will therefore be more like that of a paramagnetic material. The inductance of the coil shown in Fig. 12 or 17 can then be written as:

$$L = L_o(1 + F\chi) \quad (\text{Eq 13})$$

where L_o is the inductance without the sample, F is the filling factor of the coil-sample system, and χ is the susceptibility of the sample. The susceptibility is usually defined for only diamagnetic or paramagnetic substances by the relation:

$$B = \mu_0 H(1 + \chi) \quad (\text{Eq 14})$$

where $\chi = \chi' - i\chi''$; χ'' is the loss term and χ' is the dispersion term.

For paramagnetic materials, the susceptibility is of the order of 10^{-4} to 10^{-6} . For ferromagnetic materials, the susceptibility may be many orders of magnitude larger. However, the susceptibility seen by the RF coil is very small when the filling factor (volume of the core divided by the volume of the coil) for the ferromagnetic core is kept small. Therefore, Eq 14 can be written as:

$$B = \mu_0 H(1 + F\chi) \quad (\text{Eq 15})$$

when the filling factor F is considered. The filling factors used are in the range of 10^{-3} to 10^{-4} . Therefore, the ferromagnetic core material with a large susceptibility and a small filling factor can have the same effect as a paramagnetic material with a small susceptibility and a unity filling factor. With this approach, the frequency shift, Δf , of the oscillator with a sample in the coil is:

$$\Delta f = \frac{F\chi'}{2\pi L_0 C} \quad (\text{Eq 16})$$

and the change in conductance, ΔG , of the resonant circuit is:

$$\Delta G = \frac{F\chi''}{\omega L_0} \quad (\text{Eq 17})$$

To keep the resonance condition, then, the frequency must be changed by the factor Δf (Eq 16). If this change in frequency is accomplished automatically by making the resonant circuit the frequency-controlling circuit of an oscillator, ΔG can be measured by determining its effect on the impedance of the resonant circuit. The value of Δf can be obtained by measuring the frequency shift of the oscillator. With ΔG and Δf , the values of χ'' and χ' can be calculated and related to the material of the sample inserted in the coil and to the effects of the magnetic bias field.

When the resonant circuit illustrated in Fig. 17 undergoes an impedance change from any variation of χ'' , the change in conductance (Eq 17) will result in a change in the voltage across the resonant circuit. If the value of ΔG is much smaller than $1/R_s$ of the circuit in Fig. 17(b) and if the first approximation of linearity is assumed, then the voltage change in the oscillator can be shown to be directly proportional to the conductance change caused by the sample. Moreover, if the conductance change, ΔG , is sinusoidal, a phase change is introduced that will shift the phase of the sidebands relative to the oscillation frequency. Figure 18 shows the block diagram of a system for measuring ΔG versus the voltage change in the oscillator.

Fig. 18 Block diagram of the system for measuring ΔG versus the voltage output of a marginal oscillator

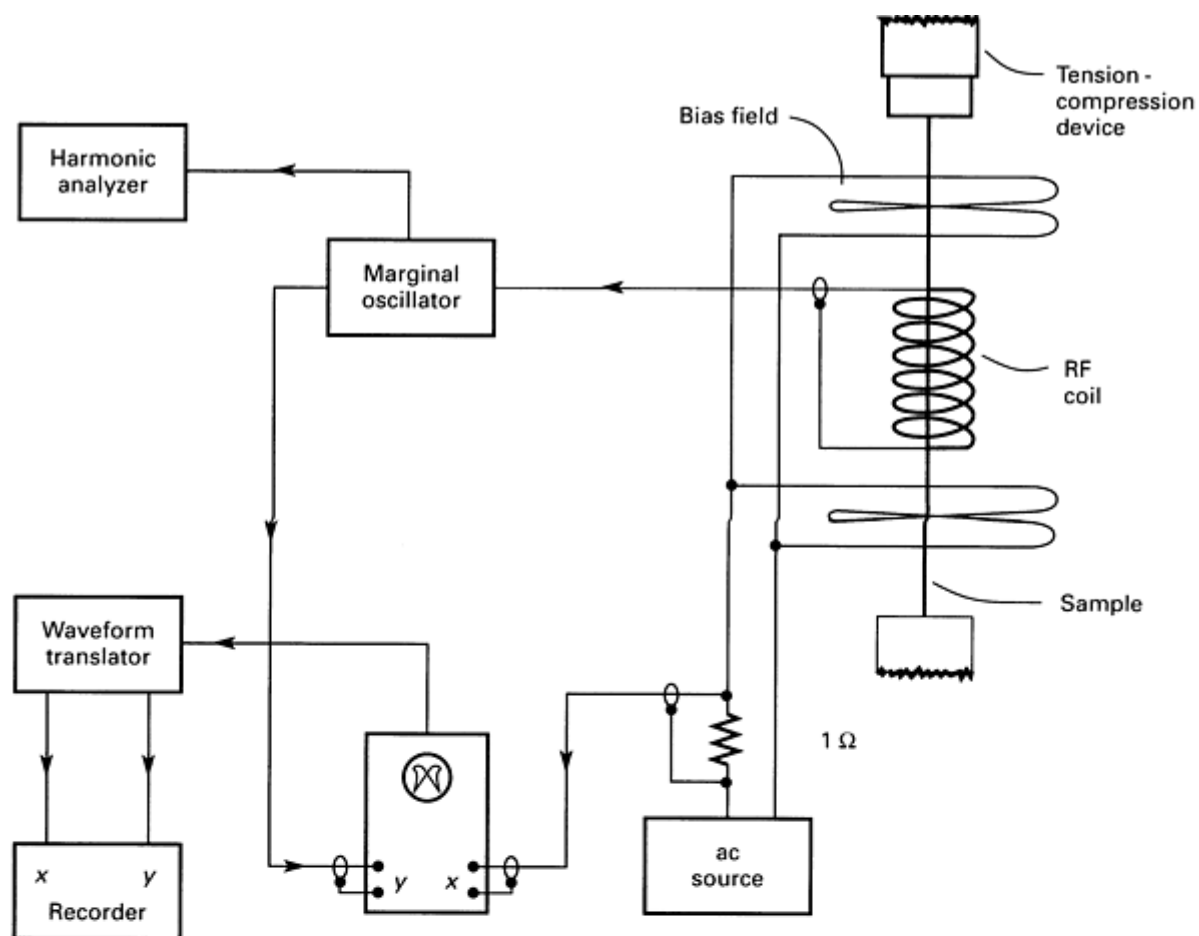

It is also interesting to compare a marginal oscillator with the passive resonant circuit of Fig. 12. The effective gain of the oscillator circuit over the passive circuit can range from 5 to 10 with readily attainable values of circuit constants. The oscillator produces a gain over that of the passive system by decreasing the bandwidth or by increasing the effective quality factor. Because the signal is amplified and detected in both cases, the marginal oscillator offers a gain advantage that may improve the signal-to-noise ratio.

Magabsorption NDE

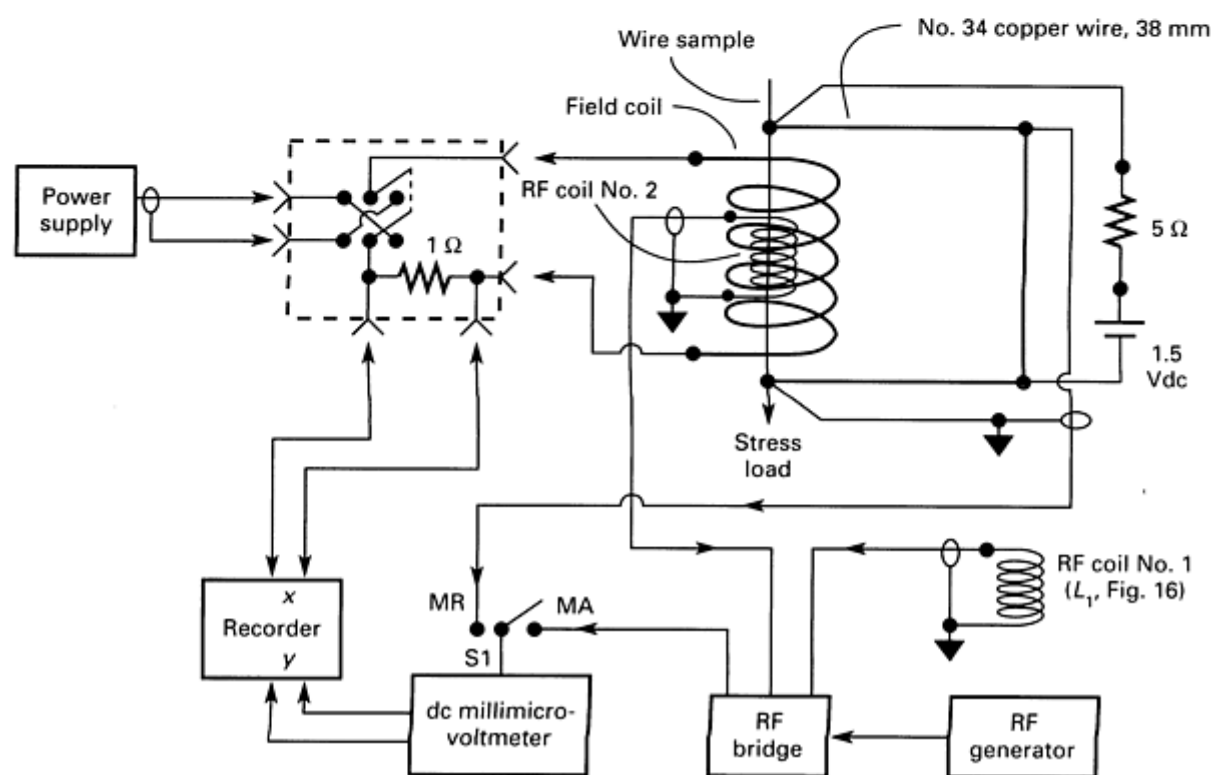

William L. Rollwitz, Southwest Research Institute

Measurements and Applications

The basic method of magabsorption measurement requires a ferromagnetic material that is excited by both an RF magnetic field and another magnetic field with a lower frequency and a much higher field strength. This basic arrangement is shown in Fig. 19 with a stressed wire placed inside the RF coil. Magabsorption measurements can also be performed with magabsorption detection heads (Fig. 20) that are placed on the surface of a specimen.

In the work discussed in Ref 3, 4, 5, 6, and 7, magabsorption measurements were performed on various materials in different applications. Some of the magabsorption signals from a variety of materials are given in Fig. 21. The potential applications of magabsorption measurements, which are described in more detail in the following sections, include:

- Magabsorption measurements on ferromagnetic and ferrimagnetic powders, along with a particle size effect in the magabsorption measurements of the powders that might be used to determine the size or range of particles
- Magabsorption measurements of applied and residual stress in ferromagnetic materials or nonferromagnetic materials having a ferromagnetic coating
- Magabsorption measurements of residual magnetism in ferromagnetic and nonferromagnetic materials (such as some stainless steels) in which the yield point or phase transition temperature has been exceeded

Magabsorption Measurements of Powders

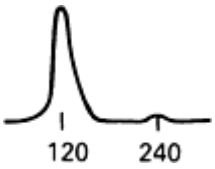

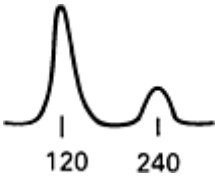

The first magabsorption measurements were made using iron oxide and iron carbonyl (Ref 3). The first measuring instrument was a Q-meter made by Boonton. When a sample is inserted into the coil, the Q of the coil changes from the Q value without a material in the coil. The changes in Q with the addition of samples of iron oxides and carbonyl iron were too small to give a measurable change in Q . However, as the radio frequency was changed from 0.7 to 3.0 MHz, the Q value of the RF coil had a maximum at a different frequency for the four particle diameters used (3, 5, 10, and 20 μm). The 3 μm (120 $\mu\text{in.}$) sample peaked at 2.6 MHz, the 5 μm (200 $\mu\text{in.}$) sample at 2.3 MHz, the 10 μm (400 $\mu\text{in.}$) sample at 1.8 MHz, and the 20 μm (800 $\mu\text{in.}$) sample at 0.8 MHz.

An NMR detector (a marginal oscillator type) was also used to give the magabsorption signals from the powder samples, and iron carbonyl was the first powdered ferromagnetic material to be measured with a marginal oscillator type magabsorption detector. The magabsorption Lissajous figures for four samples of different particle sizes (5, 8, 10, and 20 μm) are given in Table 1. The fundamental frequency for each magabsorption signal is 120 Hz for a bias frequency of 60 Hz. The first harmonic of the signal is at 240 Hz, also as shown in the "Frequency spectrum" column in Table 1. The vertical amplifier gain control was adjusted for each sample so that the magabsorption signal was of useful amplitude to display the shape of the signal. The magabsorption signal amplitude is very low for the 5 and 8 μm (200 and 320 $\mu\text{in.}$) samples and is very high for the 10 and 20 μm (400 and 800 $\mu\text{in.}$) samples when the bias field is 0.024 T (240 G) peak-to-peak. In the bottom row of Table 1, the peak-to-peak value of the bias field is reduced by 40 times to 6×10^{-4} T (6 G) peak-to-peak. This bias field reduction increased the ratio of the 240-Hz component relative to the 120-Hz component as shown by a comparison between the data in the second row from the bottom with that from the bottom row. The second row from the bottom uses a peak-to-peak bias field of 0.024 T (240 G), while the bottom row uses only 6×10^{-4} T (6 G) peak-to-peak. There is a distinctive change in the shape of the magabsorption signal from when the bias field is reduced from 0.024 to 6×10^{-4} T (240 to 6 G).

Table 1 Marginal-oscillator signals for iron carbonyl particles

The first four signals were obtained with a peak-to-peak bias field strength, H_B , of 24×10^{-3} T (240 G); the last signal, 0.6×10^{-3} T (6 G).

Particle size		Oscilloscope Lissajous patterns	Frequency spectrum	Peak-to-peak signal amplitude, mV
μm	$\mu\text{in.}$			
5	200			30
8	320			65
10 (HP)	400			2500

20	800			5000
20	800			38

There is also an increase in the ratio of the 240-Hz component to the 120-Hz component. The ratio of the amplitude of the 240-Hz component to the amplitude of the 120-Hz component is graphed in Fig. 22 for five particle sizes of carbonyl iron powder in a bias field of 0.024 T (240 G) peak-to-peak. Figure 23 shows the root mean square (rms) magnitude of the magabsorption signal plotted as a function of the peak-to-peak amplitude of the bias magnetic field.

Fig. 22 Ratio of the amplitude of the 240-Hz component to the amplitude of the 120-Hz component for various particle diameters of carbonyl iron with a magnetic field of 24×10^{-3} T (240 G) peak-to-peak

Fig. 23 Root mean square (rms) magnitude of the resistivity signal as a function of magnetization magnitude

During the experiments with powders, it was noticed that there was a difference in the magabsorption signal shape and amplitude for iron oxide powders in different suspension media. The results with iron carbonyl particles indicate that the more tightly the medium holds the particle, or the greater the viscosity of the medium, the larger the magabsorption signal is. It was also noticed that when the iron carbonyl particles were allowed to settle, the signal decreased in amplitude by ten times. When the particles were redistributed, the signal returned to its larger value.

Magabsorption Measurement of Stresses

As discussed in the section "*B-H* Characteristics" in this article and as illustrated in Fig. 4, stress can affect the orientation of magnetic domains. When tension is applied to a saturated ferromagnetic material, with a positive magnetostriction constant, some of the parallel-aligned domains have their direction reversed so that there are domains parallel and antiparallel to the applied field. On the other hand, when tension is applied to a saturated ferromagnetic material such as nickel with a negative magnetostriction constant, some of the parallel-aligned domains have their direction rotated 90° so that there are domains perpendicular to the applied field. Therefore, the peak-to-peak magnitude and the shape of the magabsorption signal depend on the direction of the magnetic bias field relative to the direction of the applied stress and on whether the material has a positive or negative magnetostriction constant. The work on many types of materials has shown that when the magnetic field bias, H_B , is parallel to the direction of the applied stress, the following conditions result:

- For materials with a positive magnetostriction constant, increasing tension increases the signal magnitude, while increasing compression decreases the amplitude (Fig. 24a)
- For materials with a negative magnetostriction constant, increasing tension decreases the signal

magnitude, while increasing compression increases the amplitude (Fig. 24b)

Fig. 24 Amplitude (peak-to-peak) of the magabsorption signals graphed as a function of stress (both tension and compression) for materials with both positive and negative magnetostriction constants. The magnetic bias field is applied parallel to the stress direction.

These effects of stress on the peak-to-peak amplitude of the magabsorption signal are exactly the opposite for the condition in which the direction of the magnetic bias field is perpendicular to the direction of the stress. The behavior of the magabsorption signal peak-to-peak amplitude with the stress parallel to the direction of the magnetic bias field is shown in Fig. 24. The maximum stress in each case is below the yield point of the material. The solid lines are for the increasing stress in Fig. 24, while the broken lines are for the decreasing stress. In most materials, the magabsorption amplitude for decreasing stress will not follow the curve for increasing stress, because there is a hysteresis.

Applied Stresses in Ferromagnetic Materials. Measurement of the magabsorption signal as a function of stress has been performed on a variety of specimens. Measurements were made on iron and nickel wire and on a variety of bar specimens.

Magabsorption Measurements on Wire. The block diagram of one system used to measure the magabsorption signal in wires is shown in Fig. 19(a). The detection head consists of an RF coil and a Helmholtz pair of coils that supply the bias magnetic field parallel to the axis of the wire. The RF magnetic field is also applied parallel to the axis of the wire. The RF detection coil is fed through a coaxial cable to a marginal oscillator. The output of the marginal oscillator is the magabsorption signal, and it is applied to the y-axis input of the oscilloscope. A voltage proportional to the current in the bias field coils is fed to the horizontal input of the oscilloscope.

Another system for measuring the magabsorption signals from wires is a bridge circuit (Fig. 19b). The relative reversible permeability curves for iron wire, unannealed nickel wire, and annealed nickel wire shown in Fig. 8 were taken with an ac bridge. The magabsorption curves will also be similar to the curves of the relative reversible permeability.

Measurements of the magabsorption signal were made on iron and nickel wire as a function of stress. For the positive magnetostriction constant material (iron), the peak-to-peak magnitude of the magabsorption signal from the material increased with tension and decreased with compression when the bias field was parallel to the applied stress. The reverse occurred when the material had a negative magnetostriction constant (nickel). When iron and nickel have residual stress and additional stress is applied, the peak-to-peak magnitude of the magabsorption signal may be less than that for no residual stress.

Magabsorption Measurements on Bar Specimens. Many measurements with magabsorption detector heads (such as the one shown in Fig. 20) have been made on bar specimens with the bias field both perpendicular (Fig. 25a) and parallel (Fig. 25b) to the stress direction.

Fig. 25 Probe specimen geometry for parallel and perpendicular magabsorption measurements on a bent steel bar. (a) Probe in transverse or perpendicular position. (b) Probe in axial or parallel position

A number of measurements were made on type 1018 steel bars (Ref 7). Graphs were constructed of the peak-to-peak magabsorption signal amplitude as a function of the stress, both tension and compression, applied as a bending moment. Additional similar measurements were made on bars of 410 and 4340 steel.

Another series of measurements was obtained from a 5046 steel crankshaft throw (Ref 11). The measurement procedure was very similar to that described above except that the detection heads (Fig. 20) were made much smaller and were ground curved to fit the curves of the crankshaft throw.

Stresses in Nonferromagnetic Materials. It has also been shown that when a nonferromagnetic material is coated with a thin layer of ferromagnetic material, there exists a possibility of measuring stress at the surface of the nonferromagnetic material from the magabsorption signals of the ferromagnetic coating (Ref 6). This requires good adherence of the coating in order to reduce the distortion of strain transmitted from the base material to the coating. The strain transmitted to the coating may also exhibit additional distortion if the testpiece is not plane-stressed.

If the strains are assumed equal in the plating and in the base material, the stresses are related by:

$$\frac{\tau_1}{E_1} = \frac{\tau_2}{E_2} \quad (\text{Eq 18})$$

within the proportional limit where τ_i is the stress and E_i (where $i = 1,2$) is the modulus of elasticity for the two materials. In Eq 18, $i = 1$ refers to the substrate and $i = 2$ refers to the ferromagnetic coating. Thus, if the ratio of the moduli is known and T_2 is the stress in the ferromagnetic coating as measured by the magabsorption technique, then the stress at the surface of the substrate can be determined.

For the experimental work reported in Ref 6, aluminum welding rods were plated with nickel. As mentioned previously, it is important that the coating adheres well to the base material. It has been reported in the literature "that the bond strength of a nickel plating is of the order of the tensile strength of the base material when a phosphoric acid anodizing pretreatment process is employed." Studies of this anodizing process by the Southwest Research Institute have shown no blistering or separation in nickel-plated aluminum samples when subjected to a 180° bend of one thickness radius. Because the nickel plating adheres this well, the strain in the base metal was assumed to be the same as that in the plated material.

A loading device was used to apply the stress (tension) to the nickel-plated aluminum welding rods. Both tension and strain were measured. The marginal oscillator type of magabsorption detector was used to deliver the in-phase magabsorption signal. For each sample, the data were reduced so that strain and peak-to-peak magabsorption magnitude could be plotted as a function of stress. The graph of strain versus stress for a nickel-plated 3 mm ($\frac{1}{8}$ in.) diam aluminum rod and a graph of the peak-to-peak amplitude of the magabsorption signals from the nickel plating as a function of stress are given in Fig. 26. For this test, the plated aluminum sample is not annealed after plating. The dashed line in Fig. 26 is the empirical (curve-fitted) relationship between the magabsorption amplitude, A , and the applied stress (in psi) is given by the equation $A = 0.96 \exp (-\tau_1/1360)$.

Fig. 26 Variations of the magabsorption signal and strain with stress for a nickel plated 3 mm ($\frac{1}{8}$ in.) diam aluminum rod

Another plated rod was annealed for 30 min at 360 °C (680 °F). The graphs of strain versus stress and magabsorption as a function of stress are given in Fig. 27. The magabsorption amplitude, A , from the nickel is proportional directly to the applied stress (in psi) to the nickel plated aluminum rod within the range of $2400 \leq \tau \leq 10,000$ psi and can be expressed as $A = -1.31 \times 10^{-4} (\tau - 16,000)$. In the region of $10,000 \leq \tau \leq 17,000$ psi, the curve is fitted by the exponential $A = 3.21 \exp (-\tau/7150)$ as shown by the dashed line in Fig. 27.

Fig. 27 Variations of the magabsorption signal and stress with strain for an annealed nickel plated 3 mm ($\frac{1}{8}$ in.) diam aluminum rod

These meager data show that with a calibration curve, the stress in nonferromagnetic materials can be measured using the magabsorption signals from a thin nickel plating on the nonferromagnetic material. The magabsorption versus stress graph for the nickel plated aluminum seems to obey nearly the same equation as does the nickel wire. To date, no measurements of the stress in bars of aluminum with small areas of nickel plating have been accomplished as yet, but are planned for the future.

Residual Stresses and Magnetism. Asymmetries in magabsorption signals may be indicative of residual stresses or magnetism. In the case of residual magnetism, the magnetic domains are not entirely haphazard; instead they do some ordering in a particular direction (Fig. 4f). This will produce asymmetries in the magnitude of the magabsorption signal, depending on the orientation of the bias field, H_B , with respect to the orientation of the residual magnetism.

Similarly, residual stresses are indicated by the ratio of magabsorption signals from two orientations (0° , 90°) of the bias coil. When the 0° and 90° amplitudes are equal, the stress is zero whatever the amplitudes are. When the parallel/perpendicular ratio is greater than 1, the stress value is positive and is tensile; when the ratio is less than 1, the stress is negative or compressive. For example, in one investigation, magabsorption measurements were made on steel samples before and after turning, cutting, and shaping operations. For the turning operation, the sample was reduced in diameter with a cutting tool; for the cutting operation, a sample was reduced in thickness by a ram shaper; for the shaping operation, the sample was reduced in thickness by an end mill. With the turning operation, the ratio of the 0° to the 90° magnitude of the magabsorption decreased from 0.91 to 0.89 when a $130\text{ }\mu\text{m}$ (5 mil) cut was made. When a $230\text{ }\mu\text{m}$ (9 mil) cut was made, the magabsorption ratio decreased from 0.89 to 0.65. When a $500\text{ }\mu\text{m}$ (20 mil) cut was made, the magabsorption ratio decreased from 0.65 to 0.60. These changes indicated that the turning operation was placing compressive stress on the testpiece. The testpiece used with the ram shaper was in tension along its length before being reduced in width. A reduction in width of $760\text{ }\mu\text{m}$ (30 mils) by the ram shaper applied perpendicular to the length caused the surface magabsorption signal ratio to indicate compression after the reduction. With the end mill, the reduction in thickness resulted in the stress changing from tensile to compressive.

Example 1: Magabsorption Measurement of Residual Stress in a Crankshaft Throw.

Quantitative estimates of residual stress from magabsorption measurements were also performed on a large crankshaft throw (Fig. 28) made of 5046 steel. The estimates first required the development of calibration curves as described below.

Fig. 28 Magabsorption detector and three detector heads used to perform measurements on the throw of the crankshaft shown on the left. A closeup view of the detector heads is shown in Fig. 20.

The calibration curves were developed from two samples made of the same material as the crankshaft throw (type 5046 steel). The graph of the parallel-versus-perpendicular peak-to-peak values of the magabsorption signals from two of the calibration samples are given in Fig. 29. Two straight lines at angles of 45° and 50° relative to the horizontal axis are also drawn in Fig. 29. The one at 45° is a zero-stress line where the parallel and perpendicular magabsorption signals are the same magnitude. The line at 50° is the calibration line to be used to determine the calibration constant for the estimate of residual stress from the magabsorption measurements. Five stress levels (A, B, C, D, and E in Fig. 29) were applied at the measuring point on each test bar, and the calibration constant was determined as described below.

Fig. 29 Graph showing the plot of the parallel/perpendicular ratios for sample 6 (type 5046 steel) and sample 7 (type 5046 steel)

Previous experiments have indicated that the intersections of the parallel and perpendicular magnitudes for magabsorption signals at one point for the residual stresses seldom occur along the same line as applied stresses. However, it has been indicated that the applied stress lines in Fig. 29 probably can be used to determine the residual stress values in general by following the rule: All points on a radial line from the origin at some angle with respect to the abscissa have the same value of residual stress. The 45° line should be the locus of points of zero stress where the parallel and perpendicular values of the magabsorption curve are equal. With the 45° line as a reference, residual or applied stress can be expressed mathematically as:

$$\text{Stress (residual or applied)} = K \left[\tan^{-1} \left(\frac{\text{Parallel}}{\text{Perpendicular}} \right) - 45^\circ \right] \quad (\text{Eq 19})$$

where K is the calibration constant for the material. When the parallel and perpendicular amplitudes are equal, the stress is zero whatever the amplitudes are. When the parallel/perpendicular ratio is greater than one, the stress value is positive and is tension; when the ratio is less than one, the stress is negative or compression.

The calibration constant, K, is obtained from Fig. 29 by the following procedure: (a) draw a calibration line through the origin at an angle for which an applied stress can be assigned to the intersection of the parallel/perpendicular ratio for the applied stress and (b), calculate the value of the constant K by inserting the applied stress and the angle into Eq 19.

Before this procedure could be used with the data in Fig. 29, the usable applied stress curve had to be chosen. One of the applied stress curves from sample No. 7 was chosen because its amplitude was the closest to the residual stress data, and because its curve shape was close to that obtained from the throw. The calibration proceeded as described. The line at 50° was chosen for the first calibration value because it intersected the lowest amplitude (dashed curve) for the data from sample 7 at nearly the value of applied stress level B (closed circle) (55 MPa, or 8 ksi). The 45° line passes through the No. 7 stress curve (dashed) nearly at level C (open triangle), or where an estimated value of 160 MPa (23.5 ksi) had been applied. Therefore, the line at an angle of 50° represents a differential applied stress relative to the 45° line of $160 - 55 = 105$ MPa ($23.5 - 8 = 15.5$ ksi). When several values are taken from several lines both above and below the 45° line, the average value for a line 5° above or below 45° is 100 MPa (15 ksi). Therefore, if both the value of $\tan^{-1} 50^\circ$ and the stress equal to 100 MPa (15 ksi) are inserted into Eq 19, the value of K is found to be 20 MPa/degree (3 ksi/degree). This implies that for every degree of offset from the 45° line, points along the line at that offset resulting from signal amplitude measurements will have the same value of residual stress.

When the value of K is used, calibration lines can be drawn through zero at useful angles relative to the 45° line. Using these calibration lines and marks, the values of the residual stresses for points on the crankshaft throw were determined. Residual stress values as high as 600 MPa (87 ksi) tension and 90 MPa (13 ksi) compression were determined.

Electromagnetic Techniques for Residual Stress Measurements

H. Kwun and G.L. Burkhardt, Southwest Research Institute

Introduction

RESIDUAL STRESSES in materials can be nondestructively measured by a variety of methods, including x-ray diffraction, ultrasonics, and electromagnetics (Ref 1, 2, 3). With the x-ray diffraction technique, the interatomic planar distance is measured, and the corresponding stress is calculated (Ref 4). The penetration depth of x-rays is of the order of only 10 μ in. (400 μ in.) in metals. Therefore, the technique is limited to measurements of surface stresses. Its use has been generally limited to the laboratory because of the lack of field-usable equipment and concern with radiation safety.

With ultrasonic techniques, the velocity of the ultrasonic waves in materials is measured and related to stress (Ref 5). These techniques rely on a small velocity change caused by the presence of stress, which is known as the acoustoelastic effect (Ref 6). In principle, ultrasonic techniques can be used to measure bulk as well as surface stresses. Because of the difficulty in differentiating stress effects from the effect of material texture, practical ultrasonic applications have not yet materialized.

With electromagnetic techniques, one or more of the magnetic properties of a material (such as permeability, magnetostriction, hysteresis, coercive force, or magnetic domain wall motion during magnetization) are sensed and correlated to stress. These techniques rely on the change in magnetic properties of the material caused by stress; this is known as the magnetoelastic effect (Ref 7). These techniques, therefore, apply only to ferromagnetic materials, such as steel.

Of the many electromagnetic stress-measurement techniques, this article deals with three specific ones: Barkhausen noise, non-linear harmonics, and magnetically induced velocity changes. The principles, instrumentation, stress dependence, and capabilities and limitations of these three techniques are described in the following sections.

Electromagnetic Techniques for Residual Stress Measurements

Barkhausen Noise

The magnetic flux density in a ferromagnetic material subjected to a time-varying magnetic field does not change in a strictly continuous way, but rather by small, abrupt, discontinuous increments called Barkhausen jumps (after the name of the researcher who first observed this phenomenon), as illustrated in Fig. 1. The jumps are due primarily to discontinuous movements of boundaries between small magnetically saturated regions called magnetic domains in the material (Ref 7, 8, 9). An unmagnetized macroscopic specimen consists of a great number of domains with random magnetic direction so that the average bulk magnetization is zero. Under an external magnetic field, the specimen becomes magnetized mainly by the growth of volume of domains oriented close to the direction of the applied field, at the expense of domains unfavorably oriented. The principal mechanism of growth is the movement of the walls between adjacent domains. Because of the magnetoelastic interaction, the direction and magnitude of the mechanical stress strongly influence the distribution of domains and the dynamics of the domain wall motion and therefore the behavior of Barkhausen jumps (Ref 8). This influence, in turn, is used for stress measurements. Because the signal produced by Barkhausen jumps resembles noise, the term Barkhausen noise is often used.

Fig. 1 Hysteresis loop for magnetic material showing discontinuities that produce Barkhausen noise. Source: Ref 2

Instrumentation. The arrangement illustrated in Fig. 2 is used for the Barkhausen noise technique (Ref 8). A small C-shaped electromagnet is used to apply a controlled, time-varying magnetic field to the specimen. The abrupt movements of the magnetic domains are typically detected with an inductive coil placed on the specimen. The detected signal is a burst of noiselike pulses, as illustrated in Fig. 3. Certain features of the signal, such as the maximum amplitude or root mean square (rms) amplitude of the Barkhausen noise burst or the applied magnetic field strength at which the maximum amplitude occurs, are used to determine the stress state in the material (Ref 1, 8, 9, 10, 11, and 12).

Fig. 2 Arrangement for sensing the Barkhausen effect

Fig. 3 Schematic showing the change in magnetic field H with time, variation in flux density over the same period, and the generation of the Barkhausen noise burst as flux density changes. Source: Ref 14

In addition to inductive sensing of the magnetic Barkhausen noise, magnetoacoustic Barkhausen activity can also be detected with an acoustic emission sensor (Ref 13). This phenomenon occurs when Barkhausen jumps during the magnetization of a specimen produce mechanical stress pulses in a manner similar to the inductive Barkhausen noise burst shown in Fig. 3. It is caused by microscopic changes in strain due to magnetostriction when discontinuous, irreversible domain wall motion of non-180° domain walls occurs (Ref 14, 15). This acoustic Barkhausen noise is also dependent on the stress state in the material and can therefore be used for stress measurements (Ref 15, 16, 17, 18, and 19).

Stress Dependence. The magnetic Barkhausen effect is dependent on the stress as well as the relative direction of the applied magnetic field to the stress direction. To illustrate this, Fig. 4 shows a typical stress dependence of the inductively detected Barkhausen noise in a ferrous material. In the case where the magnetic field and the stress are parallel, the Barkhausen amplitude increases with tension and decreases with compression (Ref 8, 10, 20, and 21). In the case where the two are perpendicular, the opposite result is obtained. The behavior shown in Fig. 4 holds for materials with a positive magnetostriction coefficient; for materials with a negative magnetostriction, the Barkhausen amplitude exhibits the opposite behavior.

Fig. 4 Typical stress dependence of Barkhausen noise signal amplitude with the applied magnetic field parallel (curve A) and perpendicular (curve B) to the stress direction

For a given stress, the dependence of the Barkhausen amplitude on the angle between the magnetic field and stress directions is proportional to the strain produced by the stress (Ref 21). Because the Barkhausen noise is dependent on the strain, Barkhausen measurements can be used as an alternative to strain gages (Ref 20, 21).

A typical stress dependence of the acoustic Barkhausen noise is illustrated in Fig. 5, in which the magnetic field is applied parallel to the stress direction. As shown, the amplitude of the acoustic signal decreases with tension. Under compression, it increases slightly and then decreases with an increasing stress level. The acoustic Barkhausen noise, therefore, cannot distinguish tension from compression.

Fig. 5 Dependence of acoustic emission during the magnetization of low-carbon steel on stress. Total gain: 80 dB. Magnetic field strength (rms value): 13,000 A/m (160 Oe) for curve A; 6400 A/m (80 Oe) for curve B. Source: Ref 13

Capabilities and Limitations. Because of the eddy current screening, the inductively detected Barkhausen noise signals reflect the activity occurring very near the surface of the specimen to a depth of approximately 0.1 mm (0.004 in.). Therefore, the Barkhausen noise technique is suitable for measuring near-surface stresses. The effective stress-measurement range is up to about 50% of the yield stress of the material because the change in the Barkhausen noise with stress becomes saturated at these high stress levels.

Barkhausen measurements can usually be made within a few seconds. Continuous measurements at a slow scanning speed (~ 10 mm/s, or 0.4 in./s) are possible. Preparation of the surface of a part under testing is generally not required. Portable, field-usable Barkhausen instruments are available.

The results of Barkhausen noise measurements are also sensitive to factors not related to stress, such as microstructure, heat treatment, and material variations. Careful instrument calibration and data analysis are essential for reliable stress measurements. As can be seen in Fig. 4, the Barkhausen amplitude at zero stress is approximately isotropic and shows no dependence on the relative orientation of the magnetic field and stress directions. When the specimen is subjected to a stress, the Barkhausen noise exhibits dependence on the magnetic field direction and becomes anisotropic. This stress-induced anisotropy in the Barkhausen noise is effective for differentiating stress from nonstress-related factors whose effects are approximately isotropic. The accuracy of the technique is about ± 35 MPa (± 5 ksi).

The acoustic Barkhausen noise technique can be used in principle to measure bulk stresses in materials because the acoustic waves travel through materials. However, practical application of this technique is currently hampered by the difficulty in differentiating acoustic Barkhausen noise from other noise produced from surrounding environments.

The inductive Barkhausen noise technique has been used for measuring welding residual stresses (Ref 20, 22), for detecting grinding damage in bearing races (Ref 23), and for measuring compressive hoop stresses in railroad wheels (Ref 24).

Electromagnetic Techniques for Residual Stress Measurements

H. Kwun and G.L. Burkhardt, Southwest Research Institute

Nonlinear Harmonics

Because of the magnetic hysteresis and nonlinear permeability, the magnetic induction, B , of a ferromagnetic material subjected to a sinusoidal, external magnetic field, H , is not sinusoidal but distorted, as illustrated in Fig. 6. This distorted waveform of the magnetic induction contains odd harmonic frequencies of the applied magnetic field. Mechanical stresses greatly influence the magnetic hysteresis and permeability of the material (Ref 7). An example of the stress effects on the hysteresis loops is shown in Fig. 7. Accordingly, the harmonic content of the magnetic induction is also sensitive to the stress state in the material. With the nonlinear harmonics technique, these harmonic frequencies are detected, and their amplitudes are related to the state of stress in the material (Ref 26, 27).

Fig. 6 Distortion of magnetic induction caused by hysteresis and nonlinearity in magnetization curve. The curve for magnetic induction, B , is not a pure sinusoid; it has more rounded peaks.

Fig. 7 Hysteresis loops of an AISI 410 stainless steel specimen having ASTM No. 1 grain size and a hardness of 24 HRC under various levels of uniaxial stress. x-axis: 1600 A/m (20 Oe) per division; y-axis: 0.5 T (5 kG) per division. Source: Ref 25

Instrumentation. The nonlinear harmonics technique is implemented with the arrangement shown schematically in Fig. 8. The magnetic field is applied to a specimen with an excitation coil, and the resulting magnetic induction is measured with a sensing coil. A sinusoidal current of a given frequency is supplied to the excitation coil with a function generator (or oscillator) and a power amplifier. The induced voltage in the sensing coil is amplified, and the harmonic frequency content of the signal is analyzed. The amplitude of the harmonic frequency, typically the third harmonics, is used to determine the stress.

Fig. 8 Block diagram of nonlinear harmonics instrumentation

Stress Dependence. The harmonic amplitudes are dependent on the stress as well as the relative orientation between the stress and the applied magnetic field directions. Like the stress dependence of the Barkhausen noise amplitude illustrated in Fig. 4, the harmonic amplitude for materials with a positive magnetostriction increases with tension when the direction of the stress and the applied field are parallel (Ref 27). When the directions are perpendicular, the opposite result is obtained. As with Barkhausen noise, the nonlinear harmonics depend on strain and can be used to determine stress.

Capabilities and Limitations. The nonlinear harmonics technique can be used to measure near-surface stresses, with sensing depth approximately equal to the skin depth of the applied magnetic field. Because the skin depth is a function of the frequency of the applied magnetic field, the depth of sensing can be changed by varying the frequency. Therefore, the technique can potentially be used to measure stress variations with depth.

The results of nonlinear harmonic measurements are sensitive to factors not related to stress, such as microstructure, heat treatment, and material variations. The stress-induced anisotropy in the harmonic amplitude has been shown to be effective for differentiating stress from factors not related to stress (Ref 27). When the stress-induced anisotropy is used for stress determination, the accuracy of the technique is about ± 35 MPa (± 5 ksi). The range of stress to which the technique is effective is up to about 50% of the yield stress of the material, with the response becoming saturated at higher stress levels. With this technique, it would be feasible to measure stress while scanning a part at a high speed (~ 10 m/s, or 30 ft/s); therefore, this technique has potential for rapidly surveying stress states in pipelines or continuously welded railroad rails (Ref 28).

Magnetically Induced Velocity Changes (MIVC) for Ultrasonic Waves

Because of the magnetoelastic interaction, the elastic moduli of a ferromagnetic material are dependent on the magnetization of the material. This phenomenon is known as the ΔE effect (Ref 7). Consequently, the velocity of the ultrasonic waves in the material changes when an external magnetic field is applied to the material. This MIVC for ultrasonic waves is characteristically dependent on the stress as well as the angle between the stress direction and the direction of the applied magnetic field (Ref 29, 30, 31, and 32). This characteristic stress dependence of the MIVC is used for stress determination (Ref 33, 34, 35, and 36).

Instrumentation. Figure 9 shows a block diagram of instrumentation for measuring MIVC. An electromagnet is used to apply a biasing magnetic field to the specimen. The applied magnetic field is measured with a Hall probe. An ultrasonic transducer is used to transmit ultrasonic waves and to detect signals reflected from the back surface of the specimen. For surface waves, separate transmitting and receiving transducers are used. The shift in the arrival time of the received ultrasonic wave caused by the velocity change due to the applied magnetic field is detected with an ultrasonic instrument. Because MIVC is a small effect (of the order of only 0.01 to 0.1%), the measurements are typically made using the interferometer principle, called the phase comparison technique, in the ultrasonic instrumentation (Ref 33).

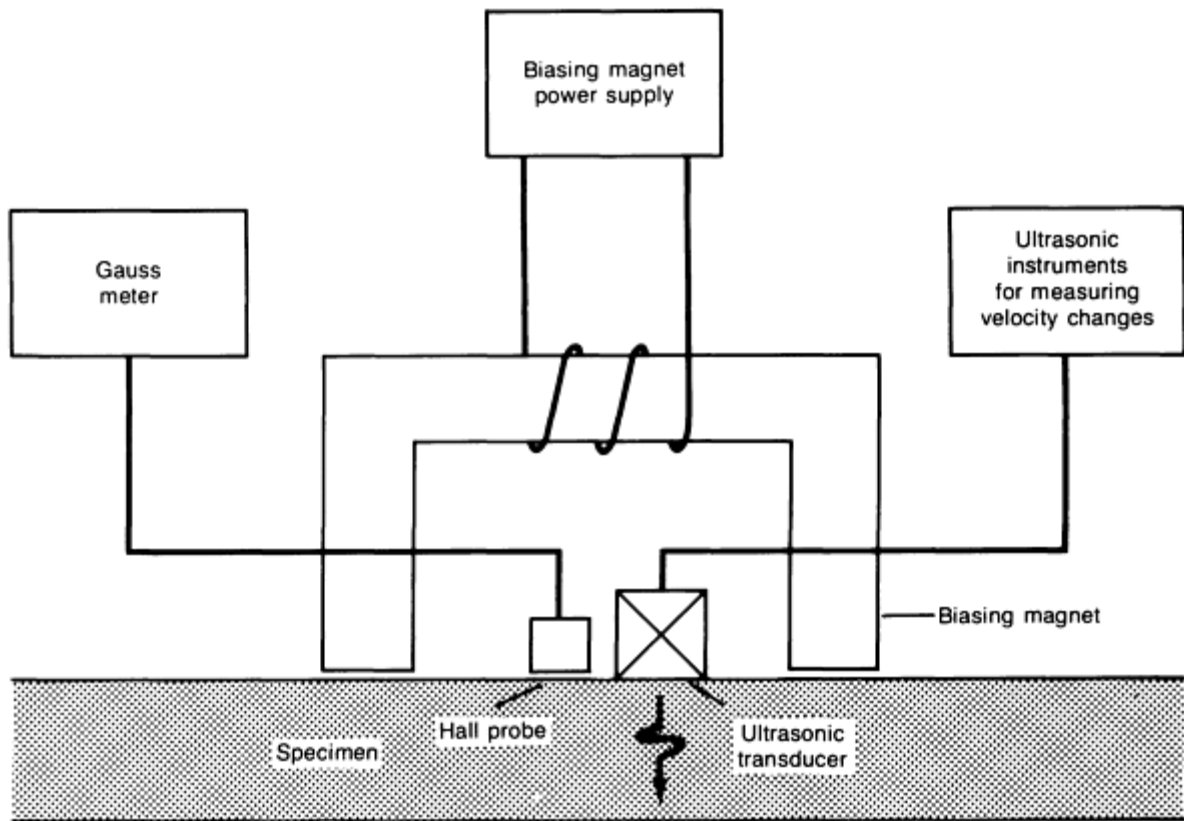

Fig. 9 Block diagram of instrumentation for measuring MIVC for ultrasonic waves

Stress Dependence. A typical stress dependence of the MIVC is illustrated in Fig. 10. At zero stress, the MIVC at first generally increases rapidly with the applied magnetic field, H , and then gradually levels off toward a saturation value. When the material is subjected to stress, the magnitude of the MIVC decreases, and the shape of the MIVC curve as a function of H changes. Under tension, the shape of the MIVC curve remains similar to that at zero stress, but with reduced magnitude in proportion to the stress level. Under compression, the MIVC curve exhibits a minimum, which drastically changes the shape and reduces the magnitude. The magnitude of the minimum and the value of H where the minimum occurs increase with stress level.

Fig. 10 Schematic showing the change in ultrasonic velocity, ΔV , with magnetic field H under various stress

The detailed stress dependence of MIVC, however, varies with the mode of ultrasonic wave used (longitudinal, shear, or surface) and with the relative orientation between the stress and the magnetic field directions (Ref 29, 30, 31, 32, 33, 34, and 35). The stress dependence shown in Fig. 10 holds for longitudinal waves in materials with a positive magnetostriction coefficient (Ref 31, 33). With this technique, the stress state in the material, including the magnitude, direction, and sign (tensile or compressive) of the stress, is characterized by analyzing the shape and magnitude of the MIVC curves measured at two or more different magnetic field directions.

Capabilities and Limitations. The MIVC technique can be used to measure bulk and surface stresses by applying both bulk (shear or longitudinal) and surface ultrasonic waves. A measurement can be made within a few seconds. Because the magnitude of MIVC depends on material type, reference or calibration curves must be established for that material type prior to stress measurements. However, this technique is insensitive to variations in the texture and composition of nominally the same material. The accuracy in stress measurements is about ± 35 MPa (± 5 ksi). This technique has been used to measure residual welding stresses (Ref 34) and residual hoop stresses in railroad wheels Ref 36).

A relatively large electromagnet is needed to magnetize the part under investigation and may be cumbersome to handle in practical applications. Because of difficulty in magnetizing complex-geometry parts, the application of the technique is limited to simple geometry parts.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Introduction

EDDY CURRENT INSPECTION is based on the principles of electromagnetic induction and is used to identify or differentiate among a wide variety of physical, structural, and metallurgical conditions in electrically conductive ferromagnetic and nonferromagnetic metals and metal parts. Eddy current inspection can be used to:

- Measure or identify such conditions and properties as electrical conductivity, magnetic permeability, grain size, heat treatment condition, hardness, and physical dimensions
- Detect seams, laps, cracks, voids, and inclusions
- Sort dissimilar metals and detect differences in their composition, microstructure, and other properties
- Measure the thickness of a nonconductive coating on a conductive metal, or the thickness of a nonmagnetic metal coating on a magnetic metal

Because eddy currents are created using an electromagnetic induction technique, the inspection method does not require direct electrical contact with the part being inspected. The eddy current method is adaptable to high-speed inspection and, because it is nondestructive, can be used to inspect an entire production output if desired. The method is based on indirect measurement, and the correlation between the instrument readings and the structural characteristics and serviceability of the parts being inspected must be carefully and repeatedly established.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Advantages and Limitations of Eddy Current Inspection

Eddy current inspection is extremely versatile, which is both an advantage and a disadvantage. The advantage is that the method can be applied to many inspection problems provided the physical requirements of the material are compatible with the inspection method. In many applications, however, the sensitivity of the method to the many properties and characteristics inherent within a material can be a disadvantage; some variables in a material that are not important in terms of material or part serviceability may cause instrument signals that mask critical variables or are mistakenly interpreted to be caused by critical variables.

Eddy Current Versus Magnetic Inspection Methods. In eddy current inspection, the eddy currents create their own electromagnetic field, which can be sensed either through the effects of the field on the primary exciting coil or by means of an independent sensor. In nonferromagnetic materials, the secondary electromagnetic field is derived exclusively from eddy currents. However, with ferromagnetic materials, additional magnetic effects occur that are usually of sufficient magnitude to overshadow the field effects caused by the induced eddy currents. Although undesirable, these additional magnetic effects result from the magnetic permeability of the material being inspected and can normally be eliminated by magnetizing the material to saturation in a static (direct current) magnetic field. When the permeability effect is not eliminated, the inspection method is more correctly categorized as electromagnetic or magnetoinductive inspection. Methods of inspection that depend mainly on ferromagnetic effects are discussed in the article "Magnetic Particle Inspection" in this Volume.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Development of the Inspection Process

The development of the eddy current method of inspection has involved the use of several scientific and technological advances, including the following:

- Electromagnetic induction
- Theory and application of induction coils
- The solution of boundary-value problems describing the dynamics of the electromagnetic fields within the vicinity of induction coils, and especially the dynamics of the electromagnetic fields, electric current flow, and skin effect in conductors in the vicinity of such coils

- Theoretical prediction of the change in impedance of eddy current inspection coils caused by small flaws
- Improved instrumentation resulting from the development of vacuum tubes, semiconductors, integrated circuits, and microprocessors which led to better measurement techniques and response to subtle changes in the flow of eddy currents in metals
- Metallurgy and metals fabrication
- Improved instrumentation, signal display, and recording

Electromagnetic induction was discovered by Faraday in 1831. He found that when the current in a loop of wire was caused to vary (as by connecting or disconnecting a battery furnishing the current), an electric current was induced in a second, adjacent loop. This is the effect used in eddy current inspection to cause the eddy currents to flow in the material being inspected and it is the effect used to monitor these currents.

In 1864, Maxwell presented his classical dissertation on a dynamic theory of the electromagnetic field, which includes a set of equations bearing his name that describe all large-scale electromagnetic phenomena. These phenomena include the generation and flow of eddy currents in conductors and the associated electromagnetic fields. Thus, all the electromagnetic induction effects that are basic to the eddy current inspection method are described in principle by the equations devised by Maxwell for particular boundary values for practical applications.

In 1879, Hughes, using an eddy current method, detected differences in electrical conductivity, magnetic permeability, and temperature in metal. However, use of the eddy current method developed slowly, probably because such an inspection method was not needed and because further development of the electrical theory was necessary before it could be used for practical applications.

Calculating the flow of induced current in metals was later developed by the solution of Maxwell's equations for specific boundary conditions for symmetrical configurations. These mathematical techniques were important in the electric power generation and transmission industry, in induction heating, and in the eddy current method of inspection.

An eddy current instrument for measuring wall thickness was developed by Kranz in the mid-1920s. An example of early well-documented work that also serves as an introduction to several facets of the eddy current inspection method is that of Farrow, who pioneered in the development of eddy current systems for the inspection of welded steel tubing. He began his work in 1930 and by 1935 had progressed to an inspection system that included a separate primary energizing coil, differential secondary detector coil, and a dc magnetic-saturating solenoid coil. Inspection frequencies used were 500, 1000, and 4000 Hz. Tubing diameters ranged from 6.4 to 85 mm ($\frac{1}{4}$ to $3\frac{1}{3}$ in.). The inspection system also included a balancing network, a high-frequency amplifiers, a frequency discriminator-demodulator, a low-frequency pulse amplifier, and a filter. These are the same basic elements that are used in modern systems for eddy current inspection.

Several artificial imperfections in metals were tried for calibrating tests, but by 1935 the small drilled hole had become the reference standard for all production testing. The drilled hole was selected for the standard because:

- It was relatively easy to produce
- It was reproducible
- It could be produced in precisely graduated sizes
- It produced a signal on the eddy current tester that was similar to that produced by a natural imperfection
- It was a short imperfection and resembled hard-to-detect, short natural weld imperfections. Thus, if the tester could detect the small drilled hole, it would also detect most of the natural weld imperfections

Vigners, Dinger, and Gunn described eddy current type flaw detectors for nonmagnetic metals in 1942, and in the early 1940s, Förster and Zuschlag developed eddy current inspection instruments. Numerous versions of eddy current inspection equipment are currently available commercially. Some of this equipment is useful only for exploratory inspection or for inspecting parts of simple shape. However, specially designed equipment is extensively used in the inspection of production quantities of metal sheet, rod, pipe, and tubing.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Principles of Operation

The eddy current method of inspection and the induction heating technique that is used for metal heating, induction hardening, and tempering have several similarities. For example, both are dependent on the principles of electromagnetic induction for inducing eddy currents within a part placed within or adjacent to one or more induction coils. The heating is a result of I^2R losses caused by the flow of eddy currents in the part. Changes in coupling between the induction coils and the part being inspected and changes in the electrical characteristics of the part cause variations in the loading and tuning of the generator.

The induction heating system is operated at high power levels to produce the desired heating rate. In contrast, the system used in eddy current inspection is usually operated at very low power levels to minimize the heating losses and temperature changes. Also, in the eddy current system, electrical-loading changes caused by variations in the part being inspected, such as those caused by the presence of flaws or dimensional changes, are monitored by electronic circuits. In both eddy current inspection and induction heating, the selection of operating frequency is largely governed by skin effect (see the section "Operating Variables" in this article). This effect causes the eddy currents to be concentrated toward the surfaces adjacent to the coils carrying currents that induce them. Skin effect becomes more pronounced with increase in frequency.

The coils used in eddy current inspection differ from those used in induction heating because of the differences in power level and resolution requirements, which necessitate special inspection coil arrangements to facilitate the monitoring of the electromagnetic field in the vicinity of the part being inspected.

Functions of a Basic System. The part to be inspected is placed within or adjacent to an electric coil in which an alternating current is flowing. As shown in Fig. 1, this alternating current, called the exciting current, causes eddy currents to flow in the part as a result of electromagnetic induction. These currents flow within closed loops in the part, and their magnitude and timing (or phase) depend on:

- The original or primary field established by the exciting currents
- The electrical properties of the part
- The electromagnetic fields established by currents flowing within the part

Fig. 1 Two common types of inspection coils and the patterns of eddy current flow generated by the exciting current in the coils. Solenoid-type coil is applied to cylindrical or tubular parts; pancake-type coil, to a flat surface.

The electromagnetic field in the region in the part and surrounding the part depends on both the exciting current from the coil and the eddy currents flowing in the part. The flow of eddy currents in the part depends on:

- The electrical characteristics of the part
- The presence or absence of flaws or other discontinuities in the part
- The total electromagnetic field within the part

The change in flow of eddy currents caused by the presence of a crack in a pipe is shown in Fig. 2. The pipe travels along the length of the inspection coil as shown in Fig. 2. In section A-A in Fig. 2, no crack is present and the eddy current flow is symmetrical. In section B-B in Fig. 2, where a crack is present, the eddy current flow is impeded and changed in direction, causing significant changes in the associated electromagnetic field. From Fig. 2 it is seen that the electromagnetic field surrounding a part depends partly on the properties and characteristics of the part. Finally, the condition of the part can be monitored by observing the effect of the resulting field on the electrical characteristics of the exciting coil, such as its electrical impedance, induced voltage, or induced currents. Alternatively, the effect of the electromagnetic field can be monitored by observing the induced voltage in one or more other coils placed within the field near the part being monitored.

Fig. 2 Effect of a crack on the pattern of eddy current flow in a pipe

Each and all of these changes can have an effect on the exciting coil or other coil or coils used for sensing the electromagnetic field adjacent to a part. The effects most often used to monitor the condition of the part being inspected are the electrical impedance of the coil or the induced voltage of either the exciting coil or other adjacent coil or coils.

Eddy current systems vary in complexity depending on individual inspection requirements. However, most systems provide for the following functions:

- Excitation of the inspection coil
- Modulation of the inspection coil output signal by the part being inspected
- Processing of the inspection coil signal prior to amplification
- Amplification of the inspection coil signals
- Detection or demodulation of the inspection coil signal, usually accompanied by some analysis or discrimination of signals
- Display of signals on a meter, an oscilloscope, an oscillograph, or a strip chart recorder; or recording of signal data on magnetic tape or other recording media
- Handling of the part being inspected and support of the inspection coil assembly or the manipulation of the coil adjacent to the part being inspected

Elements of a typical inspection system are shown schematically in Fig. 3. The particular elements in Fig. 3 are for a system developed to inspect bar or tubing. The generator supplies excitation current to the inspection coil and a synchronizing signal to the phase shifter, which provides switching signals for the detector. The loading of the inspection coil by the part being inspected modulates the electromagnetic field of the coil. This causes changes in the amplitude and phase of the inspection coil voltage output.

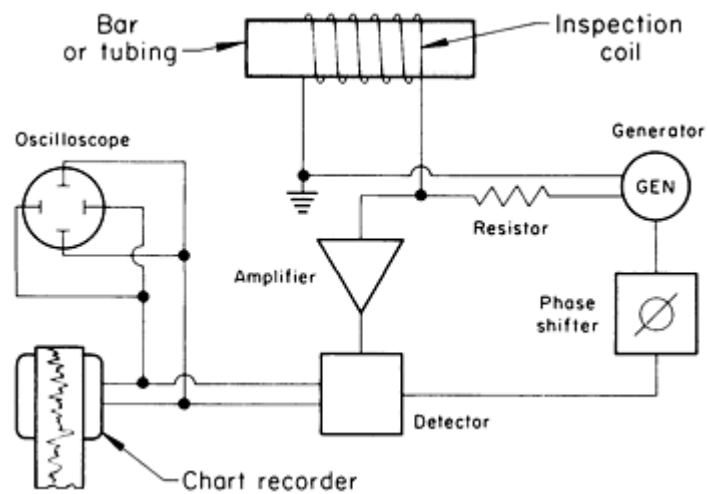

Fig. 3 Principal elements of a typical system for eddy current inspection of bar or tubing. See description in text.

The output of the inspection coil is fed to the amplifier and detected or demodulated by the detector. The demodulated output signal, after some further filtering and analyzing, is then displayed on an oscilloscope or a chart recorder. The displayed signals, having been detected or demodulated, vary at a much slower rate, depending on:

- The speed at which the part is fed through an inspection coil
- The speed with which the inspection coil is caused to scan past the part being inspected

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Operating Variables

The principal operating variables encountered in eddy current inspection include coil impedance, electrical conductivity, magnetic permeability, lift-off and fill factors, edge effect, and skin effect. Each of these variables will be discussed in this section.

Coil Impedance

When direct current is flowing in a coil, the magnetic field reaches a constant level, and the electrical resistance of the wire is the only limitation to current flow. However, when alternating current is flowing in a coil, two limitations are imposed:

- The ac resistance of the wire, R
- A quantity known as inductive reactance, X_L

The ac resistance of an isolated or empty coil operating at low frequencies or having a small wire diameter is very nearly the same as the dc resistance of the wire of the coil. The ratio of ac resistance to dc resistance increases as either the frequency or the wire diameter increases. In the discussion of eddy current principles, the resistance of the coil wire is often ignored, because it is nearly constant. It varies mainly with wire temperature and the frequency and spatial distribution of the magnetic field threading the coil.

Inductive reactance, X_L , is the combined effect of coil inductance and test frequency and is expressed in ohms. Total resistance to the flow of alternating current in a coil is called impedance, Z , and comprises both ac resistance, R , and inductive reactance, X_L . The impedance can be expressed as $Z = \sqrt{R^2 + X_L^2}$, where $X_L = 2\pi fL_0$, f is the test frequency (in Hertz), and L_0 is the coil inductance (in henrys).

When a metal part is placed adjacent to or within a test coil, the electromagnetic field threading the coil is changed as a result of eddy current flow in the test object. In general, both the ac resistance and the inductive reactance of the coil are affected. The resistance of the loaded coil consists of two components, namely, the ac resistance of the coil wire and the apparent, or coupled, resistance caused by the presence of the test object. Changes in these components reflect conditions within the test object.

Impedance is usually plotted on an impedance-plane diagram. In the diagram, resistance is plotted along one axis and inductive reactance along the other axis. Because each specific condition in the material being inspected may result in a specific coil impedance, each condition may correspond to a particular point on the impedance-plane diagram. For example, if a coil were placed sequentially on a series of thick pieces of metal, each with a different resistivity, each piece would cause a different coil impedance and would correspond to a different point on a locus in the impedance plane. The curve generated might resemble that shown in Fig. 4, which is based on International Annealed Copper Standard (IACS) conductivity ratings. Other curves would be generated for other material variables, such as section thickness and types of surface flaws.

Fig. 4 Typical impedance-plane diagram derived by placing an inspection coil sequentially on a series of thick pieces of metal, each with a different IACS electrical resistance or conductivity rating. The inspection frequency was 100 kHz.

Impedance Components. Figure 5(a) shows a simplified equivalent circuit of an inspection coil and the part being inspected. The coil is assumed to have inductance, L_0 , and negligible resistance. The part being inspected consists of a

very thin tube having shunt conductance, G , closely coupled to the coil. When an alternating current is caused to flow into the system under steady-state conditions, some energy is stored in the system and returned to the generator each cycle and some energy is dissipated or lost as heat each cycle. The inductive-reactance component, X_L , of the impedance, Z , of the circuit is proportional to the energy stored per cycle, and the resistance component, R , of the impedance is proportional to the energy dissipated per cycle. The impedance, Z , is equal to the complex ratio of the applied voltage, E , to the current, I , in accordance with Ohm's law. The term complex is used to indicate that, in general, the alternating current and voltage do not have the same phase angle.

Fig. 5 Simplified equivalent circuit (a) of an eddy current inspection coil and the part being inspected. (b) to (d) Three impedance diagrams for three conditions of the equivalent circuit. See text for explanation.

Figures 5(b) to (d) show three impedance diagrams for three conditions of the equivalent circuit in Fig. 5(a). When only the coil is present, the circuit impedance is purely reactive; that is, $Z = X_L = \omega L = 2\pi f L$, as shown in Fig. 5(b). When only the conductance of this equivalent circuit is present (a hypothetical condition for an actual combination of inspection coil and part being inspected), the impedance is purely resistive; that is, $Z = 1/G = R$, as shown in Fig. 5(c). When both coil and conductance are connected, the impedance has both reactive and resistive components in the general instance, and the

impedance $Z = \sqrt{R^2 + X_L^2}$, as shown in Fig. 5(d). Here, R is the series resistance and X_L is the series reactance. An angle, θ , is associated with the impedance, Z . This angle is a function of the ratio of the two components of the impedance, R and X_L . In Fig. 5(d), this angle, θ , is about 45° .

Points and loci on impedance-plane diagrams can be displayed using phasor representation because of the close relationship between the impedance diagrams and the phasor diagrams. In a given circuit with input impedance Z , applying an impressed fixed current I , will produce a signal voltage E in accordance with Ohm's law ($E = IZ$). This signal voltage can be displayed as a phasor. With I fixed, the signal voltage E is directly proportional to the impedance Z . Thus, the impedance plane can be readily displayed using the phasor technique.

Phasor Representation of Sinusoids. One method often used in signal analysis and in the representation of eddy current inspection signals is the phasor method schematically shown in Fig. 6. In Fig. 6(a) are shown three vectors, **A**, **B**, and **C**, which are rotating counterclockwise with radian velocity $2\pi ft = \omega t$. The equations that describe these vectors are of the form $K \sin(\omega t + \phi)$, where K is a constant equal to **A**, **B**, or **C** and ϕ is the electrical phase angle. These equations are plotted in Fig. 6(b). The length of the vectors **A**, **B**, and **C** determine the amplitude of the sinusoids generated in Fig. 6(b). The physical angle between the vectors **A** and **B**, or between **A** and **C**, determines the electrical phase angle, ϕ , between sinusoids. In Fig. 6(b), these angles are $+90^\circ$ and -45° , respectively.

Fig. 6 Phasor representation of sinusoids. See text for explanation.

The three vectors, **A**, **B**, and **C**, are considered to be rotating at frequency, f , generating three rather monotonous sinusoids. This system of three vectors rotating synchronously with the frequency of the sinusoids is not very useful, because of its high rate of rotation. However, if rotation is stopped, the amplitudes and phase angles of the three sine waves can be easily seen in a representation called a phasor diagram.

In eddy current inspection equipment, the sine wave signals are often expanded in quadrature components and displayed as phasors on an x - y oscilloscope, shown in Fig. 6(c). Usually, only the tips of the phasors are shown. Thus, **A** and **B** in Fig. 6(c) show the cathode ray beam position representing the two sinusoids of Fig. 6(b). Point **C** represents a sinusoid $C \sin \omega t$ having the same amplitude as $A \sin \omega t$, but which lags or follows it in phase by an electrical angle equal to 45° . The points indicated as C' represent sinusoids having the same phase angle as $C \sin \omega t$, but with different amplitudes. The concept of a phasor locus is introduced by varying the amplitude gradually from the maximum at **C** to zero at the origin **O**. This results in the beam spot moving from **C** to **O**, producing a locus. In contrast, a shift of the phase angle of a sinusoid causes a movement of the phasor tip around the origin **O** as shown by the arc **DE**. Here, **D** represents a sinusoid having the same amplitude as the sinusoid represented by **A** but leading it by 30° . Increasing this phase angle from 30 to 60° results in the phasor locus **DE**. When both amplitude and phase changes occur, more complicated loci can be formed as shown at **F** and **G**.

Electrical Conductivity

All materials have a characteristic resistance to the flow of electricity. Those with the highest resistivity are classified as insulators, those having an intermediate resistivity are classified as semiconductors, and those having a low resistivity are classified as conductors. The conductors, which include most metals, are of greatest interest in eddy current inspection. The relative conductivity of the common metals and alloys varies over a wide range.

Capacity for conducting current can be measured in terms of either conductivity or resistivity. In eddy current inspection, frequent use is made of measurement based on the International Annealed Copper Standard. In this system, the conductivity of annealed, unalloyed copper is arbitrarily rated at 100%, and the conductivities of other metals and alloys are expressed as a percentage of this standard. Thus, the conductivity of unalloyed aluminum is rated 61% IACS, or 61% that of unalloyed copper. The resistivity and IACS conductivity ratings of several common metals and alloys are given in Table 1.

Table 1 Electrical resistivity and conductivity of several common metals and alloys

Metal or alloy	Resistivity, $\mu\Omega \cdot \text{mm}$	Conductivity, % IACS
Silver	16.3	105
Copper, annealed	17.2	100

Gold	24.4	70
Aluminum	28.2	61
Aluminum alloys		
6061-T6	41	42
7075-T6	53	32
2024-T4	52	30
Magnesium	46	37
70-30 brass	62	28
Phosphor bronzes	160	11
Monel	482	3.6
Zirconium	500	3.4
Zircaloy-2	720	2.4
Titanium	548	3.1
Ti-6Al-4V alloy	1720	1.0
Type 304 stainless steel	700	2.5
Inconel 600	980	1.7
Hastelloy X	1150	1.5
Waspaloy	1230	1.4

Many factors influence the conductivity of a metal, notably, temperature, composition, heat treatment and resulting microstructure, grain size, hardness, and residual stresses. Conversely, eddy currents can be used to monitor composition and various metallurgical characteristics, provided their influence on conductivity is sufficient to provide the necessary contrast. For example, it is possible to monitor the heat treatment of age-hardenable aluminum alloys because of the marked effect of hardness on conductivity (Fig. 7).

Fig. 7 Relation of hardness and electrical conductivity in an age-hardenable aluminum alloy that permits the eddy current monitoring of heat treatment of the alloy

Magnetic Permeability

Ferromagnetic metals and alloys, including iron, nickel, cobalt, and some of their alloys, act to concentrate the flux of a magnetic field. They are strongly attracted to a magnet or an electromagnet, have exceedingly high and variable susceptibilities, and have very high and variable permeabilities.

Magnetic permeability is not necessarily constant for a given material but depends on the strength of the magnetic field acting upon it. For example, consider a sample of steel that has been completely demagnetized and then placed in a solenoid coil. As current in the coil is increased, the magnetic field associated with the current will increase. The magnetic flux within the steel, however, will increase rapidly at first and then level off so that an additionally large increase in the strength of the magnetic field will result in only a small increase in flux within the steel. The steel sample will then have achieved a condition known as magnetic saturation. The curve showing the relation between magnetic field intensity and the magnetic flux within the steel is known as a magnetization curve. Magnetization curves for annealed commercially pure iron and nickel are shown in Fig. 8. The magnetic permeability of a material is the ratio between the strength of the magnetic field and the amount of magnetic flux within the material. As shown in Fig. 8, at saturation (where there is no appreciable change in induced flux in the material for a change in field strength) the permeability is nearly constant for small changes in field strength.

Fig. 8 Magnetization curves for annealed commercially pure iron and nickel

Because eddy currents are induced by a varying magnetic field, the magnetic permeability of the material being inspected strongly influences the eddy current response. Consequently, the techniques and conditions used for inspecting magnetic materials differ from those used for inspecting nonmagnetic materials. However, the same factors that may influence electrical conductivity (such as composition, hardness, residual stresses, and flaws) may also influence magnetic permeability. Thus, eddy current inspection can be applied to both magnetic and nonmagnetic materials. Although magnetic conductors also have an electrical conductivity that can vary with changes in material conditions, permeability changes generally have a much greater effect on eddy current response at lower test frequencies than conductivity variations.

The fact that magnetic permeability is constant when a ferromagnetic material is saturated can be used to permit the eddy current inspection of magnetic materials with greatly reduced influence of permeability variations. The part to be inspected is placed in a coil in which direct current is flowing. The magnitude of current used is sufficient to cause magnetic saturation of the part. The inspection (encircling) coil is located within the saturation coil and close to the part being inspected. This technique is generally used when inspecting magnetic materials for discontinuities because small variations in permeability are not of interest and may cause rejection of acceptable material.

Lift-Off Factor

When a probe inspection coil, attached to a suitable inspection instrument, is energized in air, it will give some indication even if there is no conductive material in the vicinity of the coil. The initial indication will begin to change as the coil is moved closer to a conductor. Because the field of the coil is strongest close to the coil, the indicated change on the instrument will continue to increase at a more rapid rate until the coil is directly on the conductor. These changes in indication with changes in spacing between the coil and the conductor, or part being inspected, are called lift-off. The lift-off effect is so pronounced that small variations in spacing can mask many indications resulting from the condition or conditions of primary interest. Consequently, it is usually necessary to maintain a constant relationship between the size and shape of the coil and the size and shape of the part being inspected. The lift-off effect also accounts for the extreme difficulty of performing an inspection that requires scanning a part having a complex shape.

The change of coil impedance with lift-off can be derived from the impedance-plane diagram shown in Fig. 9. When the coil is suspended in air away from the conductor, impedance is at a point at the upper end of the curve at far left in Fig. 9. As the coil approaches the conductor, the impedance moves in the direction indicated by the dashed lines until the coil is in contact with the conductor. When contact occurs, the impedance is at a point corresponding to the impedance of the part being inspected, which in this case represents its conductivity. The fact that the lift-off curves approach the conductivity curve at an angle can be utilized in some instruments to separate lift-off signals from those resulting from variations in conductivity or some other parameter of interest.

Fig. 9 Impedance-plane diagram showing curves for electrical conductivity and lift-off. Inspection frequency was 100 kHz.

Although troublesome in many applications, lift-off can also be useful. For example, with the lift-off effect, eddy current instruments are excellent for measuring the thickness of nonconductive coatings, such as paint and anodized coatings, on metals.

Fill Factor

In an encircling coil, a condition comparable to lift-off is known as fill factor. It is a measure of how well the part being inspected fills the coil. As with lift-off, changes in fill factor resulting from such factors as variations in outside diameter must be controlled because small changes can give large indications. The lift-off curves shown in Fig. 9 are very similar to those for changes in fill factor. For a given lift-off or fill factor, the conductivity curve will shift to a new position, as indicated in Fig. 9. Fill factor can sometimes be used as a rapid method for checking variations in outside diameter measurements in rods and bars.

For an internal, or bobbin-type, coil, the fill factor measures how well the inspection coil fills the inside of the tubing being inspected. Variations in the inside diameter of the part must be controlled because small changes in the diameter can give large indications.

Edge Effect

When an inspection coil approaches the end or edge of a part being inspected, the eddy currents are distorted because they are unable to flow beyond the edge of a part. The distortion of eddy currents results in an indication known as edge effect. Because the magnitude of the effect is very large, it limits inspection near edges. Unlike lift-off, little can be done to eliminate edge effect. A reduction in coil size will lessen the effect somewhat, but there are practical limits that dictate the sizes of coils for given applications. In general, it is not advisable to inspect any closer than 3.2 mm ($\frac{1}{8}$ in.) from the edge of a part, depending on variables such as coil size and test frequency.

Skin Effect

In addition to the geometric relationship that exists between the inspection coil and the part being inspected, the thickness and shape of the part itself will affect eddy current response. Eddy currents are not uniformly distributed throughout a part being inspected; rather, they are densest at the surface immediately beneath the coil and become progressively less dense with increasing distance below the surface--a phenomenon known as the skin effect. At some distance below the surface of a thick part there will be essentially no currents flowing.

Figure 10 shows how the eddy current varies as a function of depth below the surface. The depth at which the density of the eddy current is reduced to a level about 37% of the density at the surface is defined as the standard depth of penetration. This depth depends on the electrical conductivity and magnetic permeability of the material and on the frequency of the magnetizing current. Depth of penetration decreases with increases in conductivity, permeability, or inspection frequency. The standard depth of penetration can be calculated from:

$$S = 1980 \sqrt{\rho / \mu f} \quad (\text{Eq 1})$$

where S is the standard depth of penetration (in inches), ρ is the resistivity (in ohm-centimeters), μ is the magnetic permeability (1 for nonmagnetic materials), and f is the inspection frequency (in hertz). Resistivity, it should be noted, is the reciprocal of conductivity. The standard depth of penetration, as a function of inspection frequency, is shown for several metals at various electrical conductivities in Fig. 11.

Fig. 10 Variation in density of eddy current as a function of depth below the surface of a conductor--a variation commonly known as skin effect

Fig. 11 Standard depths of penetration as a function of frequencies used in eddy current inspection for several metals of various electrical conductivities

The eddy current response obtained will reflect the workpiece material thickness. It is necessary, therefore, to be sure that either the material has a constant thickness or is sufficiently thick so that the eddy currents do not penetrate completely through it. It should be remembered that the eddy currents do not cease at the standard depth of penetration but continue for some distance beyond it. Normally, a part being inspected must have a thickness of at least two or three standard

depths before thickness ceases to have a significant effect on eddy current response. By properly calibrating an eddy current instrument, it is possible to measure material thickness because of the varying response with thickness. Changing material thickness follows curves in the impedance plane such as those shown in Fig. 12. As indicated by the curves, measurements of thickness by the eddy current method are more accurate on thin materials (Fig. 12b) than they are on thick materials (Fig. 12a). The opposite is true of thickness measurements made by ultrasonics; thus, the two methods complement each other.

Fig. 12 Typical impedance-plane diagrams for changing material thickness. (a) Diagram for thick material. (b) Diagram for thin material on an expanded scale. Inspection frequency was 100 kHz.

Principal Impedance Concepts

This section considers in detail some of the principal impedance concepts that are fundamental to an understanding and effective application of eddy current inspection.

Impedance of a Long Coil Encircling a Thin-Wall Tube. An impedance diagram for a long coil encircling a thin-wall nonferromagnetic tube, with reactance values plotted as ordinates (horizontal axes) and resistance values plotted as abscissas (vertical axes), is shown in Fig. 13. When a tube being inspected has zero conductance (the empty-coil condition), the impedance point is at A. The coil input impedance is all reactance and is equal to ωL or $2\pi fL$ ohms. The resistance component is zero. The ac resistance of the coil wire is assumed to be constant and is not included in these diagrams. As the conductance of the part being inspected is caused to increase, the impedance, Z , follows the locus ABO, for which an example is shown in Fig. 13. This is a circular arc and occurs as shown in Fig. 13 if the tube wall is very thin compared with the skin depth at the frequency of operation. The impedance locus is marked with reference numbers calculated from the dimensionless constant $\sqrt{\omega L_0 G}$ and placed on the locus at points corresponding to the respective impedance values.

Fig. 13 Impedance diagram for a long coil encircling a thin-wall nonferromagnetic tube, showing also an equivalent circuit. R : series resistance; R_s : effective shunt resistance; ω : $2\pi f$; f : frequency; G : shunt conductance; L_0 : coil inductance; Z : impedance; j : $\sqrt{-1}$; $\sqrt{\omega L_0 G}$: dimensionless constant

Several characteristics of the eddy current inspection of tubes or bars are shown in Fig. 13. The simplification resulting from the assumption that skin effect is absent alters the detailed loci in important ways, as shown in subsequent diagrams. However, this simplified diagram serves as an introduction to the more detailed diagrams, which include the variations caused by the skin effect. The locus ABO in Fig. 13 shows the effect on the effective coil impedance of changing the conductance of the thin-wall tube; because the tube conductance is proportional to the product of the wall thickness of the tube and the conductivity of the tube material, the impedance loci resulting from variation of thickness coincide with the locus associated with varying tube material conductivity.

Effects of Changing Operating Frequency. One effect of changing operating frequency is to increase the empty-coil reactance in direct proportion to the frequency; thus, the impedance diagram grows in size. However, with the part being inspected in place within the coil, the impedance of the coil for different part conditions and different frequency values changes at different rates as the frequency changes. This is shown in Fig. 14 as a prelude to introducing the concept of impedance normalization. Although frequency is contained in the diagram in Fig. 13, the discussion of that diagram is based on a fixed frequency. In contrast, Fig. 14 shows the impedance of a long coil encircling a thin-wall nonferromagnetic tube as a function of frequency. As in Fig. 13, the shape of the impedance locus is semicircular because of the negligible skin effect, but now there is a separate locus for each frequency considered. Impedance loci are shown for ten different operating frequencies (ω_1 through $10\omega_1$). Each locus represents a condition of maximum coupling between the long solenoid and the encircled tube. This maximum coupling cannot be realized in practice, because the diameter of the tube and of the coil would need to be equal. The coil wire must occupy some space; therefore, it is not possible for the exciting current to flow exactly at the surface.

Fig. 14 Impedance diagram for a long coil encircling a thin-wall nonferromagnetic tube showing impedance as a function of frequency

The ten curves in Fig. 14 show that the impedance of the empty coil, assuming the coil resistance is negligible, increases in direct proportion to increases in operating frequency and that this impedance is reactive. The coil at the operating frequency of ω_1 has a reactance of $\omega_1 L_0$ ohms. At a frequency of $2\omega_1$, the reactance is doubled, and so on, until at $10\omega_1$,

the reactance is $10\omega_1 L_0$. In contrast to this linear change of impedance or reactance with frequency, note the nonlinear change of impedance when the coil has a part within it. First, assume that the part being inspected is a thin-wall tube and that its reference number $\sqrt{\omega L_0 G}$ is 0.316 at radian frequency ω_1 . This corresponds to point A on the conductance locus of the coil at radian frequency ω_1 . Locus ABC shows the change in impedance of this particular combination of coil and tube as the frequency is increased from ω_1 to $10\omega_1$. The impedance variation is far from linear with respect to frequency variation. Locus DEF similarly shows the impedance variation as frequency varies from ω_1 to $10\omega_1$ when the tube reference number $\sqrt{\omega L_0 G} = 0.2$ at radian frequency ω_1 .

It is customary to normalize groups of impedance curves, such as those in Fig. 14, by dividing both reactance and resistance values by the impedance or reactance of the empty coil. This transforms all the curves into a single curve, such as the outer or large curve in Fig. 15, which can be used under a wide range of conditions. When using the single curve, the nature of its origin must be recalled in interpreting the real effect of varying frequency. Correct relative changes in impedance are shown on the normalized curve as the frequency is changed in the reference number $\sqrt{\omega L_0 G}$, but the actual growing nature of the impedance plane as frequency is increased is hidden.

Fig. 15 Effects of variations in tube radius on the impedance of a long coil of fixed diameter encircling a thin-wall nonferromagnetic tube. G : conductance; r : tube radius; r_c : coil radius.

Several other characteristics of the impedance diagrams for a long coil encircling a tube or bar are shown for simplified conditions in Fig. 15. The tube wall is assumed to be very thin in relation to the skin depth at the frequency of operation. The large semi-circular curve represents the locus of impedance resulting from changing tube conductance. Because the tube wall is assumed to be very thin, skin effect is minimal. Maximum coupling exists between the coil and the tube, and

because the conductance is equal to the product of conductivity of the tube material and the wall thickness in this simplified example, the conductivity locus and thickness locus are identical. Note, however, that the skin effect must be negligible for this condition to be obtained. The curves of smaller radius (arcs ABC, ADE, and AFG) are for tubes having diameters smaller than the coil diameters. As the tube diameter becomes smaller, the electromagnetic coupling between the coil and tube decreases, and loci such as HBDFA or HIJKA would be generated. The curvature of the loci depends on the rate at which the conductance of the thin-wall tube varies as the radius is decreased. Figure 15, therefore, shows that increases in conductance of the thin-wall tube produce semicircular loci whose radii depend on tube diameter and the amount of coupling (fill factor) between the inspection coil and the tube. The change in conductance may be caused by a change in either the wall thickness or the electrical conductivity of the tube.

Solid Cylindrical Bar. The normalized impedance diagram for a long encircling coil closely coupled to a solid cylindrical nonferromagnetic bar is shown in Fig. 16. The locus for the thin-wall tube in Fig. 16 is similar to that discussed in Fig. 14 and 15. The locus for the solid bar is constructed from an analytical solution of Maxwell's equations for the particular conditions existing for the solid bar. The reference number quantity for the bar is different from that of the thin-wall tube to satisfy the new conditions for the solid bar for which the skin effect is no longer negligible. The new reference number quantity $\sqrt{r^2\omega\mu\sigma}$ or $r\sqrt{\omega\mu\sigma}$ is from the theory developed in the application of Maxwell's equations for a cylindrical conductor. The quantity $\sqrt{\omega\mu\sigma}$ is the electromagnetic wave propagation constant for a conducting material, and the quantity $\sqrt{\omega L_0 G}$ is the equivalent of $\sqrt{\omega\mu\sigma}$ for simplified electric circuits. The quantity $\sqrt{r^2\omega\mu\sigma}$ or $r\sqrt{\omega\mu\sigma}$ is dimensionless and serves as a convenient reference number for use in entering on the impedance diagram.

Fig. 16 Normalized impedance diagram for a long coil encircling a solid cylindrical nonferromagnetic bar showing also the locus for a thin-wall tube (which is similar to the loci in Fig. 14 and 15). k , electromagnetic wave propagation constant for a conducting material, or $\sqrt{\omega\mu\sigma}$; r , radius of conducting cylinder, meters; ω , $2\pi f$; f , frequency; $\sqrt{\omega L_0 G}$, equivalent of $\sqrt{\omega\mu\sigma}$ for simplified electric circuits; μ , magnetic permeability of bar, or $= 4\pi \times 10^{-7}$ H/m if bar is nonmagnetic; σ , electrical conductivity of bar, mho/m; 1.0, coil fill factor

In Fig. 16, the impedance region between the semicircular locus of the impedance for the thin-wall tube and the locus for the solid cylinder represents impedance values for hollow cylinders or tubes of various wall thicknesses and of materials with different electrical conductivities. In each case, the outer radius of the tube is equal to the radius of the coil--the ideal for maximum coupling. The effect on impedance of changing the outer radius of the tube can be projected from the effects illustrated in Fig. 15, in which a group of electrical-conductivity loci are shown generated by varying the tube radius. The effect on impedance of varying the outer radius or diameter of the solid cylinder is shown in Fig. 17.

Fig. 17 Effect of variation in bar diameter on the impedance of a long coil encircling a solid cylindrical nonferromagnetic bar

The locus resulting from varying the outer diameter of the cylindrical bar does not follow a straight path. The reference number is a function of bar radius, r , and as the radius becomes smaller, the reference number is likewise reduced, producing a curved radius locus such as the locus ABCD in Fig. 17. At lower values of $r\sqrt{\omega\mu\sigma}$, the radius locus intercepts the conductivity locus at slighter angles and nearly parallels the conductivity locus, as shown in locus EFD in Fig. 17. This difference in intercept angle is of importance when it is required to discriminate between conductivity variations and diameter variations. The larger intercept angle permits better discrimination. The factor $(r_a/r_c)^2$, where r_a is

the cylindrical bar radius and r_c is the coil radius, is called the fill factor and represents that fraction of the coil area occupied by the bar.

Thickness Loci. Transition from the very thin-wall tube to the solid cylinder produces impedance loci extending generally from the thin-wall tube locus to a final or end point on the solid-cylinder locus determined by the conductivity and frequency, as shown in Fig. 18. These loci curve or spiral in a clockwise direction. When the end points of the thickness loci are points on the solid-cylinder conductivity locus having low values of the reference number $kr = r\sqrt{\omega\mu\sigma}$, the thickness loci are curved but do not rotate around the end point. The spiral effect is more pronounced at the higher values of $kr = r\sqrt{\omega\mu\sigma}$. As in each instance where loci are observed, an opportunity exists to calibrate the instrument readings so that specific points along a locus represent specific values of the variable of interest. In this case, the variable is tube-wall thickness. It is important that other inspection variables such as outer radius of tube and conductivity of tube remain constant if the calibration is to be valid and usable. For example, in Fig. 18, if the tube radius is varied, whole groups of thickness curves can be generated with accompanying changes of position on the phasor diagram and changes in sensitivity.

Fig. 18 Impedance diagram showing thickness-loci transition from tube to solid cylinder

The phase-discrimination technique is often used to reduce the effect of a particular variable on one output signal channel of the eddy current instrument (Fig. 19). The impedance diagram for a probe or pancake coil in the vicinity of a nonferromagnetic part is shown in Fig. 19(a). Assume that this diagram can be displayed on an oscilloscope. The locus ABCD represents a thickness locus obtained when the probe coil is in position on the surface of the part. The point D is called an end point of the thickness locus and as such is located on a conductivity locus for this particular probe. If C

represents the impedance point for nominal or specified thickness, then variations above or below this nominal thickness value will give readings along the thickness loci at perhaps E or F, respectively. If the probe is lifted from the surface for the condition of nominal thickness, locus point C, the locus CGA is generated. This new locus is sometimes called a coil lift-off locus. When thickness is being measured, it is often desired to reduce the effect of small excursions of the probe from the surface. The phase-discrimination technique can be used for this purpose.

Fig. 19 Phase-discrimination technique for reducing the effect of a particular variable on one output-signal channel during eddy current inspection. (a) Impedance diagram for a probe or pancake coil in the vicinity of a nonferromagnetic part. (b) Enlarged view of the area in the vicinity of impedance point C in diagram (a) as seen on an oscilloscope with the thickness locus in the normal position. (c) Pattern shown in (b) rotated until the coil lift-off locus is horizontal on the oscilloscope. See text for explanation.

The region of the diagram in the vicinity of impedance point C in Fig. 19(a) is shown enlarged in Fig. 19(b). One output channel of the instrument produces beam deflections in the vertical direction, and the other in the horizontal direction. The enlarged diagram in Fig. 19(b) shows that variations in coil lift-off produce signals on both vertical and horizontal channels. Thus, the lift-off signals will interfere significantly when it is desired to read the effect of thickness variations. Rotation of the phase-shift control, or phase-discrimination control, rotates the pattern or phasor diagram at the output of the instrument. Rotating the pattern in Fig. 19(b) until the lift-off locus in the vicinity of point C is horizontal (Fig. 19c) minimizes the lift-off signal that is effective in the channel producing vertical deflections. Thus, the signal on the vertical channel now varies with thickness variation with little or no effect from small excursions of the probe. Actually, the thickness calibration still changes slightly as a function of probe position, and significant errors can still be introduced by large lift-off excursions of the probe.

Impedance Changes Caused by Small Flaws. ^{**}The first widely used formula for the impedance change of an eddy current inspection coil due to a small flaw was given by Burrows (Ref 1). Burrows assumed the flaw to be small enough that the electromagnetic fields were essentially uniform in the vicinity of the flaw. In practice, this means that the flaw is small compared to the standard depth of penetration (the skin depth) and the coil radius. He also assumed that, in general, the flaw was subsurface, and the flaw was small compared to the distance below the surface. For certain flaw geometries, he was also able to apply the formula to surface flaws. Although these restrictions do not fit the description of all flaws of interest, the formula allows calculation of the response to very small flaws at the limit of detectability. This information can be used for estimating ultimate performance and optimizing coil design for detectability.

By restricting the class of materials to nonferromagnetic materials with conductivity σ and the flaws to voids, Burrows's formula can be simplified to the following useful version (Ref 2). If a current I_1 of radian frequency ω in coil 1 causes a uniform magnetic vector potential of magnitude A_1 at the flaw and if a current I_2 in coil 2 causes a uniform potential of magnitude A_2 at the flaw, then the change in the mutual impedance due to the presence of the flaw is:

$$\Delta Z_{12} = \left[\left(\frac{1}{2} \right) \sigma \omega^2 \left(\frac{A_1}{I_1} \right) \left(\frac{A_2}{I_2} \right) \right] \cdot [\text{Volume} \cdot \text{SOF}] \quad (\text{Eq 2})$$

where SOF is the shape and orientation factor of the flaw. If there is only one coil, then $A_1 = A_2$, and the mutual impedance becomes the self-impedance of the coil.

In general, the SOF is a complex function of the shape and orientation of the flaw relative to the eddy current fields. However, there are two special cases of interest for which the SOF is relatively simple: the sphere and the circular disk, or penny flaw. For the spherical void, the shape and orientation factor SOF is 1, and the volume is $(\frac{4}{3})\pi a^3$, where a is the radius of the sphere. For a circular disk oriented with the circle perpendicular to the eddy current field direction, the product of the volume and SOF is $(\frac{16}{9})a^3$. The same theory can also be applied to surface counterparts of these two flaws: the hemisphere and the half disk, or half penny flaw. In both of these cases, the product of the volume of SOF is half that of their subsurface counterparts, because of the volume being halved.

The other part of Burrows's formula requires determination of the magnitudes of the magnetic vector potentials, A_1 and A_2 . Formulas for calculating the magnetic vector potential fields of coils in proximity to conductors are given in Ref 3. These formulas are in the form of definite integrals, which can be evaluated by computer for the geometry of interest.

There have been numerous extensions to the Burrows formulation of the impedance change formula that relax the restriction that the flaw size be small compared to the skin depth and extend the range of flaw shapes for which the SOF can be calculated. However, the solution remains in the basic form given by Burrows, which shows the dependence of the impedance change on the square of the field strength and the effective volume and orientation of the flaw.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection Frequencies

The inspection frequencies used in eddy current inspection range from about 200 Hz to 6 MHz or more. Inspections of nonmagnetic materials are usually performed at a few kilohertz. In general, the lower frequencies, which start at about 1 kHz, are used for inspecting magnetic materials. However, the actual frequency used in any specific eddy current inspection will depend on the thickness of the material being inspected, the desired depth of penetration, the degree of sensitivity or resolution required, and the purpose of the inspection.

Selection of inspection frequency is normally a compromise. For example, penetration should be sufficient to reach any subsurface flaws that must be detected. Although penetration is greater at lower frequencies, it does not follow that as low a frequency as possible should be used. Unfortunately, as the frequency is lowered, the sensitivity to flaws decreases somewhat, and the speed of inspection can be curtailed. Normally, therefore, an inspection frequency as high as possible that is still compatible with the penetration depth required is selected. The choice is relatively simple when detecting surface flaws only, in which case frequencies up to several megahertz can be used. When detecting flaws at some

considerable depth below the surface, very low frequencies must be used and sensitivity is sacrificed. Under these conditions, it is not possible to detect small flaws.

In inspecting ferromagnetic materials, relatively low frequencies are normally used because of the low penetration in these materials. Higher frequencies can be used when it is necessary to inspect for surface conditions only. However, even the higher frequencies used in these applications are still considerably lower than those used to inspect nonmagnetic materials for similar conditions.

Selection of operating frequency for the inspection of nonferromagnetic cylindrical bars can be estimated using the chart in Fig. 20. The three main variables on the chart are conductivity, diameter of the part, and operating frequency. A fourth variable, the operating point on the simple impedance curve, is also taken into account. Usually, the desired operating point for cylindrical bars corresponds to a value of $kr = r\sqrt{\omega\mu\sigma}$, which is approximately 4, but which can be in the range 2 to 7. In a typical problem, the two variables of the part, conductivity and radius (or diameter), are known, and it is necessary to find the frequency of operation to determine a particular operating point on the single impedance diagram.

Step 1 Select the value of electrical conductivity (σ) of the bar in per cent IACS (International Annealed Copper Standard) on line A.

Step 2 Select the value of the bar diameter (d) in mils or in inches on either of the scales in line B.

Step 3 Lay a straightedge between these two points, extending the line connecting them to intersect line C.

Step 4 Extend a line vertically from the point on line C found in step 3 until it intersects with a horizontal line corresponding to

the desired value of kr .

Step 5 The desired operating frequency is read from the frequency chart (slanted lines), selecting the frequency line that intersects the intersection determined in step 4.

Fig. 20 Chart for selection of frequency for the inspection of nonferromagnetic cylindrical bars

Some typical impedance points and the corresponding kr values are shown in the small impedance diagram at the top left of Fig. 20. A column of values of $r^2\omega\mu\sigma = (kr)^2 = f/f_g$ are also given as a common point between the use of $r\sqrt{\omega\mu\sigma}$ or $f/f_g = r^2\omega\mu\sigma$ as the reference number.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Multifrequency Techniques**

Instrumentation capable of operating at two or more test frequencies has expanded the capabilities of the eddy current method by allowing the user to perform simultaneous tests and to provide for signal combinations using multiparameter techniques. The most widely used application of multifrequency technology has been the inspection of installed heat exchanger tubing. The thin-wall nonferromagnetic tubing used in the production of steam by nuclear power has been extensively tested using these multifrequency techniques since 1977. These steam generators contain thousands of tubes, all of which form a pressure boundary that must be periodically inspected to ensure the safe operating condition of the power plant. In addition to the necessity for inspecting with inside coils, all test probe positioning for tube selection and probe insertion/withdrawal functions must be performed remotely due to the radiation levels in the vicinity of the tube access areas.

Instrumentation Methods. Test coils are typically excited with multifrequency signals using either continuous or sequential methods.

In the continuous method, excitation currents at each test frequency are simultaneously impressed on the test coil. The test coil outputs are separated by bandpass filters tuned to the individual test frequencies.

The sequential technique relies on switching between test frequencies and is often referred to as a multiplexed system. Detection or demodulation, along with signal display capabilities, is provided for each test frequency. Virtually all the equipment used for this application provides phase and amplitude signal representation through the use of either a cathode ray oscilloscope or a computer screen. The x and y signal components are derived from phase detector circuits electrically separated by 90° . The two signal components are displayed as a single moving point on the screen. Through the use of the storage capabilities of an oscilloscope or other computer methods, the point is traced on the screen to describe what is commonly called a Lissajous signal. Additional instrumentation capabilities can include provisions for both differential and absolute coil arrangements as well as the use of multiple-coil arrays.

Test Frequency and Coil Arrangement Selection. The test frequency for the inspection of installed nonferromagnetic tubing is selected to provide both flaw detection and depth measurement.

Differential Coil Arrangement. With a differential coil arrangement, flaw depth can be related to the change in the angle of the displayed Lissajous signal. Figures 21(a) and 22(a) show the Lissajous signals resulting from artificial flaws in Inconel 600 tubing having a wall thickness of 1.3 mm (0.050 in.) tested at both 400 and 100 kHz. The flaws are 100, 80, 60, 40, and 20% through wall flat-bottom holes originating from the outside diameter of this tube. Although a test frequency of 400 kHz provides a larger range of angles with which to measure flaw depth, testing at 100 kHz can provide for better detection of minor flaws on the tube outside diameter. The capability to test simultaneously at both frequencies can be used to accomplish two goals and to confirm a flawed condition by noting the flaw signal with both tests.

Fig. 21 Lissajous signals resulting from 100, 60, 40, and 20% through wall outside diameter flows when tested (a) at 400 kHz, (b) at 400 kHz with tube support plate added, and (c) with a digital mixing technique used to eliminate the signal noise that originates from the tube support plate

Fig. 22 Lissajous signals resulting from 100, 80, 40, and 20% through wall outside diameter flaws tested at 100 kHz (a) without tube support plate and (b) with tube support plate.

Absolute Coil Arrangement. Another factor in determining test frequency might be the desire to measure either conductive and magnetic depositions occurring on the tube. A lower test frequency can provide better sensitivity to magnetic deposits that have accumulated on the tube outside diameter. This has been a common practice in an attempt to determine the relationship between deposits on the outer tube wall surface and the presence of flaws originating in the same area. On the other hand, testing at a higher frequency might be desirable to provide increased sensitivity to variations on the inside diameter of the tubing. The latter method, using an absolute coil arrangement, has been implemented to profile the inside diameter of installed tubing that had been incorrectly expanded with mechanical rollers. This test has provided information that enabled an assessment of the induced high-stress areas as well as a basis for selective repair procedures.

The ability to test at multiple frequencies and with both differential and absolute coil arrangements can allow the discrimination and detection of various flaw mechanisms as well as other anomalies of interest in one test scan. This is of great importance where inspection time is critical.

Multiparameter techniques are used to separate test variables by combining the results of testing at more than one frequency. The test variables, or parameters, can include effects such as:

- Lift-off variation caused by probe wobble
- Tube dimension changes resulting from dents, pilgering, and tube expansion processes
- Extraneous signals resulting from tube support plates or depositions (Figures 21(b) and 22(b) illustrate the same flaw signals as shown in Fig. 21(a) and 22(a), with the additional signal resulting from the tube support plate)
- Flaws caused by wastage, cracking, pitting, and so on

By far the most important aspect of the multiparameter method is to provide for the detection and sizing of flawed conditions in the presence of the effects of the other variables.

One commonly used technique combines the signal from the selected test frequency for flaw detection with a lower frequency to eliminate the effects of the signal resulting from a tube support plate. This mixing process has been accomplished using both analog and digital techniques and combines the output signals from two test frequencies in such a way that the support plate signal is suppressed or eliminated while the signals resulting from flawed conditions remain.

In the analog instrumentation approach, the x and y signal components of the lower-frequency signal are rotated and/or scaled such that the resulting support plate signal closely matches the support plate signal from the test frequency used for flaw detection. The outputs are then combined in a way that subtracts the manipulated lower-frequency signal outputs from the flaw detection frequency output. The result is a mixed signal that shows no response to support plate influences yet can be used to detect and measure flaws.

Digitally, results of equal or better quality can be achieved. Rather than manually manipulating the signal with phase rotators and amplifiers, as is typically done in analog instrumentation, a computer can solve for the best result using mathematical techniques. Figure 21(c) shows the data of Fig. 21(b) resulting from a digital combination or mix used to suppress the support plate response. One approach is to establish a set of simultaneous linear equations prescribing a general signal combination condition. The coefficients of the independent variables are then determined through a least-squares method to provide the signal output desired.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection Coils

The inspection coil is an essential part of every eddy current inspection system. The shape of the inspection coil depends to a considerable extent on the purpose of the inspection and on the shape of the part being inspected. When inspecting for flaws, such as cracks or seams, it is essential that the flow of the eddy currents be as nearly perpendicular to the flaws as possible to obtain a maximum response from the flaws. If the eddy current flow is parallel to flaws, there will be little or no distortion of the currents and therefore very little reaction on the inspection coil.

Probe and Encircling Coils. Of the almost infinite variety of coils employed in eddy current inspection, probe coils and encircling coils are the most commonly used. Normally, in the inspection of a flat surface for cracks at an angle to the surface, a probe-type coil would be used because this type of coil induces currents that flow parallel to the surface and therefore across a crack, as shown in Fig. 23(a). On the other hand, a probe-type coil would not be suitable for detecting a

laminar type of flaw. For such a discontinuity, a U-shaped or horseshoe-shaped coil, such as the one shown in Fig. 23(b), would be satisfactory.

Fig. 23 Types and applications of coils used in eddy current inspection. (a) Probe-type coil applied to a flat plate for detection of a crack. (b) Horseshoe-shaped or U-shaped coil applied to a flat plate for detection of a laminar flaw. (c) Encircling coil applied to a tube. (d) Internal or bobbin-type coil applied to a tube

To inspect tubing or bar, an encircling coil (Fig. 23c) is generally used because of complementary configuration and because of the testing speeds that can be obtained with this type of coil. However, an encircling coil is sensitive only to discontinuities that are parallel to the axis of the tube or bar. The coil is satisfactory for this particular application because, as a result of the manufacturing process, most discontinuities in tubing and bar are parallel to the major axis. If it is necessary to locate discontinuities that are not parallel to the axis, a probe coil must be used, and either the coil or the part must be rotated during scanning. To detect discontinuities on the inside surface of a tube or when testing installed tubing, an internal or bobbin-type coil (Fig. 23d) can be used. The bobbin-type coil, like the encircling coil, is sensitive to discontinuities that are parallel to the axis of the tube or bar.

Multiple Coils. In many setups for eddy current inspection, two coils are used. The two coils are normally connected to separate legs of an alternating current bridge in a series-opposing arrangement so that when their impedances are the same, there is no output from the pair. Pairs of coils can be used in either an absolute or a differential arrangement (Fig. 24).

Fig. 24 Absolute and differential arrangements of multiple coils used in eddy current inspection. See text for discussion.

Absolute Coil Arrangements. In the absolute arrangement (Fig. 24a), a sample of acceptable material is placed in one coil, and the other coil is used for inspection. Thus, the coils are comparing an unknown against a standard, with the differences between the two (if any) being indicated by a suitable instrument. Arrangements of this type are commonly employed in sorting applications.

Differential Coil Arrangement. In many applications, an absolute coil arrangement is undesirable. For example, in tubing inspection, an absolute arrangement will indicate dimensional variations in both outside diameter and wall thickness even though such variations may be well within allowable limits. To avoid this problem, a differential coil arrangement such as that shown in Fig. 24(b) can be used. Here, the two coils compare one section of the tube with an adjacent section. When the two sections are the same, there is no output from the pair of coils and therefore no indication on the eddy current instrument. Gradual dimensional variations within the tube or gross variations between individual tubes are not indicated, while discontinuities, which normally occur abruptly, are very apparent. In this way, it is possible to have an inspection system that is sensitive to flaws and relatively insensitive to changes that normally are not of interest.

Sizes and Shapes. Inspection coils are available in a variety of sizes and shapes. Selection of a coil for a particular application depends on the type of discontinuity. For example, when an encircling coil is used to inspect tubing or bar for short discontinuities, optimum resolution is obtained with a short coil. Alternatively, a short coil has the disadvantage of being sensitive to the position of the part in the coil. Longer coils are not as sensitive to the position of the part, but are not as effective in detecting very small discontinuities. Small-diameter probe coils have greater resolution than larger ones, but are more difficult to manipulate and are more sensitive to lift-off variations.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Eddy Current Instruments

This section discusses the various types of detection and readout instrumentation used in eddy current inspection.

Instrument System Operations

Eddy current instruments can be classified as belonging to one of the following categories:

- Resistor and single-coil system
- Bridge unbalance system
- Induction bridge system
- Through transmission system

Resistor and Single-Coil System. A simple eddy current instrument, in which the voltage across an inspection coil is monitored, is shown in Fig. 25(a). This circuit is adequate for measuring large lift-off variations if accuracy is not extremely important.

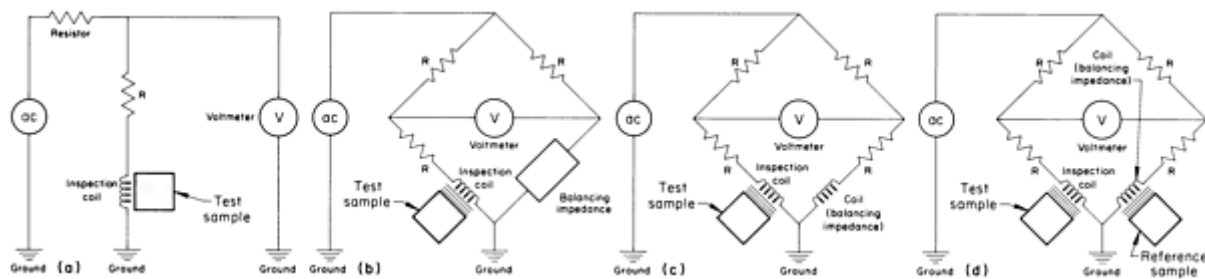

Fig. 25 Four types of eddy current instruments. (a) A simple arrangement, in which voltage across the coil is monitored. (b) Typical impedance bridge. (c) Impedance bridge with dual coils. (d) Impedance bridge with dual coils and a reference sample in the second coil

Bridge Unbalance System. A circuit designed for greater accuracy is shown in Fig. 25(b). This instrument consists of a signal source, an impedance bridge with dropping resistors, an inspection coil in one leg, and a balancing impedance in the other leg. The differences in voltage between the two legs of the bridge are measured by an ac voltmeter. Alternatively, the balancing impedance in the leg opposite the inspection coil may be a coil identical to the inspection coil, as shown in Fig. 25(c), or it may have a reference sample in the coil, as shown in Fig. 25(d). In the latter, if all the other components in the bridge were identical, a signal would occur only when the inspection coil impedance deviated from that of the reference sample.

There are other methods of achieving bridge balance, such as varying the resistance values of the resistor in the upper leg of the bridge and one in series with the balancing impedance. The most accurate bridges can measure absolute impedance to within 0.01%. However, in eddy current inspection, it is not how an impedance bridge is balanced that is important, but rather how it is unbalanced. Because of the effect of undesired variables, eddy current inspections are seldom performed with the bridge balance.

Figure 26 plots the voltages across an inspection coil, V_1 , and a reference coil, V_2 , for a bridge such as that shown in Fig. 25(c). For simplification, the loading effects the voltmeter has on the system have been omitted. Voltage inspection values for nine different samples, representing three different levels of magnetic permeability and three different levels of

electrical conductivity, are shown. The voltage measured by the voltmeter is the magnitude of the difference between the voltages of the inspection coil and the reference coil. The voltage of the reference coil can be moved to any point on the diagram by varying the components in the bridge. For this particular inspection, the intent was to measure the small permeability changes without being affected by the conductivity changes. If the bridge were balanced at the nominal value so that the \mathbf{V}_2 vector terminated on the point $\sigma = \sigma_0$ and $\mu = 1.005$, changes in permeability would result in a large change in the magnitude of the difference voltage, $|\Delta \mathbf{V}|$, but a similarly large change would result if the conductivity varied. However, if the voltage of the reference coil were adjusted equidistant from $\sigma = \sigma_0 - \Delta\sigma$ and $\sigma_0 + \Delta\sigma$, then the same difference voltage will result for both points (for changes in conductivity), but a large change in difference voltage will result with changes in permeability. If the line between $\sigma_0 - \Delta\sigma$ and $\sigma_0 + \Delta\sigma$ is the arc of a circle and if the voltage of the reference coil is adjusted to the center of that circle, then there will be no change in the magnitude of the difference voltage as the conductivity varies between $\sigma_0 - \Delta\sigma$ to $\sigma_0 + \Delta\sigma$, but the voltage will vary with permeability changes. Thus, the effects of the undesired variable--conductivity--can be reduced or eliminated, and the measurement can be made sensitive to the desired variable--permeability. This indicates how bridge unbalance is used to eliminate a single undesired variable.

Fig. 26 Complex voltage diagram for an inspection coil and a reference coil. The voltage inspection values are for nine different samples, representing three different levels of magnetic permeability and three different levels of electrical conductivity.

A major limitation of this technique is that there are usually several undesirable variables in any eddy current inspection, and not all of them can be eliminated completely. Normalized coil impedance variations with conductivity and lift-off produce changes in impedance that are not parallel to each other. Regardless of where the reference-voltage point is set, the effects of both variables cannot be eliminated completely. Thus, with a single-frequency inspection, it is preferable to select operating conditions so that undesired variables are all approximately parallel to each other and perpendicular to the variable to be measured. A two-frequency inspection would allow for the measurement of four variables.

In some applications, it is more desirable to measure the phase rather than the magnitude of the voltage difference. For example, Fig. 27 shows how both the magnitude and phase of the unbalance voltage vary as functions of electrical conductivity and lift-off. Thus, it is possible to measure the phase shift as a function of conductivity and be relatively insensitive to changes in lift-off, the usual method of phase measurement. On the other hand, magnitude can be measured as a function of lift-off and can be relatively insensitive to the conductivity. As a result, the unbalanced bridge can function as a decoding network to separate the two variables.

Fig. 27 Complex voltage diagram for inspection coil and reference coil for various electrical conductivities and lift-off

Temperature stability is also more of a problem when the bridge is unbalanced. When the bridge is balanced and two corresponding components in opposite legs of the bridge drift with exactly the same temperature coefficient, the bridge remains in balance. However, when the bridge is operated in an unbalanced mode, the thermal drift in components fails to cancel by an amount proportional to the amount of unbalance.

Another limitation in bridge unbalance procedures is the difficulty in finding the proper unbalance. There are many poor choices for setting the reference voltage, and the few good choices are difficult to identify when only one meter is used to monitor voltage.

Induction Bridge System. Another type of bridge system is an induction bridge, in which the power signal is transformer-coupled into an inspection coil and a reference coil. In addition, the entire inductance-balance system is placed in the probe, as shown in Fig. 28. The probe consists of a large transmitter, or driver, coil, and two small detector, or pickup, coils wound in opposite directions as mirror images to each other. An alternating current is supplied to the large transmitter coil to generate a magnetic field. If the transmitter coil is not in the vicinity of a conductor, the two detector coils detect the same field, and because they are wound in opposition to each other, the net signal is zero. However, if one end of the probe is placed near a metal surface, the field is different at the two ends of the probe, and a net voltage appears across the two coils. The resultant field is the sum of a transmitted signal, which is present all the time, and a reflected signal due to the presence of a conductor (the metal surface). The intensity of the transmitted signal decreases rapidly as the distance between the coil and conductor is increased, and the intensity of the reflected wave does the same. The detector coil nearer the conductor detects this reflected wave, but the other detector coil (the reference coil) does not, because the amplitude of the wave has greatly decreased in the distance from the reflecting metal surface to the rear detector coil.

Fig. 28 Reflection (transmit-receive) probe in place at the surface of a workpiece. Schematic shows how power signal is transformer-coupled from a transmitter coil into two detector coils--an inspection coil (at bottom) and a reference coil (at top).

The magnitude and phase obtained for a system such as this are similar to those in a bridge unbalance system (Fig. 27) with the reference coil in air. However, the effects of temperature variations of the probe can be completely eliminated from the phase-shift measurements.

Through Transmission System. Another system of eddy current measurements is the through transmission system, in which a signal is transmitted from a coil through a metal and detected by a coil on the opposite side of the metal. If the distance between the two coils is fixed and the driving and detecting circuits have high impedances, the signal detected is

independent of position of the metal provided it remains between them. This type of measurement completely eliminates lift-off but requires that the two coils be positioned.

Table 2 outlines the types of eddy current instruments commercially available and lists the capabilities. The features listed are intended to cover all instruments of a given type. No one instrument includes all the features listed for a given type of instrument; several manufacturers produce each of the types listed. Each manufacturer will provide more precise details and specifications on instrument type, performance, and coil parameters.

Table 2 Types and capabilities of commercially available eddy current instruments

Type of instrument	Frequency range	Signals measured	Simultaneous frequencies	Features
Resistor and single coil	1 kHz to 5 MHz	Magnitude	1	Direct reading, analog meters
Inspection coil and balance coil, bridge unbalance	1 kHz to 5 MHz	Magnitude, phase x_1 , x_r	1	Phase rotation of signals, storage scope, display of impedance planes, continuously variable frequency, x-y alarm gates. Portable up to 500 kHz
Inspection coil and variable impedance, bridge unbalance	1 kHz to 2 MHz	Magnitude, phase x_1 , x_r	1	Direct digital readout of thickness and electrical conductivity, binary coded decimal output
Induction bridge	100 Hz to 50 MHz	Magnitude, phase	2	Simultaneous measurement of four variables, analog computers, binary coded decimal output, direct digital readout of thickness and lift-off. Portable up to 500 kHz

Readout Instrumentation

An important part of an eddy current inspection system is the instrument used for a readout. The readout device can be an integral part of the system, an interchangeable plug-in module, or a solitary unit connected by cable. The readout instrument should be of adequate speed, accuracy, and range to meet the inspection requirements of the system. Frequently, several readout devices are employed in a single inspection system. The more common types of readout, in order of increasing cost and complexity, are discussed in the following sections.

Alarm lights alert the operator that a test parameter limit has been exceeded.

Sound alarms serve the same purpose as alarm lights, but free the attention of the operator so that he can manipulate the probe in manual scanning.

Kick-out relays activate a mechanism that automatically rejects or marks a part when a test parameter has been exceeded.

Analog meters give a continuous reading over an extended range. They are fairly rapid (with a frequency of about 1 Hz), and the scales can be calibrated to read parameters directly. The accuracy of the devices is limited to about 1% of full scale. They can be used to set the limits on alarm lights, sound alarms, and kick-out relays.

Digital meters provide much greater accuracy and range than analog meters. The chance of operator error is much less in reading a digital meter, but fast trends are more difficult to interpret. Although many digital meters have binary coded decimal output they are relatively slow.

X-y plotters can be used to display impedance-plane plots of the eddy current response. They are very helpful in designing and setting up eddy current bridge unbalance inspections and in discriminating against undesirable variables. They are also useful in sorting out the results of inspections. They are fairly accurate and provide a permanent copy.

X-y storage oscilloscopes are very similar to *x-y* plotters but can acquire signals at high speed. However, the signals have to be processed manually, and the screen can quickly become cluttered with signals. In some instruments, high-speed *x-y* gates can be displayed and set on the screen.

Strip chart recorders furnish a fairly accurate ($\sim 1\%$ of full scale) recording at reasonably high speed (~ 200 Hz). However, once on the chart, the data must be read by an operator. Several channels can be recorded simultaneously, and the record is permanent.

Magnetic tape recorders are fairly accurate and capable of recording at very high speed (1 kHz). Moreover, the data can be processed by automated techniques.

Computers. The data from several channels can be fed directly to a high-speed computer, either analog or digital, for online processing. The computer can separate parameters and calculate the variable of interest and significance, catalog the data, print summaries of the result, and store all data on tape for reference in future scans.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Discontinuities Detectable by Eddy Current Inspection

Basically, any discontinuity that appreciably alters the normal flow of eddy currents can be detected by eddy current inspection. With the encircling coil inspection of either solid cylinders or tubes, surface discontinuities having a combination of predominantly longitudinal and radial dimensional components are readily detected. When discontinuities of the same size are located beneath the surface of the part being inspected at progressively greater depths, they become increasingly difficult to detect and can be detected at depths greater than 13 mm ($\frac{1}{2}$ in.) only with special equipment designed for this purpose.

On the other hand, laminar discontinuities such as can be found in welded tubes may not alter the flow of the eddy currents enough to be detected unless the discontinuity breaks either the outside or inside surfaces or unless it produces a discontinuity in the weld from upturned fibers caused by extrusion during welding. A similar difficulty could arise in the detection of a thin planar discontinuity that is oriented substantially perpendicular to the axis of the cylinder.

Regardless of the limitations, a majority of objectionable discontinuities can be detected by eddy current inspection at high speed and at low cost. Some of the discontinuities that are readily detected are seams, laps, cracks, slivers, scabs, pits, slugs, open welds, miswelds, misaligned welds, black or gray oxide weld penetrators, pinholes, hook cracks, and surface cracks.

Reference Samples. A basic requirement for eddy current inspection is a reliable and consistent means for setting the sensitivity of the tester to the proper level each time it is used. A standard reference sample must be provided for this purpose. Without this capability, eddy current inspection would be of little value. In selecting a standard reference sample, the usual procedure is to select a sample of product that can be run through the inspection system without producing appreciable indications from the tester. Several samples may have to be run before a suitable one is found; the suitable one then has reference discontinuities fabricated into it.

The type of reference discontinuities that must be used for a particular application are specified (for example, by the American Society for Testing and Materials and the American Petroleum Institute). Some of the major considerations in selecting reference discontinuities are that they:

- Must meet the required specification
- Should be easy to fabricate
- Should be reproducible
- Should be producible in precisely graduated sizes
- Should produce an indication on the eddy current tester that closely resembles those reduced by the

natural discontinuities

Several discontinuities that have been used for reference standards are shown in Fig. 29. These include a filed transverse notch, milled or electrical discharge machined longitudinal and transverse notches, and drilled holes. Figure 30 shows the eddy current signals generated when testing a hollow tube with an internal rotating probe and the discontinuities in the positions shown.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Tubes†

The techniques used in the eddy current inspection of tubes differ depending on the diameter of the tube. Additional information is available in the articles "Remote-Field Eddy Current Inspection" and "Tubular Products" in this Volume.

Tube Outside Diameter Under 75 mm (3 in.)

Tubes up to 75 mm (3 in.) in diameter can be eddy current inspected for discontinuities using an external encircling coil. The diameter limitation is imposed primarily by resolution requirements; that is, as the diameter is increased, the area of a given discontinuity becomes an increasingly smaller percentage of the total inspected area.

The inspection is performed by passing the tube longitudinally through a concentric coil assembly. The coil assembly contains an energizing (primary) coil, a differentially wound detector (secondary) coil, and when inspecting ferromagnetic materials, a magnetic-saturating (direct current) coil. A typical coil assembly and V-roll conveyor for transporting the tube are shown in Fig. 31.

Fig. 31 Setup and encircling coil components for continuous eddy current inspection of ferromagnetic or nonferromagnetic tubes up to about 75 mm (3 in.) in diameter

The energizing coil is energized with alternating current at a frequency compatible with the inspection situation (typically 1 kHz for many ferromagnetic products) and induces the eddy currents in the tube. The detector coil monitors the flow of the induced currents and permits detection of current variations, which are indicative of discontinuities. The saturating coil, when used, is energized with direct current at high current levels to produce magnetic saturation in the cylinder. This increases the eddy current penetration and nullifies the effects of magnetic variables that may otherwise degrade the signal-to-noise ratio of the inspection. Because of the orientation of eddy current flow, this type of inspection is best suited to the detection of such discontinuities as pits, slugs, seams, laps, and cracks. The inside diameter of the coil assembly is about 9.5 mm ($\frac{3}{8}$ in.) larger than the outside diameter of the tube to allow for mechanical or geometric irregularities. The coil is centered on the tube. The cylinder-conveying mechanism must provide smooth, uniform propulsion. Throughput speeds of 30 m/min (100 sfm) are common. Because inspection instrumentation is normally designed for a fixed throughput speed, conveyor speed should be held within about $\pm 10\%$ of nominal.

Encircling coil inspection offers simplicity of application, both electrically (a single inspection coil assembly and circuit for total wall inspection) and mechanically (no scanning mechanisms required). A disadvantage is that the discontinuity is located with respect to only its longitudinal, not its circumferential, position. For best results, each inspection system must be carefully adapted to the product it is to inspect. When this is achieved, a large majority of objectionable discontinuities can be detected at high speed and at low cost using eddy current methods. Eddy current inspection is excellent for detecting discontinuities that are below the surface or within 13 mm ($\frac{1}{2}$ in.) of the surface. The three examples that follow show typical applications of eddy current inspection on tubes of up to 75 mm (3 in.) outside diameter.

Example 1: Quality Control of Nonferromagnetic Heat Exchanger Tubesheet Rolled Joints.

General inspection of heat exchanger tubes can be performed with differential or absolute probes. For dimensional measurements, however, absolute probes are normally used.

The absolute probe (Fig. 32) uses a toroidal reference coil that matches the characteristic impedance of the test coil within 10% over a wide frequency range, making it effective for multifrequency testing. Good guidance is essential for absolute probes; flexible wafer guides (Fig. 32) center the probe by peripheral contact, but collapse to cope with diametral variations and deposits.

Fig. 32 Absolute bobbin probe with flexible wafer guides used for the eddy current evaluation of heat exchanger tubesheet rolled joints

One application of an absolute probe is the measurement for location of the rolled joint relative to the tubesheet secondary face and the degree of rolling in tubesheet rolled joints. Heat exchangers and steam generators are normally assembled with nonferromagnetic tubes rolled into the tubesheet and then welded at the primary tubesheet face. Rolling is primarily performed to eliminate corrosion-prone crevices. However, if tubes are rolled beyond the tubesheet secondary face, they are prone to cracking. Therefore, the location and, to a lesser extent, the degree of rolling are critical. These dimensions cannot be readily measured directly. A dual-frequency eddy current method, using an absolute probe, can provide such measurements rapidly and reliably. A high test frequency locates tube-expanded regions, and a low frequency simultaneously locates the tubesheet face. As shown in Fig. 33(a), the tubesheet has an Inconel nonferromagnetic overlay, which makes detection easier.

Fig. 33 Dual-frequency inspection of tubesheet showing tube expansion, offset, and overlay regions of rolled areas. (a) Cross-sectional view of tubesheet region. (b) Traces showing typical rolled joints. (c) Traces showing incorrect tubesheet rolled joints. The high-frequency (700 kHz) traces display tube expansion dimensions, while

the low-frequency (100 kHz) traces display the tubesheet overlay location.

Strip chart traces of a typical tube are illustrated in Fig. 33(b). One channel displays the high-frequency (700 kHz) signal, and the other the low-frequency (100 kHz) signal. The location of the rolled joint relative to the tubesheet secondary face and degree of rolling can be readily determined. Figure 33(c) illustrates the results from an improperly rolled tube, with a large crevice region (9.5 mm, or $\frac{3}{8}$ in.) and without the secondary rolled joint. Using this technique, the distance between the rolled joint and tubesheet face can be measured rapidly to an accuracy of ± 1 mm (± 0.04 in.), and the increase in diameter of the rolled sections can be measured to better than $\pm 10\%$. No surface preparation of the tubing is required prior to testing.

Example 2: Probes for Inspecting Ferromagnetic Heat Exchanger Tubes.

Ferromagnetic tubes present special problems in eddy current testing. Real defect signals are normally indistinguishable from those due to normal permeability variations. Permeability values can range from 20 to several hundred in engineering materials and can vary with composition, cold work, and thermal history. The best remedy for the eddy current testing of magnetic tubes is magnetic saturation in the vicinity of the test coil(s). If greater than 98% saturation can be achieved, the signals from defects and other anomalies display the characteristic phase expected for nonferromagnetic tubes. Unfortunately, not all magnetic tubes can be completely saturated. In these cases, eddy current inspection reduces to a measurement of magnetic perturbation. A thin, internal surface layer adjacent to the probe responds to the distortion of the magnetic flux at defects from the saturation field. This classifies the technique with nondestructive testing methods such as magnetic particle inspection and flux leakage testing (see the articles "Magnetic Particle Inspection" and "Magnetic Field Testing" in this Volume).

The importance of achieving maximum saturation is illustrated in Fig. 34, which shows results from a type 439 stainless steel heat exchanger tube. A 15.9 mm (0.625 in.) OD by 1.2 mm ($\frac{3}{64}$ in.) thick tube with internal and external calibration defects and shot-peened area was used to compare the performance of various saturation probes. As shown in Fig. 34(a), the external defects ranged from 20 to 100% deep. Figure 34(b) shows the signals obtained with a probe capable of 98% saturation; the eddy current signals from the external calibration holes display the characteristic phase rotation with depth expected for nonmagnetic materials. In contrast, with only 89% saturation the signals are distorted and indistinguishable from change-in-magnetic-permeability signals (Fig. 34c). From similar tests on other ferromagnetic tubes it has been found that at least 98% saturation is needed (relative permeability < 1.2) for reliable test results. This requires detailed optimization of the saturation magnet design for each ferromagnetic tube material.

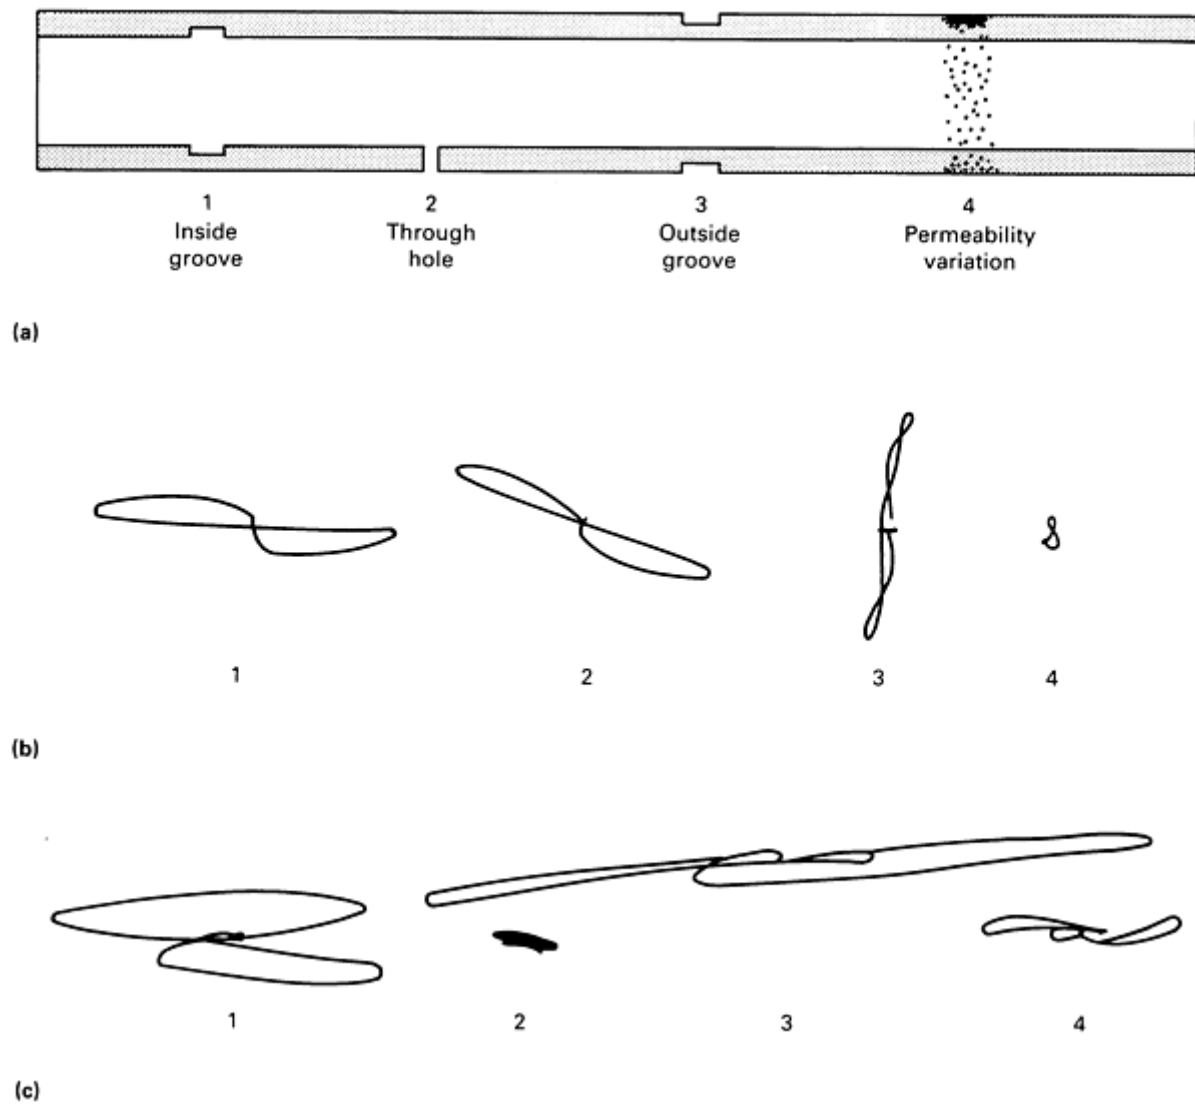

Fig. 34 Signals obtained from type 439 stainless steel calibration tube when using saturation probes. (a) Cross-sectional view of calibration tube showing location of discontinuities. (b) Signals obtained at each discontinuity shown in (a) using a probe with 98% saturation. (c) Signals obtained at each discontinuity shown in (a) using a probe with 89% saturation

Inspection for fretting wear in ferromagnetic tubes presents an even more difficult problem. Probes capable of complete saturation of unsupported tube sections cannot normally saturate the tube under a carbon steel support. This is because the magnetic flux takes the lower-reluctance path through the support rather than along the tube.

To saturate under baffle plates requires a probe with radial magnetization. In this case, the magnetic flux remains almost undisturbed and actually increases slightly under baffle plates. Eddy current signals from a radial saturation probe are illustrated in Fig. 35. The large signal in Fig. 35(b) from the baffle plate is due to the probe sensing an increase in permeability of the Monel tube. As a result, the 40% fretting wear, when under the support, causes only minor distortion to this large signal and is virtually undetectable. The radial saturation probe continues to saturate the Monel tube as it passes under the carbon steel baffle. As illustrated in Fig. 35(c), 40% fretting wear under the baffle plate is readily detectable by the vertical component of the vectorially additive signals.

(a)

(b)

(c)

Fig. 35 Signals obtained from Monel 400 calibration tube with simulated fretting wear. (a) Cross-sectional view of calibration tube illustrating locations of fretting wear and carbon steel baffles. (b) Signals obtained using an axial saturation probe at the three locations shown in (a). (c) Signals detected using a radial saturation probe at the three locations shown in (a). The gain of the signals shown in the center and right in (b) has been decreased by a factor of two, as designated by -6 dB above each curve, to reduce the amplitude of the traces in both the x and y directions. The remaining four traces are drawn to scale.

Permanent-magnet probes can achieve high magnetic saturation and can provide clear, undistorted defect signals. False ferromagnetic indications are eliminated, and defect depth can be determined, eliminating unnecessary tube plugging.

Inspection can be performed on ferromagnetic tubing such as Monel 400, 3Re60, and type 439 stainless steel. Only if thick deposits are present in the bore of the tube must the tube be cleaned prior to testing; no other surface preparation is required. Inspection speeds are comparable to nonferromagnetic testing, typically 0.5 m/s (1.6 ft/s). Inspection costs are similar to those of nonferromagnetic tube inspections, and only conventional instrumentation is needed.

Example 3: Comparison of Skin Depth Test Frequency Versus Foerster Limit Frequency Methods to Obtain Optimum Test Frequency in Eddy Current Inspection of Type 304 Stainless Tubing.

In eddy current inspection, test frequency is an essential test parameter. Traditional nonmagnetic testing methods employ the standard depth of penetration (SDP) or skin depth approach for frequency selection (Ref 5, 6). Figure 36 shows a comparison between the SDP and the Förster limit frequency, F_g , approaches to frequency selection for defect testing in stainless tubing filled with conducting material (Ref 7, 8, 9). The standard used in the comparison was a type 304 stainless steel tube (6.35 mm, or 0.250 in., OD \times 5.54 mm, or 0.218 in., ID) with through holes 3.81 mm (0.150 in.) and 1.11 mm (0.0437 in.) in diameter drilled at opposite ends. At one end, lead slugs were placed inside the tube beneath the through holes.

No.	Defect type	Hole diameter through one wall
-----	-------------	--------------------------------

		mm	in.
1	Through hole	1.11	0.044
2	Through hole	3.81	0.150
3	Through hole with slug	3.81	0.150
4	Through hole with slug	1.11	0.044

Fig. 36 Comparison of skin depth test frequency, F_{SDP} , versus optimum test frequency, F_T , for a type 304 stainless steel tube. (a) Schematic indicating size and location of discontinuities in tube. (b) Plot of eddy current inspection of tube with 1.2-MHz test frequency. (c) Plot of eddy current inspection of tube with 2.1-MHz optimum test frequency derived from F_g . See text for discussion.

Figure 36(b) shows the results when the SDP method was used to select frequency. In this case, the lead slugs masked the through holes. For the SDP method, the test frequency was determined as follows:

$$F = \frac{1}{(SDP)^2 \pi \mu \sigma} = 1.2 \text{ MHz} \quad (\text{Eq 3})$$

where $\sigma = 0.14 \times 10^7$ mho/m, $\mu = (\mu_{rel} \times \mu_0) = (1.02 \times 4\pi \times 10^{-7} \text{ H/m})$, and $SDP = 3.81 \times 10^{-4}$ m (tube wall thickness).

Figure 36(c) shows the results of testing at a frequency determined by the F_g method. In this case, the presence of lead slugs was suppressed. For test situations of this type, the optimum test frequency, F_T , will be in the range of 2 to 20 times F_g or $2 \leq F_T/F_g \leq 20$. In this case:

$$F_g = \frac{C}{\mu_{rel} \sigma g_1 g_2} = 0.15 \text{ MHz} \quad (\text{Eq 4})$$

where $C = 5.066 \times 10^5$ (unitless constant of proportionality), $\sigma = 0.14 \times 10^7$ mho/m (conductivity of type 304 stainless steel), $\mu_{rel} = 1.02$ (relative permeability), $g_1 = 5.54 \times 10^{-3}$ m (tube inside diameter), and $g_2 = 6.35 \times 10^{-3}$ m (tube outside diameter).

By testing the multiple frequencies in the range ($F_T = 0.3$ to 3.0 MHz), an optimum is determined. In this case, 2.1 MHz was found to be the best frequency, using:

$$F_T = 14F_g \quad (\text{Eq 5})$$

Substituting for F_g yields:

$$F_T = 14(0.15 \text{ MHz}) = 2.1 \text{ MHz} \quad (\text{Eq 6})$$

In practical applications, the inspector can try both the SDP and F_g approaches for selecting an optimum frequency. A practical application would be the inspection of nuclear fuel rods. Uranium pellets encased in thin-wall metal tubing require defect inspection of the tube wall. Gaps between adjacent fuel pellets yield nonrelevant indications at low values of F_g . Therefore, in this case, the Foerster frequency selection method would produce the best results (Ref 10). It should

be noted that the F/F_g equation derived from normalized impedance diagrams does not relate to the depth of penetration and therefore cannot be used to measure skin depth using eddy current testing.

Tube Outside Diameter Over 75 mm (3 in.)

When the diameter of a tube exceeds about 75 mm (3 in.), it is generally no longer practical to inspect with an external encircling coil for reasons of flaw resolution. A satisfactory technique for larger diameters is the use of multiple probes.

In many respects, a multiple-probe inspection is similar to encircling coil inspection (Fig. 37). An encircling saturating coil is used when inspecting ferromagnetic materials, and an encircling energizing, or primary, coil is employed. Instead of an encircling detector, or secondary, coil, however, the detector is composed of several mechanically and electrically separate probe-coil assemblies. The number of probe assemblies is dependent on the diameter of the tube to be inspected. Each probe assembly consists of several individual probes. The probes are typically about 50 mm (2 in.) long and have a 19 mm ($\frac{3}{4}$ in.) square cross section containing differential windings. The probes are electrically balanced individually and then wired in series. A probe assembly for the inspection of a 245 mm (9 $\frac{5}{8}$ in.) diam tube, for example, would contain 14 probes.

Fig. 37 Multiple-probe setup and encircling coil components for the continuous eddy current inspection of ferromagnetic or nonferromagnetic tubes over 75 mm (3 in.) in diameter

As shown in Fig. 37, the probe assemblies are contoured to the curvature of the tube and are designed to ride directly on the surface of the tube on hardened wear shoes embedded in the assemblies. Typically, four probe assemblies are employed. In this case, each assembly inspects slightly more than one-quarter of the circumference of the tube. The assemblies are stagger-mounted so that there is some overlapping of inspected areas. The probe assemblies are each mounted to an arm that brings them into contact with the tube for inspection or retracts them to a protected location when the end of the tube is being inserted into the inspection station.

Test signals from each probe assembly are usually fed to a separate inspection circuit and marking system, although the outputs of the circuits can be combined for operating a common alarm or marker. In terms of area covered per detector, inspection of a 305 mm (12 in.) diam tube in this manner is comparable to inspecting a 75 mm (3 in.) diam tube with an encircling coil.

Another advantage of multiple probes is improved inspection sensitivity, because the detector is always in close proximity to the part being inspected. The use of multiple-probe assemblies also localizes discontinuity position within the sector.

Reflection and Transmission Methods

Discontinuities in nonmagnetic tubing such as that made of copper, brass, or aluminum can be detected by the reflection and transmission methods of eddy current inspection, depending on such variables as the size, location, and orientation of the discontinuity. When the reflection method is employed, both the primary coil, which excites the electromagnetic field, and the secondary coil, which detects the discontinuity, are arranged adjacent to each other on either the outside or inside wall of the tube. When the transmission method is employed, the exciting and receiving coils are placed at opposite walls,

either on the outside or inside diameter. With the transmission method, the receiving coil is affected only by those electromagnetic fields that have passed through the entire wall of the tube. Consequently, the transmission method is ideal for indicating tube discontinuities of the same magnitude on inner and outer surfaces with discontinuity signal amplitudes of the same height.

There are two distinct coil designs associated with the reflection and transmission methods:

- The encircling coil, which encircles the part completely
- The rotating probe, which spins around the part in a circular path, with or without making contact with the part

When a cylindrical coil is used inside a tube, it is referred to as an internal coil. Eight possible coil combinations employed in the eddy current reflection and transmission methods are shown in Fig. 38.

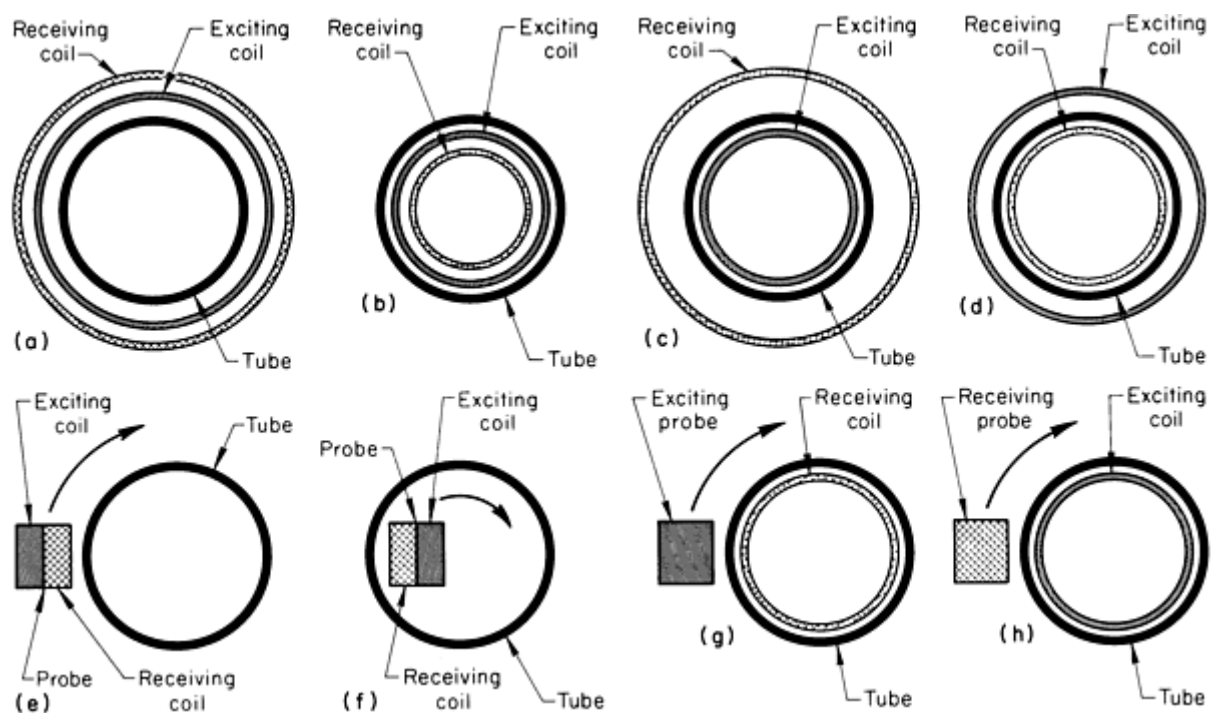

Fig. 38 Eight possible coil combinations employed in the eddy current reflection and transmission methods of inspecting nonmagnetic tubes. See text for description.

The arrangement shown in Fig. 38(a) is used with the reflection method, and both the exciting and receiving coils (encircling coils) are located outside the tube. This arrangement is suitable for detecting outer-surface and transverse discontinuities; it is used for inspecting radioactive fuel cans under water.

The arrangement shown in Fig. 38(b) is also used with the reflection method; both the exciting and receiving coils are inside the tube. The arrangement is suitable for detecting inner- and outer-surface transverse discontinuities. It is used for the internal inspection of heat exchanger and reactor tubing.

The arrangement shown in Fig. 38(c) is used with the transmission method and consists of a receiving coil outside the tube and an exciting coil inside the tube. This arrangement provides good sensitivity to both inner- and outer-surface discontinuities and is more sensitive to outer-surface discontinuities than the arrangement shown in Fig. 38(a). It is used in the inspection of six-finned tubes on a continuous basis.

The arrangement shown in Fig. 38(d) is used with the transmission method and consists of an exciting coil outside the tube and a receiving coil inside the tube. The arrangement provides good sensitivity to both outer- and inner-surface

discontinuities, but provides increased sensitivity to inner-surface discontinuities. It has been used in conjunction with the arrangement shown in Fig. 38(c) in the inspection of six-finned tubes.

The arrangement shown in Fig. 38(e) is used with the reflection method and consists of an external rotating probe comprising both the exciting and receiving coils. The arrangement has exceptionally high resolving power for detecting discontinuities on or beneath the outer surface of the tube and is capable of detecting the smallest surface blemishes. It is used for inspecting reactor components and fuel elements.

Another rotating probe for use with the reflection method is shown in Fig. 38(f). This probe is similar to that shown in Fig. 38(e), but is located inside the tube and detects inner-surface discontinuities most effectively. The arrangement is used for the inspection of reactor U-shaped heat exchanger tubes for corrosion and cracks.

The arrangements shown in Fig. 38(g) and 38(h) are combinations used with the transmission method. That shown in Fig. 38(g) is a combination of exciting rotating probe outside the tube and receiving encircling coil inside the tube. It provides high sensitivity in the measurement of wall thickness and eccentricity on both thin-wall and thick-wall tubes. The reverse arrangement is shown in Fig. 38(h); it too is used for measuring tube-wall thickness and eccentricity. Additionally, it is used to detect and to precisely locate surface and subsurface discontinuities.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Solid Cylinders

As with tubing, the techniques used in the eddy current inspection of solid cylinders differ depending on the diameter of the cylinder.

Solid Cylinders up to 75 mm (3 in.) in Diameter. Inspection of solid cylinders up to 75 mm (3 in.) in diameter with an external encircling coil is similar to the inspection of tubes in this size range. The limitation regarding resolution of discontinuities applies equally to tubes and solid cylinders.

The inspection is performed by passing the cylinder longitudinally through a concentric coil assembly containing a primary, secondary, and sometimes a saturating coil. When inspecting a solid material using eddy current techniques, it is difficult to detect discontinuities that are located more than 13 mm ($\frac{1}{2}$ in.) below the surface. Magnetic field and eddy current densities decrease to zero at the centers of a cylinder. In addition, the magnetic field density decreases

exponentially with increasing distance from a short coil. The skin effect adds to the decreases in magnetic field density and eddy current density, but it can be controlled by decreasing the frequency. Eddy current penetration is dependent on the electrical conductivity and magnetic permeability of the part and on the frequency of the energizing current.

For a given part, the conductivity is fixed. The permeability of ferromagnetic materials can be made to approach unity through use of the saturating coil. This permits greater penetration of the eddy currents. For maximum penetration, a low inspection frequency, such as 400 Hz, is employed. However, as the frequency is lowered, inspection efficiency drops off rapidly, so that some compromise is usually necessary. Also, at low inspection frequencies, the throughput speed of the part is limited because the inspection circuit requires interaction with a certain number of cycles of energizing signal in order to register a discontinuity.

Solid Cylinders Over 75 mm (3 in.) in Diameter. Because of loss of resolution, the inspection of solid cylinders of 75 mm (3 in.) in diameter, using an external encircling coil, generally is not practical. Consequently, the use of multiple probes as described above and shown in Fig. 37 for tubes is applied. The multiple-probe techniques for tubes and solid cylinders are virtually identical.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Machine for Inspection of Tubes on Solid Cylinders

An eddy current inspection machine for detecting surface discontinuities that can be applied to either tubes or solid cylinders having a wide range of diameters is known as the Orbitest machine. Orbitest machines are provided with a rotating drum through which the cylinder to be inspected is conveyed. The drum is so mounted that it is free to float to compensate for any lack of straightness in the part being inspected. Mounted to the drum are two or more search heads, each of which contains one or two search probes. The search probes are caused to engage the cylinder and orbit about it. Signal information is taken from the probes to the detection circuitry by way of slip rings. The longitudinal feeding of the cylinder by conveyor, together with the orbiting of the probes, results in a helical scanning path.

Two paint-marking systems can be utilized at the same time. One orbits with the search heads and marks the precise locations of discontinuities on the cylinder or tube as they are detected; the other is a stationary system that marks with a different color the longitudinal position of deep discontinuities. When a dual marking system is used, the depth thresholds on both marking systems are independently adjustable. In normal operation, one threshold is adjusted to ignore harmless shallow discontinuities and to mark only those that are deep enough to require removal. The second marking system identifies only very deep discontinuities. The deepest discontinuity can be removed first if it is not too deep. If it is too deep, the cylinder or tube can be scrapped before time is wasted in removing shallower discontinuities.

The conveyor speed through the Orbitest machine varies from 12 to 46 m/min (40 to 150 ft/min). Drum rotation speed ranges from 100 to 180 rev/min. Thus, the scanning path can be controlled as required for products of various diameters and for the length of discontinuities to be detected.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Round Steel Bars

High-speed automatic eddy current inspection machines have been developed to detect seams, laps, cracks, slivers, and similar surface discontinuities in round steel bars. The machines detect the discontinuities, mark their exact location on the bar, and automatically sort the bars into three cradles in relation to the depth, length, and frequency of the discontinuities. One cradle is for prime bars, a second cradle is for bars that can be salvaged by grinding, and the third cradle is for scrap bars.

Inspection is accomplished by eddy currents that are induced in the bar from a small probe coil, which also serves as the detector coil. When a surface discontinuity is encountered, the eddy currents are forced to flow beneath the discontinuity to complete their path. This increases the length of the path of the eddy currents and thus increases the electrical resistance to the flow of eddy currents in the bar. The change in resistance is proportional to the depth of the discontinuity. The probe coil detects the change in resistance, and this is interpreted by the instrument in terms of the depth of the discontinuity.

The probe coil is about 16 mm ($\frac{5}{8}$ in.) in diameter. It is encapsulated and mounted in a stainless steel housing between two carbide wear shoes. The probe coil is flexibly supported and mechanically biased to ride against the surface of the bar. The bars are rotated and propelled longitudinally. This combination of rotary and longitudinal motion causes the probe (detector) coil to trace on the bar a helical path with a pitch of approximately 75 mm (3 in.). The rolling process by which bars are produced greatly elongates the natural discontinuities so that they are usually several inches in length. The 75 mm (3 in.) pitch of the helical scan has been found to be more than adequate to detect almost all discontinuities.

A nominal helical scanning speed of 30 m/min (100 sfm) has provided good results. Where higher inspection rates are desired, multiple-probe-coil machines are used. Such machines have been built with as many as six probe coils.

The locations of discontinuities are marked exactly on the bar by a small, high-speed rotary milling device mounted downstream of the probe. The milling cutter is brought into momentary contact with the bar precisely one revolution after the discontinuity has passed the probe coil. This provides a shallow mark exactly on the discontinuity. Because the mark is a bright milled spot, it is easy to see and will not smear or rub off.

These machines are completely automatic and, after setup, require no attention other than crane service for loading the feed table and for unloading the cradles after the bars have been inspected. The instrumentation is provided with two separate alarm controls that can be set as required. For example, one alarm might be set to register all discontinuities over 0.25 mm (0.010 in.) in depth. The second alarm might be set to register all discontinuities over 1.52 mm (0.060 in.) in depth.

When a bar is being inspected, the outputs from the two alarms are fed into a discontinuity analyzer (computer). This device can be set to respond to a wide variety of conditions, depending on requirements. For example, a bar that produced no response from either alarm would always be rated as prime. However, if it is acceptable for a specified percentage of discontinuities over 0.25 mm (0.010 in.) but less than 1.52 mm (0.060 in.) to be in the material, the discontinuity analyzer can be set to classify as prime whatever length of discontinuity is permissible. Perhaps a few very short discontinuities over 1.52 mm (0.060 in.) can be accepted either as prime or as salvageable. If so, the analyzer is set to meet either of these requirements. The combination of two alarms at different, but adjustable, levels and the versatility of the discontinuity analyzer provide great flexibility in meeting specific material requirements. Inspection efficiency is also improved because the inspection can be adjusted to give a product that meets requirements but is not overgraded. This minimizes costs and scrap losses. These machines have been built to inspect round bars from 9.5 to 114 mm ($\frac{3}{8}$ to $4\frac{1}{2}$ in.) in diameter and from 1.5 to 15 m (5 to 50 ft) in length.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Welds in Welded Tubing and Pipe

Longitudinal welds in welded tubing and pipe can be inspected for discontinuities using eddy current techniques with an external encircling primary energizing coil and a probe-type differential detector coil. The probe-type detector coil is located at the longitudinal center in the inner periphery of the primary coil and is arranged so that it inspects the outside surface of the longitudinal weld.

The inspection, as shown in Fig. 39, is performed by passing the tube or pipe longitudinally through the primary energizing coil, causing the probe-type detector coil to traverse the longitudinal weld from end to end. The primary coil is energized with alternating current at a frequency that is suitable for the part being inspected (typically 1 kHz for ferromagnetic products) and induces the eddy currents in the tube or pipe.

Fig. 39 Setup and coil arrangement for the eddy current inspection of longitudinal welds in ferromagnetic welded tubing

For the inspection of ferromagnetic products, a dc magnetic-saturating coil is located concentrically around the primary energizing coil. The dc coil is energized at high current levels to magnetically saturate the tube or pipe. This improves the penetration of the eddy currents and cancels the effect of magnetic variables.

Because of the circumferential orientation of eddy current flow, this type of inspection is effective in detecting most types of longitudinal weld discontinuities, such as open welds, weld cracks, hook cracks, black spots, gray spots, penetrators, and pinholes. Certain types of cold welds having objectionably low mechanical strength may not be detected if the welds are sufficiently bonded to provide a good electrical path for the eddy currents.

With proper wear shoes and a suitable retracting mechanism to lower the probe-type detector coil onto the pipe at the front and retract it at the back, the detector-probe-coil assembly can ride directly on the weld area of the pipe. This provides optimum sensitivity and resolution for the detection of discontinuities. The primary energizing coil may have a clearance of 25 mm (1 in.) or more to provide room for the probe coil and to provide for easy passage of the pipe. It is easy to adjust the energy in the primary energizing coil to compensate for any reasonable amount of primary coil clearance.

It is important that the longitudinal weld be carefully positioned under the probe-type detector coil before the pipe is passed through the tester. It is essential to provide good conveying equipment for the pipe so that, as the pipe is propelled longitudinally, the longitudinal weld will always be located under the detector coil.

There is no limit to the maximum diameter of pipe that can be inspected by this procedure. This eddy current method offers relative simplicity with high sensitivity and resolution. With it, a large majority of objectionable discontinuities can be detected at high speed and low cost. Throughput speeds of 30 m/min (100 sfm) are common. The conveyor speed should be controlled to within about $\pm 10\%$.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Plates, Skin Sections Panels, and Sheets⁵

The following four examples illustrate typical applications of eddy current testing to detect flaws in plates, panels, and sheets. Nonferromagnetic materials (Zircaloy-2 and aluminum) are used in all four case histories. Example 7 shows the use of eddy current inspection to gage glue line thickness in adhesive bonding.

Example 4: Eddy Current Inspection to Detect Shallow Surface Defects in Zircaloy-2 Plates.

Conventional eddy current testing cannot reliably detect surface defects less than about 0.1 mm (0.004 in.) in depth. This limitation arises because signals from shallow defects are indistinguishable from lift-off noise caused by probe wobble. This problem cannot be overcome with multifrequency testing, because signal phase for shallow defects and lift-off remain nearly identical at all normal test frequencies, as shown in Fig. 40.

Fig. 40 Eddy current signals obtained with a conventional probe when inspecting a Zircaloy-2 plate. (a) Location of calibration defects. (b) Impedance display of signals at 200 kHz. (c) Impedance display of signals at 950 kHz. (d) Multifrequency residual signals, a mix of 200 and 950 kHz signals

An effective method of improving the detection of shallow defects is to obtain clear phase separation between defect and lift-off signals. A lift-off discriminating probe design (Ref 11) consists of two coils that interact to rotate the phase of a defect signal relative to lift-off (Fig. 41a). Phase rotation depends on test frequency, sample resistivity, and coil size and spacing. Through proper choice of probe parameters, defect signals can be rotated 90° from lift-off noise, as shown in Fig. 41(b). This allows positive phase discrimination between lift-off noise and signals from localized defects. Lift-off discriminating surface probes have been used to detect defects as shallow as 0.05 mm (0.002 in.) in zirconium components during in-service inspections. However, these surface probes have one main limitation: Signal phase from defects of varying depth does not change appreciably, so only signal amplitude can be used to estimate defect depth.

Fig. 41 Eddy current signals obtained with a lift-off discriminating probe when inspecting a Zircaloy-2 plate. (a) Location of calibration defects. (b) Impedance display of signals at 200-kHz test frequency

It should be noted that no surface preparation of the nonferromagnetic components is required prior to testing. Figure 41 indicates that shallow surface defects can be reliably detected in the presence of probe wobble or lift-off noise.

Example 5: Special Fixture Provides Two-Step Eddy Current Inspection of the Skin Section of the First-Stage Booster of the Saturn Rocket

(Ref 12). For continuous inspection, if the configuration of the test article permits, the operation can be automated. Ordinarily, this will require a mechanism that allows the article to move past the test transducer in a repeatable fashion. Depending on the sensitivity required, the mechanism can be:

- A rudimentary arrangement in which the test article is simply moved through the magnetic field of the test transducer
- For more stringent requirements, the test article can be precisely positioned and held fixed while an electromechanical scanning system moves the transducer over it. This arrangement reduces the possibility of the transducer detecting movement or misalignment of the specimen rather than flaws

An example of special fixturing for the inspection of cylindrical-tank-wall skin sections of the Saturn V/S-IC first stage booster is shown in Fig. 42. The contractor, under the direction of Marshall Space Flight Center, assembled this system using off-the-shelf equipment to inspect aluminum skin panels nominally 5.08 mm (0.200 in.) thick. Inspection was accomplished in two steps. First, surface discontinuities whose depths exceed 5% of the part thickness were located with

rapid (37 m/min, or 120 sfm) linear scan (Fig. 42a). Second, the length and depth of the discontinuity were measured with the rotating eddy current probe device illustrated in Fig. 42(b).

Fig. 42 Eddy current fixturing setup for locating and sizing flaws in Saturn V/S-1C rocket booster tank-wall skin sections using a two-step process. (a) Surface discontinuities with depths $\geq 5\%$ of skin section thickness are first located with 37 m/min (120 sfm) linear scanner. Radac, rapid digital automatic computing. (b) Rotating eddy current probe device then gages length and depth of discontinuities discovered by linear scanner. Source: Ref 12

Example 6: Crack Detection in First Layer or Subsurface Layers of Aluminum-To-Aluminum Structures Joined by Aluminum Rivets.

When inspecting large numbers of fastener holes for cracks in the first or second layer of metal structures, it is advisable to use a fixed or adjustable low-frequency sliding eddy current probe (Fig. 43) instead of the slower conventional types. These probes are used by sliding them over the fastener heads and observing the pattern produced on the oscilloscope. The surface may or may not be painted, but it must be cleaned prior to testing. When a crack is present, the dot will move in a different path, producing an indication proportional to its size.

Fig. 43 Low-frequency sliding-type eddy current inspection probe used to detect cracks in the first or subsurface layers of multilayered structures. Courtesy of J. Pellicer, Staveley Instruments

When inspecting for first-layer cracks, the frequency should be chosen to limit the penetration to the crack and to avoid variables in the layers below. For the second (or multiple) layer, the frequency should be low enough to penetrate the total thickness required.

Figure 44 shows a typical presentation obtained with aluminum rivets joining two 1.6 mm (0.063 in.) thick aluminum skins. Similar presentations are obtained for other fastener types and plate thicknesses up to about 12.5 mm (0.5 in.).

Fig. 44 Typical oscilloscope display obtained using the setup and sliding probe shown in Fig. 43. Instrument test frequency was 2.5 kHz, horizontal gain was 60 dB, and vertical gain was 68 dB with probe drive setting at normal.

A nonconductive straightedge is useful to use as a probe guide and should be aligned to place the probe directly above the fastener heads. Lift-off has been set slightly below horizontal, and the good fastener hole indications slightly above

horizontal as the best compromise. With this setup, crack indications give a mainly vertical increase, showing the larger crack as a greater loop.

It is possible to determine crack direction by observing the dot movement on the CRT display on the oscilloscope. If the dot moves first along the good fastener hole indication (that is, clockwise), the crack is located on the opposite side. If the dot moves up at first and then eventually comes down (that is, counterclockwise), the crack is located before the fastener or the near side. A larger crack will eventually move the dot outside the CRT area.

This method allows rapid inspection for fastener hole cracks. The sliding probes are directional units and should be used in the direction of cracking. This is normally easily determined by the stress direction in a given structure. Probes will allow approximately a $\pm 40^\circ$ angle tolerance.

Example 7: Eddy Current Inspection of Glue-Line Thickness of a Metal-To-Metal Adhesive Joint.

The objective was to measure the glue-line thickness between 7075-T6 aluminum sheets having a thickness of 1.6 mm (0.063 in.) and a conductivity of 32 IACS. Although this inspection can be performed with through transmission ultrasonics, a simple eddy current measurement was used, with one side access only (and no couplant needed). The surface may or may not be painted, but should be cleaned prior to testing.

Inspection was accomplished by a simple calibration with the help of samples of the metal used and nonconductive shims (or paper sheets) up to the desired glue thickness to be measured. Nonconductive shims measuring 0.25 and 0.38 mm (0.010 and 0.015 in.) were used.

A surface probe of the required frequency and an impedance plane (CRT) eddy current instrument were required. The 16 mm (0.63 in.) OD probe selected was usable between 300 Hz and 10 kHz.

Frequency can be adjusted experimentally for best deflection. A good starting point is the frequency of a standard depth of penetration for the first layer only (this can be obtained from a graph or by using the eddy current slide rule). The frequency is then decreased in steps of about 20% to find the best response. For this particular application, the frequency required for one standard depth of penetration was 5 kHz. However, optimum results were obtained at 3 kHz.

With lift-off set horizontal, shim spacing (glue thickness) variations gave a near-vertical movement, as shown in Fig. 45. In addition, the horizontal gain was attenuated to avoid too much movement due to changes in lift-off. The vertical gain was adjusted to give a clear vertical deflection for the shims used.

Fig. 45 Typical oscilloscope trace used to measure glue-line thickness in a metal-to-metal adhesive joint. Instrument settings: 3-kHz frequency, 60-dB horizontal gain, 76-dB vertical gain, and maximum probe drive.

Conductivity differences between materials prevent a direct correlation between the testpieces and the actual panel to be inspected (unless a sample of the panel itself is available). If necessary, the instrument can be rebalanced on the panel, and the lowest point can be found by conducting a scan. This point is then used as a reference for minimum bond-line thickness. Upward movement of the dot can be read as a thickness increase that was calibrated with the shims previously. Although this eddy current test will not show a lack of bond between parts, it is a simple and reasonably accurate method of measuring bond-line thickness (and therefore bond strength) in nonmagnetic materials.

Eddy Current Inspection

Revised by the ASM Committee on Eddy Current Inspection*

Inspection of Aircraft Structural and Engine Components⁶

Eddy current inspection has long been used to examine the quality of aircraft subassemblies. Improvements in this inspection method, especially the miniaturization of the probes themselves, have made it practical to test the intensity of aircraft maintenance procedures for aging commercial and military aircraft without the need to disassemble the aircraft and with the component in place on the plane. This minimizes component removal or disassembly and possibly masks operational and structural defects.

Inspection of Aircraft Subassemblies

As shown in the three examples that follow, aircraft components such as aluminum structural parts, titanium engine blades, and metallic composite materials can be readily inspected using eddy current inspection techniques.

Example 8: Eddy Current Inspection of Fastener Holes.

Originally, inspections for crack detection in fastener holes were performed using unshielded, absolute eddy current probes. Later, shielded differential coils provided an overall improvement in detection capability with a higher signal-to-noise ratio. Manual operation is now giving way to scanners specially designed to ensure good coverage.

Both contact and noncontact probe bodies are used in the scanners. The contact method probe relies on a spring action to ensure proper alignment of the coil assembly and friction against the hole surface (Fig. 46a). Unless ovality is present, a constant contact with the hole surface is maintained, and stable sensitivity is the end result. Nevertheless, in demanding high-gain applications, exact alignment of the scanner assembly is necessary to minimize background surface noise. In the noncontact method, the probe body is designed to be located at a depth of approximately 0.25 mm (0.010 in.) below the hole opening (Fig. 46b).

Fig. 46 Types of probe-coil bodies used in eddy current scanners. (a) Contact. (b) Noncontact

To maintain constant sensitivity, the probe must be centered in the hole, but the hand-held scanner takes this into account during calibration. Sufficient gain is set to detect the defect regardless of probe position. Scanners with noncontact probe bodies allow higher inspection speeds and typically generate lower background noise than scanners with contact probe bodies.

Some scanners are designed to traverse a helical path in the bore, typically at 0.50 mm (0.020 in.) pitch, to provide good coverage. With this method, rotational speed can be adjusted as required.

Most hand-held scanners (Fig. 47) use noncontact probes and operate at speeds in excess of 1000 rev/min. Because of its high speed of rotation, the probe can be inserted and withdrawn quickly without fear of missing a defect due to lack of coverage.

Fig. 47 Portable eddy current instrument that incorporates a hand-held scanner to detect cracks in fastener holes

Use of Trigger Pulse and Slow Sweep Modes to Detect Cracks. In addition to the normal impedance plane display in the CRT of the eddy current instrument, there are two other useful presentations that can be displayed. A trigger pulse can be generated to monitor the hole periphery along the horizontal axis of the CRT (Fig. 48). This signal will display a complete 0 to 360° cycle, along with the crack direction relative to the probe.

Fig. 48 Screen display using the trigger pulse mode to determine the position of a 1 mm (0.040 in.) long corner crack. The scanner probe indicates that it is located at the 180° position.

Alternatively, a slow sweep signal will display the length of the bore in the horizontal axis to show the depth at which the defect is located (Fig. 49). Crack indications will be obtained with the rotation of the probe, and a profile will emerge that gives the crack length along the bore on the basis of the number of hits detected. In either the trigger pulse or slow sweep mode, the magnitude of the response along the vertical direction displayed on the screen (the crack deflection) is a relative indication of the depth of the crack in the hole. Fastener hole inspection is similar to any other eddy current technique that depends on proper calibration and the use of reference standards having cracks and electric discharge machining notches of known dimensions.

Fig. 49 Screen display using slow sweep mode to determine the crack depth of a 1 mm (0.040 in.) long crack detected by a hand-held scanner probe traversing with a 0.5 mm (0.020 in.) pitch

High- and Low-Pass Filters. Scanners operating at constant speed allow for the use of filtering. High-pass filters eliminate slow changes, such as hole ovality or lift-off variations. Low-pass filters reduce high-frequency noise. When

combined, high- and low-pass filters considerably enhance the ability of the probe to detect small defects. The use of filters in scanners having manually rotated probes is normally not recommended.

Example 9: Eddy Current Inspection of Titanium Alloy Jet Aircraft Engine Blades for Cracks Resulting From Low-Cycle Fatigue.

Titanium alloy fan blades used in jet aircraft engines are subjected to very high stresses during takeoff. Maximum stresses in root sections of the blades may approach or even exceed the yield strength of the blade material, and high residual compressive stresses may cause cracking. Eddy current inspection was applied to the root sections of these fan blades to detect cracking associated with damage resulting from low-cycle fatigue.

The inspection technique utilized a commercial high-frequency (1 to 4 MHz) single-probe, eddy current instrument. The probe coil was wound on a special 1.52 mm (0.060 in.) diam ferrite core to fit the root area of the blade and to improve sensitivity to cracks. The coil was retained in a plastic holder molded to fit the blade root, using a rubbery compound that allowed a small amount of movement. By setting the coil tip slightly beyond the edge of the holder, the flexibility of the bonding compound ensured tip contact with the blade when the probe was positioned on the blade.

The instrument response was recorded on either an *x-y* or a strip chart recorder as the probe was moved across the blade root. The probe motion was represented by the time-base motion of the pen of the *x-y* recorder or by the paper motion of the strip chart recorder.

A blade with an electrical discharge machined crack in the root section was used as a standard. Sensitivity was established by setting the recorder and instrument gain to obtain a given amplitude on the recording for the machined crack in the blade root.

Example 10: Use of Eddy Current Inspection to Determine the Fiber Content of a Metallic Composite Material.

A new material, a composite of boron silicon fiber and aluminum, was evaluated for high-strength, lightweight applications. The fiber was fabricated by coating 0.013 mm (0.0005 in.) diam tungsten wire with boron to a diameter of approximately 0.11 mm (0.0045 in.) and then treating the boron with a silicon coating. The fibers were then made into a 0.13 mm (0.005 in.) thick tape by bonding them with aluminum. Structures were made by diffusion bonding layers of the tapes. Optimum properties require that the finished product contain 50% fiber and 50% aluminum.

A commercial single-probe, low-frequency eddy current instrument was used to determine and monitor the fiber content of the finished product by electrical-conductivity measurements. A calibration curve was established by measurements of electrical conductivity on a series of samples containing from 30 to 50% fiber. It was found that conductivity measurements (% IACS) varied by as much as 20 to 30% with a variation of only 3% in fiber content, thus ensuring close control.

On-Aircraft Eddy Current Inspection (Ref 13)

After an airplane enters service, ongoing inspection and maintenance of its structure are essential to ensure a continuing high level of safety. Experience has shown that the inherent structural integrity of commercial transports has been effectively maintained by operator inspection and maintenance programs specified and approved by the certifying agencies. However, after many years of service, these aircraft will reach an age at which an increase in fatigue cracking and corrosion may be expected. As reports of cracking or corrosion are received, nondestructive inspection (NDI) methods are developed and verified for use by operators to ensure the structural integrity of their aircraft.

Damage tolerance and NDI reliability programs consistently show that eddy current inspection is superior to other nondestructive testing methods for the detection of tight fatigue cracks and corrosion. Therefore, NDI engineers have developed numerous types of eddy current inspection for use in inspecting aircraft at operators maintenance bases.

Existing phase-analysis eddy current instruments enable the inspector to produce impedance-plane responses automatically on the storage oscilloscope. If the test part contains cracks or corrosion, the eddy current response on the oscilloscope immediately establishes their existence and relative severity. These instruments operate from 100 Hz to 6 MHz, allowing the inspector to choose the best frequency for a given material and test. The five examples that follow demonstrate the versatility of eddy current inspection in on-aircraft applications.

Example 11: Galvanic Exfoliation Corrosion of Aluminum Wing Skins.

Although contact between two galvanically dissimilar metals, such as steel and aluminum, is known to be a cause of corrosion, the design of aircraft structures occasionally requires that such metals be joined. When this is unavoidable, it is a design requirement that contacting surfaces be electrically insulated with organic paint or sealant or that one of the surfaces be coated with a metallic coating galvanically similar to the other surface. For example, cadmium-plated steel bolts are used on many types of aircraft. The cadmium plating not only protects the steel bolts from corrosion but also provides a surface galvanically similar to aluminum so that the possibility of corrosion is greatly reduced. However, if the cadmium in the plating is depleted or if there is a crevice where moisture can collect between the fastener head and the aluminum skin, pitting and intergranular corrosion may occur (Fig. 50a).

Fig. 50 Detection of galvanic exfoliation corrosion in aluminum wing skins. (a) Schematic showing source and growth of galvanic exfoliation corrosion. (b) Eddy current impedance responses for exfoliation corrosion around fastener holes in wing skins. (c) Schematic illustrating use of circle template to guide eddy current scanning probe around fasteners. Source: Ref 13

Intergranular corrosion occurs along aluminum grain boundaries, which in sheet and plate are oriented parallel to the surface of the material because of the rolling process. (Intergranular corrosion in its more severe form is exfoliation corrosion.) Exfoliation corrosion is basically the intergranular delamination of thin layers of aluminum parallel to the surface, with white corrosion products between the layers. Where fasteners are involved, the corrosion extends outward from the fastener hole, either from the entire circumference of the hole or in one direction from a segment of the hole. In advanced cases, the surface bulges upward; but in milder cases there may be no telltale bulging, and the corrosion can be detected only using nondestructive testing methods.

To conduct the high-frequency eddy current test, the instrument is calibrated using a corroded sample from a corroded area on the aircraft. Typical eddy current impedance plane response to exfoliation corrosion around installed fasteners is illustrated in Fig. 50(b). The use of high-frequency (100 to 300 kHz) pencil-point probes and a circle template, as illustrated in Fig. 50(c), is necessary to detect very small areas of corrosion. The circle template is centered over each fastener, and a 360° scan is made using the eddy current probe. The corrosion response will appear on the CRT and remain there until electronically erased. This method is quite slow, but has been shown to be accurate in detecting very small areas of corrosion around installed fasteners.

Example 12: Surface Cracks Through Thin Sealant Masking Protruding Fasteners.

Sealants are most frequently used around protruding fasteners in the inner wing surface. The sealants are applied to provide a fuel seal (leak prevention) and to prevent corrosion of the fasteners and wing spar caps. Unfortunately, these sealants mask the areas they cover and prevent visual inspection for possible fatigue cracking of the spar caps. Because it is difficult to remove and costly to replace the sealants, eddy current inspection through the sealant is a viable crack detection method.

This section describes the steps taken to perform eddy current inspection for surface cracks under sealant up to 1.3 mm (0.050 in.) thick. Similar methods have been developed for eddy current inspection through sealants up to 2.54 mm (0.100 in.) thick.

The equipment required consists of an impedance-plane, flying-dot, multipurpose eddy current instrument. In some cases, the instrument may be too bulky for access to the inner wing surface. If this situation exists, one operator can manipulate the probe using an extended lead connected to the remotely located instrument monitored by a second operator. The probe operator should periodically scan the defect in the reference standard during the inspection to validate the instrument operator's interpretation. The two operators must be in constant communication with each other to ensure defect detection and to prevent inspection in areas where sealant thickness is beyond the range of the equipment calibration. Thick layers of sealant do require trimming to acceptable dimensions, as shown in Fig. 51. The probe used is a reflectance-type model that is operated at 20 kHz. It measures 25.4 mm (1.0 in.) high by 7.6 mm (0.30 in.) in diameter.

Fig. 51 Sealant trimming requirements for eddy current inspection. (a) Sealant buildup that hinders detection of fatigue cracks in spar caps because probe capability is exceeded. (b) Sealant trimmed to dimension thin enough to allow probe to be positioned properly around fastener. Source: Ref 13

Example 13: Cracks Under Nonmagnetic Bushings Used in Clevis/Lug Attachments.

There are places in light piston-powered aircraft where bushings are installed by staking or interference fit, and it is difficult and costly to remove them for crack inspection. Bushings are usually used at clevis/lug attachments for assembly union with wing, horizontal stabilizer, and vertical stabilizer box sections with spar caps. A typical joint is illustrated in Fig. 52(a). The bushings in fitting 1 are identified as 2, and the bushings in clevis 5 are identified as 4. The bolt, which is removed, is identified as 3.

Fig. 52 Eddy current inspection of cracks located under installed bushings. (a) Schematic of typical assembly employing interference-fit bushings in a clevis/lug attachment assembly. (b) Reference standard incorporating an electrical discharge machined corner notch. (c) Probe coil positioned in bolthole and encircled by bushing. (d) CRT display of a crack located under a ferromagnetic bushing. Source: Ref 13

A reference standard was made from material of the proper thickness, and the electrical discharge machined corner notch was made at the edge of the appropriate-size hole. The bushing was then installed in the reference standard, as shown in Fig. 52(b). The proper-size bolthole probe was selected and inserted into the bushed hole, and the operating frequency was selected to allow the eddy current to penetrate through the bushing in order to detect the notch (Fig. 52c and d).

After calibration, the bolthole probe was inserted into the appropriate bushed hole in the lug or crevis on the aircraft. The probe was inserted at increments of about 1.59 mm (0.0625 in.) and rotated 360° through each hole to be inspected. The bushing, made of a copper alloy, had a thickness of about 1.5 mm (0.060 in.) and a conductivity between 25 and 30% IACS, which is easily penetrated at a frequency of 1 to 2 kHz.

Example 14: Detection of Fatigue Cracks in Aircraft Splice Joints.

Surface and subsurface fatigue cracks usually occur at areas of high stress concentration, such as splice joints between aircraft components or subassemblies. High-frequency (100 to 300 kHz) eddy current inspection was performed to detect surface cracks with shielded small-diameter probes. A reference standard was made from typical materials, and a small electrical discharge machining notch was placed at the corner of the external surface adjacent to a typical fastener. The

high-frequency probe was scanned around the periphery of the fastener using a circle template for a guide, as illustrated in Fig. 53(a).

Fig. 53 High-frequency eddy current inspection of surface and subsurface cracks in aircraft splice joints. (a) Calibration procedure involves introducing an electrical discharge machining notch in the reference standard to scan the fastener periphery using a circle template to guide the probe. (b) CRT trace on an oscilloscope of typical cracks in both skin and spar cap sections shown in (c). Source: Ref 13

When subsurface cracks are to be detected, low-frequency eddy current techniques are employed. Basically stated, the thicker the structure to be penetrated, the lower the eddy current operating frequency that is required. However, the detectable flaw size usually becomes larger as the frequency is lowered.

Example 15: Hidden Subsurface Corrosion in Windowbelt Panels.

There are various areas of the aircraft where subsurface (hidden) corrosion may occur. If such corrosion is detected, usually during heavy maintenance teardown, a nondestructive testing method can be developed to inspect these areas in the remainder of the fleet. Following is an example of subsurface corrosion detected by low-frequency (<10 kHz) eddy current check of the windowbelt panels. Such inspection is applicable at each window on both sides of the aircraft.

Moisture intrudes past the window seal into the inboard side of the windowbelt panel and causes corrosion thinning of the inner surface (Fig. 54). The eddy current inspection is performed using a phase-sensitive instrument operating at 1 to 2.5 kHz and either a 6.4 or 9.5 mm (0.25 or 0.375 in.) surface probe.

Fig. 54 Location of subsurface corrosion in aircraft windowbelt panels. Source: Ref 13

The edge of the inner surface of the windowbelt (where corrosion occurs) tapers from 4.06 to 2.0 mm (0.160 to 0.080 in.) over a distance of 19 mm (0.750 in.). A reference standard simulating various degrees of corrosion thinning (or, in reality, remaining material thickness) is used to calibrate the eddy current instrument (Fig. 55a). The instrument phase is rotated slightly so that probe lift-off response is in the horizontal direction of the CRT. As the probe is scanned across the steps in the standard, the eddy current response is in a vertical direction on the CRT. The amplitude of the response increases as the material thickness decreases (Fig. 55b). As each step in the standard is scanned, the eddy current response may be offset, as shown in Fig. 55(c).

Fig. 55 Eddy current calibration procedure to detect subsurface corrosion in the aircraft windowbelt panels illustrated in Fig. 51. (a) Reference standard used to simulate varying degrees of corrosion thinning from 0.5 to 2.0 mm (0.020 to 0.08 in.) in 0.5 mm (0.020 in.) increments. (b) Plot of CRT display at 2.25-kHz test frequency. (c) CRT offset display permits resolution of amplitudes at the various material thicknesses. Source: Ref 13

After calibrating the instrument, the inspector scans along the inner edge of the window and monitors the CRT for thinning responses, which are indicative of internal corrosion. When thinning responses are noted, the inspection marks the extent of the corrosion and determines the relative remaining thickness. Results are marked on a plastic overlay or sketch and submitted to the engineering department for disposition. The extent of severe corrosion and whether or not

thinning has occurred are determined by removing the internal panels, window, and insulation to expose the corroded areas. The corrosion products are removed, and the thickness is measured using an ultrasonic thickness gage or depth dial indicator.

Effect of Test Frequency on Detectable Flaw Size. Very small surface cracks, extending outward from fastener holes, are detectable using high-frequency, small-diameter eddy current probes. However, the detection of subsurface cracks requires a reduction in operating frequency that also necessitates an increase in the coil (probe) diameter resulting in a larger detectable crack. Because the depth of eddy current penetration is a function of operating frequency, material conductivity, and material magnetic permeability, increased penetration can only be accomplished by lowering the operating frequency. Therefore, the thicker the part to be penetrated, the lower the frequency to be used.

Most of the subsurface crack detection is accomplished with advanced-technology phase-sensitive CRT instruments and reflection (driver/receiver) type eddy current probes. To demonstrate the capability of this technology to detect subsurface cracks in aluminum structures adjacent to fastener holes, Fig. 56 shows a plot of operating frequency versus detectable crack size.

Fig. 56 Plot of operating frequency versus detectable crack length in aluminum structures using reflectance-type (transmit-receive) eddy current probes. Source: Ref 13

Figure 56 illustrates that the detectable flaw size increases as the frequency is reduced. The simulated subsurface flaws range in length from 4.8 to 12.7 mm (0.1875 to 0.50 in.), and the operating frequency band is from 100 Hz to 10 kHz. In addition, Fig. 57 shows a plot of detectable crack size versus thickness of the aluminum layer penetrated before the eddy currents intercepted the crack in the underlying layer.

Fig. 57 Plot of detectable crack length versus thickness of overlying aluminum layer for reflectance-type eddy current probes. Source: Ref 13

The simulated subsurface cracks range in length from 4.8 to 12.7 mm (0.1875 to 0.50 in.). The thickness of the aluminum penetrated before the crack was reached ranged from 1.3 to 7.62 mm (0.050 to 0.300 in.). Although Fig. 57 shows only one overlying layer, the actual specimens contain from one to three layers on top of the layer containing the crack. From Fig. 57, it can be seen that the detectable crack size increases as the overlying layer increases in thickness.

Remote-Field Eddy Current Inspection

J.L. Fisher, Southwest Research Institute

Introduction

REMOTE-FIELD EDDY CURRENT (RFEC) INSPECTION is a nondestructive examination technique suitable for the examination of conducting tubular goods using a probe from the inner surface. Because of the RFEC effect, the technique provides what is, in effect, a through-wall examination using only the interior probe. Although the technique is applicable to any conducting tubular material, it has been primarily applied to ferromagnetics because conventional eddy current testing techniques are not suitable for detecting opposite-wall defects in such material unless the material can be magnetically saturated. In this case, corrosion/erosion wall thinning and pitting as well as cracking are the flaws of interest. One advantage of RFEC inspection for either ferromagnetic or nonferromagnetic material inspection is that the probe can be made more flexible than saturation eddy current or magnetic probes, thus facilitating the examination of tubes with bends or diameter changes. Another advantage of RFEC inspection is that it is approximately equal (within a factor of 2) in sensitivity to axially and circumferentially oriented flaws in ferromagnetic material. The major disadvantage of RFEC inspection is that, when applied to nonferromagnetic material, it is not generally as sensitive or accurate as traditional eddy current testing techniques.

Remote-Field Eddy Current Inspection

J.L. Fisher, Southwest Research Institute

Theory of the Remote-Field Eddy Current Effect

In a tubular geometry, an axis-encircling exciter coil generates eddy currents in the circumferential direction (see the article "Eddy Current Inspection" in this Volume). The electromagnetic skin effect causes the density of eddy currents to decrease with distance into the wall of the conducting tube. However, at typical nondestructive examination frequencies (in which the skin depth is approximately equal to the wall thickness), substantial current density exists at the outer wall. The tubular geometry allows the induced eddy currents to rapidly cancel the magnetic field from the exciter coil inside the tube, but does not shield as efficiently the magnetic field from the eddy currents that are generated on the outer surface of

the tube. Therefore, two sources of magnetic flux are created in the tube interior; the primary source is from the coil itself, and the secondary source is from eddy currents generated in the pipe wall (Fig. 1). At locations in the interior near the exciter coil, the first source is dominant, but at larger distances, the wall current source dominates. A sensor placed in this second, or remote field, region is thus picking up flux from currents through the pipe wall. The magnitude and phase of the sensed voltage depend on the wall thickness, the magnetic permeability and electrical conductivity of tube material, and the possible presence of discontinuities in the pipe wall. Typical magnetic field lines are shown in Fig. 2.

Fig. 1 Schematic showing location of remote-field zone in relation to exciter coil and direct coupling zone

Fig. 2 Instantaneous field lines shown with a log spacing that allows field lines to be seen in all regions. This spacing also emphasizes the difference between the near-field region and the remote-field region in the pipe. The near-field region consists of the more closely spaced lines near the exciter coil in the pipe interior, and the remote-field region is the less dense region further away from the exciter.

Probe Operation

The RFEC probe consists of an exciter coil and one or more sensing elements. In most reported implementations, the exciter coil encircles the pipe axis. The sensing elements can be coils with axes parallel to the pipe axis, although sensing coils with axes normal to the pipe axis can also be used for the examination of localized defects. In its simplest configuration, a single axis-encircling sensing coil is used. Interest in this technique is increasing, probably because of a discovery by Schmidt (Ref 1). He found that the technique could be made much more sensitive to localized flaws by the use of multiple sector coils spaced around the inner circumference with axes parallel to the tube axis. This modern RFEC configuration is shown in Fig. 3.

Fig. 3 RFEC configuration with exciter coil and multiple sector receiver coils

The use of separate exciter and sensor elements means that the RFEC probe operates naturally in a driver-pickup mode instead of the impedance-measuring mode of traditional eddy current testing probes. Three conditions must be met to make the probe work:

- The exciter and sensor must be spaced relatively far apart (approximately two or more tube diameters) along the tube axis
- An extremely weak signal at the sensor must be amplified with minimum noise generation or coupling to other signals. Exciter and sensing coils may consist of several hundred turns of wire in order to maximize signal strength
- The correct frequency must be used. The inspection frequency is generally such that the standard depth of penetration (skin depth) is the same order of magnitude as the wall thickness (typically 1 to 3 wall thicknesses)

When these conditions are met, changes in the phase of the sensor signal with respect to the exciter are directly proportional to the sum of the wall thicknesses at the exciter and sensor. Localized changes in wall thickness cause phase and amplitude changes that can be used to detect such defects as cracks, corrosion thinning, and pitting.

Instrumentation

Instrumentation includes a recording device, a signal generator, an amplifier (because the exciter signal is of much greater power than that typically used in eddy current testing), and a detector. The detector can be used to determine exciter/sensor phase lag or can generate an impedance-plane type of output such as that obtained with conventional driver-pickup eddy current testing instruments. Instrumentation developed specifically for use with RFEC probes is commercially available. Conventional eddy current instruments capable of operating in the driver-pickup mode and at low frequencies can also be used. In this latter case, an external amplifier is usually provided at the output of the eddy current instrument to increase the drive voltage. The amplifier can be an audio amplifier designed to drive loudspeakers if the exciter impedance is not too high. Most audio amplifiers are designed to drive a 4- to 8- Ω load.

Limitations

Operating Frequency. The speed of inspection is limited by the low operating frequency. For example, the inspection of standard 50 mm (2 in.) carbon steel pipe with a wall thickness of 3.6 mm (0.14 in.) requires frequencies as low as 40 Hz. If the phase of this signal is measured (and a phase measurement can be made once per cycle), then only 40 measurements per second are obtained. If a measurement is desired every 2.5 mm (0.1 in.) of probe travel, the maximum probe speed is 102 mm/s (4 in./s), or 6 m/min (20 ft/min). Although this speed may be satisfactory for many applications, the speed must decrease directly in proportion to the spatial resolution required and inversely (approximation is based on simple skin effect model and is generally valid when the skin depth is greater than the wall thickness) with the square of the wall thickness. This limitation is illustrated in Fig. 4 for a range of wall thicknesses.

Fig. 4 Relationship between maximum probe speed and tube wall thickness for nominal assumptions of resolution and tube characteristics

Effect of Material Permeability. Another limitation is that the magnitude and phase of the sensor signal are affected by changes in the permeability of the material being examined. This is probably the limiting factor in determining the absolute response to wall thickness and the sensitivity to localized damage in ferromagnetic material. This disadvantage can be overcome by applying a large magnetic field to saturate the material, but a bulkier probe that is not easily made flexible would be required.

Effect of External Conductors on Sensor Sensitivity. A different type of limitation is that the sensor is also affected by conducting material placed in contact with the tube exterior. The most common examples of this situation are tube supports and tube sheets. This effect is produced because the sensor is sensitive to signals coming from the pipe exterior. For tube supports, a characteristic pattern occurs that varies when a flaw is present. While allowing flaw detection, this information is probably recorded at a reduced sensitivity. Geometries such as finned tubing weaken the RFEC signal and add additional signal variation to such an extent that the technique is not practical under these conditions.

Difficulty in Distinguishing Flaws. Another limitation is that measuring exciter/ sensor phase lag and correlating remaining wall thickness leads to nondiscrimination of outside diameter flaws from inside diameter flaws. Signals indicating similar outside and inside diameter defects are nearly identical. However, conventional eddy current probes can be used to confirm inside-diameter defects.

Current RFEC Research

No-Flaw Models. Most published research regarding RFEC inspection has been concerned with interpreting and modeling the remote-field effect without flaws in order to explain the basic phenomenon and to demonstrate flaw detection results. The no-flaw case has been successfully modeled by several researchers, including Fisher *et al.* (Ref 2), Lord (Ref 3), Atherton and Sullivan (Ref 4), and Palanissimiy (Ref 5), using both analytical and finite-element techniques.

This work has shown that in the remote-field region the energy detected by the sensor comes from the pipe exterior and not directly from the exciter. This effect is seen in several different ways. For example, in the Poynting vector plot shown in Fig. 5, the energy flow is away from the pipe axis in the near-field region, but in the remote-field region a large area of flow has energy moving from the pipe wall toward the axis. In the magnetic field-line plot shown in Fig. 6, the magnetic field in the remote-field region is greater near the tube outside diameter than near the inside diameter. This condition is just the opposite from what one would expect and from what exists in the near-field region. The energy diffusion is from the region of high magnetic field concentration to regions of lower field strength.

Fig. 5 Poynting vector field showing the direction of energy flow at any point in space. This more directly demonstrates that the direction of energy flow in the remote-field region is from the exterior to the interior of the pipe.

Fig. 6 Magnetic field lines generated by the exciter coil and currents in the pipe wall. The greater line density in the pipe closer to the outside wall in the remote-field region confirms the observation that field energy diffuses into the pipe interior from the exterior. A significant number of the field lines have been suppressed.

Flaw models with the RFEC geometry have been generated more rarely. The problem is that realistic flaw models require the use of three-dimensional modeling, something that is difficult to achieve with eddy current testing. One model by Fisher *et al.* (Ref 2) used a boundary-element calculation in conjunction with the two-dimensional, unperturbed-field calculation to predict the response to pitting. The response to outside-diameter and inside-diameter slots has been modeled with two-dimensional finite-element programs (Ref 3).

Techniques Used to Increase Flaw Detection Sensitivity

Two general areas--sensor configuration and signal processing--have been identified for improvements in the use of RFEC inspection that would allow it to achieve greater effective flaw sensitivity.

Sensor Configuration. For the detection of localized flaws, such as corrosion pits, the results of the unperturbed and the flaw-response models suggest that a receiver coil oriented to detect magnetic flux in a direction other than axial might provide increased flaw sensitivity. This suggestion was motivated by the fact that the field lines in the remote-field region are approximately parallel to the pipe wall, as shown in Fig. 6. Thus, a sensor designed to pick up axial magnetic flux, B_z , would always respond to the unperturbed (no-flaw) field; a flaw response would be a perturbation to this primary field. If the sensor were oriented to receive radial flux, B_r , then the unperturbed flux would be reduced and the flaw signal correspondingly enhanced. This approach has been successful; a comparison of a B_z sensor and a B_r sensor used to detect simulated corrosion pits showed that the B_r probe is much more sensitive. A B_r sensor would also minimize the transmitter coil signal from a flaw, which is always present when a B_z sensor is used, thus eliminating the double signals from a single source. This configuration appears to be very useful for the detection of localized flaws, but does not appear to have an advantage for the measurement of wall thickness using the unperturbed field.

Signal Processing. The second area of possible improvement in RFEC testing is the use of improved signal-processing techniques. Because it was observed that the exciter/sensor phase delay was directly proportional to wall thickness in ferromagnetic tubes, measurement of sensor phase has been the dominant method of signal analysis (Ref 1). However, it is possible to display both the magnitude and phase of the sensor voltage or, correspondingly, the complex components of the sensor voltage. This latter representation (impedance plane) is identical to that used in modern eddy current testing instrumentation for probes operated in a driver/pickup mode. Figures 7 and 8 show the results of using this type of display. Figure 7 shows the data from a scan through a carbon steel tube with simulated outside surface pits of 30, 50, and 70% of nominal wall thickness. A B_r probe was used for the experiment. Figure 8 shows the horizontal and vertical channels after the scan data were rotated by 100° . Much of the noise was eliminated in this step.

Fig. 7 Signal processing of impedance-plane sensor voltage in RFEC testing. (a) RFEC scan with a B_r probe through a carbon steel tube with outside surface pits that were 30, 50, and 70% of wall thickness depth. Each graduation in x and y direction is 10 V. (b) Horizontal channel at 0° rotation. (c) Vertical channel at 0° rotation. Signal amplitudes in both (b) and (c) are in arbitrary units. Only the 70% flaw stands out clearly.

Fig. 8 Horizontal (a) and vertical (b) data of Fig. 7 after 100° rotation. Signal amplitudes are in arbitrary units.

An additional possible signal-processing step is to use a correlation technique to perform pattern matching. Because the B_r sensor has a characteristic double-sided response to a flaw, flaws can be distinguished from material variations or undesired probe motion by making a test sensitive to this shape. This effect is achieved by convolving the probe signals with a predetermined sample signal that is representative of flaws. The results of one test using this pattern-matching technique are shown in Fig. 9. It is seen that even though the three flaws have a range of depths and diameters, the correlation algorithm using a single sample flaw greatly improves the signal-to-noise ratio.

Fig. 9 Data from Fig. 8 processed with the correlation technique. All three flaws are now well defined. Signal amplitude is in arbitrary units.

Other signal-processing techniques that show promise include the use of high-order derivatives of the sensor signal for edge detection and bandpass and median filtering to remove gradual variations and high-frequency noise (Ref 6).

Applications*

Remote-field eddy current testing should be considered for use in a wider range of examinations because its fundamental physical characteristics and limitations are now well understood. The following two examples demonstrate how improvements in RFEC probe design and signal processing have been successfully used to optimize the operation of key components in nuclear and fossil fuel power generation.

Example 1: Gap Measurement Between Two Concentric Tubes in a Nuclear Fuel Channel Using a Remote-Field Eddy Current Probe.

The Canadian Deuterium Uranium reactor consists of 6 m (20 ft) long horizontal pressure tubes containing the nuclear fuel bundles. Concentric with these tubes are calandria tubes with an annular gap between them. Axially positioned garter spring spacers separate the calandria and pressure tubes. Because of unequal creep rates, the gap will decrease with time. Recently, it was found that some garter springs were out of position, allowing pressure tubes to make contact with the calandria tubes.

Because of this problem, a project was initiated to develop a tool to move the garter springs back to their design location for operating reactors. Successful use of this tool would require measurement of the gap during the garter spring unpinching operation. The same probe could also be used to measure the minimum gap along the pressure tube length. Because the gap is gas filled, an ultrasonic testing technique would not have been applicable.

At low test frequencies, an eddy current probe couples to both the pressure tube and the calandria tube (Fig. 10a). The gap component of the signal is obtained by subtracting the pressure tube signal from the total signal. Because the probe is near or in contact with the pressure tube and nominally 13 mm ($\frac{1}{2}$ in.) away from the calandria tube, most of the signal comes from the pressure tube. In addition, the calandria tube is much thinner and of higher electrical resistivity than the pressure tube, further decreasing the eddy current coupling. To overcome the problem of low sensitivity with large distances (>10 mm, or 0.4 in.), a remote-field eddy current probe was used. Errors in gap measurement can result from variations in:

- Lift-off
- Pressure tube electrical resistivity
- Ambient temperature
- Pressure tube wall thickness

Multifrequency eddy current methods exist that significantly reduce the errors from the first three of the above-mentioned variations, but not for wall thickness variations. This is because of minimal coupling to the calandria tube and because the signal from the change in gap is similar (in phase) to the signal from a change in wall thickness (at all test frequencies).

Fig. 10 Gap measurement between two concentric tubes in a nuclear fuel channel with an RFEC probe. (a) Cross-sectional view of probe and test sample. Dimensions given in millimeters. (b) Plot of eddy current signals illustrating effect of gap, wall thickness, and lift-off. Dimensions given in millimeters. (c) Plot of y-component of signal versus gap at a frequency of 3 kHz. Source: V.S. Cecco, Atomic Energy of Canada Limited

The inducing magnetic field from an eddy current probe must pass through the pressure tube wall to sense the calandria tube. The upper test frequency is limited by the high attenuation through the pressure tube wall and the lower test frequency by the low coupling to the pressure tube and calandria tube. In addition, at low test frequency, there is poor signal discrimination because of variations in lift-off, electrical resistivity, wall thickness, and gap. In practice, 90° phase

separation between lift-off and gap signals gives optimum signal-to-noise and signal discrimination. For this application, the optimum test frequency was found to be between 3 and 4 kHz.

Typical eddy current signals from a change in pressure tube to calandria tube gap, lift-off, and wall thickness are shown in Fig. 10(b). The output signal for the complete range in expected gap is linear, as shown in Fig. 10(c). To eliminate errors introduced from wall thickness variations, the probe body includes an ultrasonic normal beam transducer located between the eddy current transmit and receive coils. This combined eddy current and ultrasonic testing probe assembly with a linear output provides an accuracy of ± 1 mm (± 0.04 in.) over the complete gap range of 0 to 18 mm (0 to 0.7 in.).

Example 2: RFEC Inspection of Carbon Steel Mud Drum Tubing in Fossil Fuel Boilers.

Examination of the carbon steel tubing used in many power boiler steam generators is necessary to ensure their safe, continuous operation. These tubes have a history of failure due to attack from acids formed from wet coal ash, as well as erosion from gas flow at high temperatures. Failure of these tubes from thinning or severe pitting often requires shutdown of the system and results in damage to adjacent tubes or to the entire boiler. The mud drum region of the steam generator is one such area. Here the water travels up to the superheater section, and the flame from the burners is directed right at the tubes just leaving the mud drum. The tubes in this region are tapered and rolled into the mud drum (Fig. 11), then they curve sharply upward into the superheater section.

Fig. 11 Geometry and dimensions of 64 mm (2.5 in.) OD carbon steel generating tubes at a mud drum. The tube is rolled into a tube sheet to provide a seal as shown. Dimensions given in millimeters

The tubes are constructed of carbon steel typically 64 mm (2.5 in.) in outside diameter, and 5.1 mm (0.2 in.) in wall thickness. A conventional eddy current test would be ineffective, because the eddy currents could not penetrate the tube wall and still influence coil impedance in a predictable manner. Ultrasonic testing could be done, but would be slow if 100% wall coverage were required. The complex geometry of the tube, the material, and the 41 mm (1.6 in.) access opening necessitated that a different technique be applied to the problem.

Because the RFEC technique behaves as if it were a double through transmission effect, changes in the fill factor are not as significant as they would be in a conventional eddy current examination. This allowed the transmitter and receiver to be designed to enter through the 41 mm (1.6 in.) opening. Nylon brushes recentered the RFEC probe in the 56.6 mm (2.23 in.) inside diameter of the tube. To maintain flexibility of the assembly and still be able to position the inspection head, universal joints were used between elements.

The instrumentation used in this application was a combination of laboratory standard and custom-designed components (Fig. 12). The Type 1 probe was first used to locate any suspect areas, then the Type 2 probe was used to differentiate

between general and local thinning of the tube wall. This technique was applied to the examination of a power boiler, and the results were compared to outside diameter ultrasonic readings where possible. Agreement was within 10%.

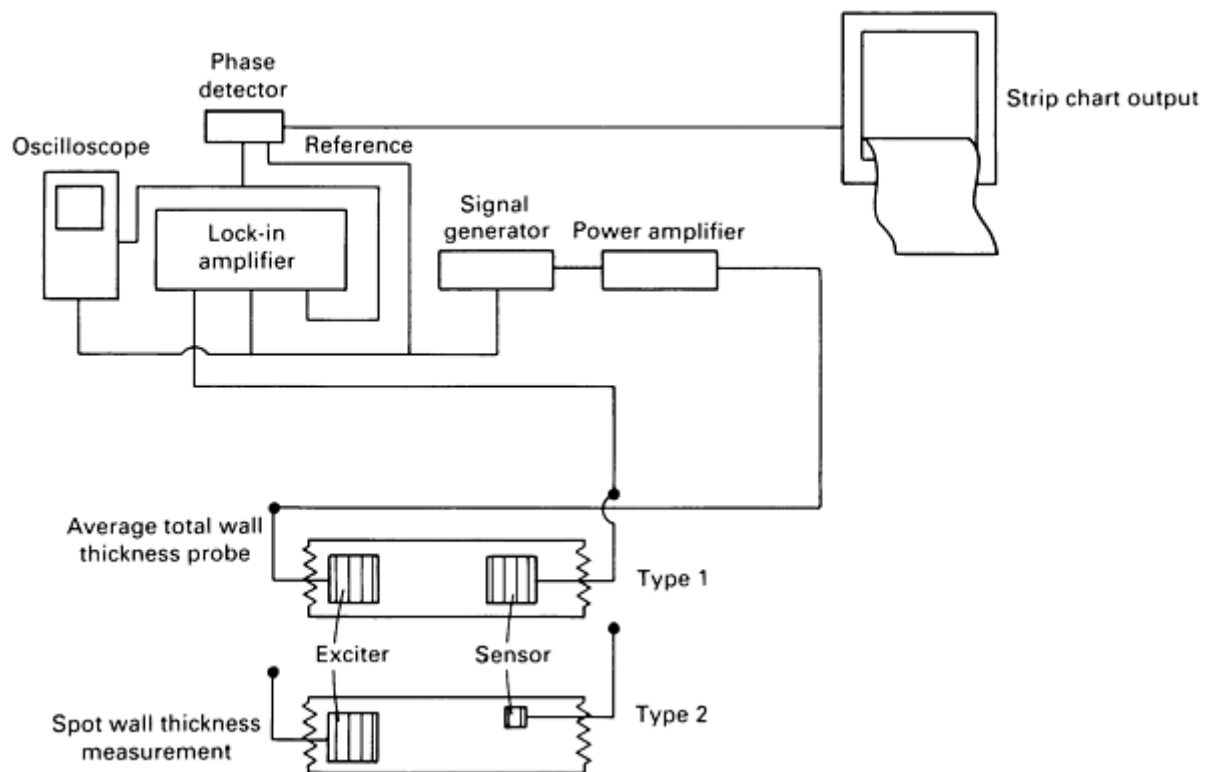

Fig. 12 Breadboard instrumentation necessary to excite and receive the 45-Hz signal. Analysis was based on the phase difference between the reference and received signals.

Introduction

MICROWAVES (or radar waves) are a form of electromagnetic radiation located in the electromagnetic spectrum at the frequencies listed in Table 1. Major subintervals of the microwave frequency band are designated by various letters; these are listed in Table 2. The microwave frequency region is between 300 MHz and 325 GHz. This frequency range corresponds to wavelengths in free space between 1000 cm and 1 mm (40 and 0.04 in.).

Table 1 Divisions of radiation, frequencies, wavelengths, and photon energies of the electromagnetic spectrum

Division of radiation	Frequency, Hz	Wavelength, m	Photon energy	
			J	eV

Source: Ref 1

Although the general nature of microwaves has been known since the time of Maxwell, not until World War II did microwave generators and receivers useful for the inspection of material become available. One of the first important uses of microwaves was for radar. Their first use in nondestructive evaluation (NDE) was for components such as waveguides, attenuators, cavities, antennas, and antenna covers (radomes). The interaction of microwave electromagnetic energy with a material involves the effect of the material on the electric and magnetic fields that constitute the electromagnetic wave, that is, the interaction of the electric and magnetic fields with the conductivity, permittivity, and permeability of the material. Microwaves behave much like light waves in that they travel in straight lines until they are reflected, refracted, diffracted, or scattered. Because microwaves have wavelengths that are 10^4 to 10^5 times longer than those of light waves, microwaves penetrate deeply into materials, with the depth of penetration dependent on the conductivity, permittivity, and permeability of the materials. Microwaves are also reflected from any internal boundaries and interact with the molecules that constitute the material. For example, it was found that the best source for the thickness and voids in radomes was the microwaves generated within the radomes. Both continuous and pulsed incident waves were used in these tests, and either reflected or transmitted waves were measured.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Microwave Inspection Applications

The use of microwaves for evaluating material properties and discontinuities in materials other than radomes began with the evaluation of the concentration of moisture in dielectric materials. Microwaves of an appropriate wavelength were found to be strongly absorbed and scattered by water molecules. When the dry host material is essentially transparent to the microwaves, the moisture measurement is readily made.

Next, the thickness of thin metallic coatings on nonmetallic substrates and of dielectric slabs was measured. In this case, incident and reflected waves were allowed to combine to form a standing wave. Measurements were then made on the standing wave because it provided a scale sensitive to the material thickness.

The measurement of thickness was followed by the determination of voids, delaminations, macroporosity, inclusions, and other flaws in plastic or ceramic materials. Microwave techniques were also used to detect flaws in bonded honeycomb structures and in fiber-wound and laminar composite materials. For most measurements, the reflected wave was found to be most useful, and the use of frequency modulation provided the necessary depth sensitivity. Success in these measurements also indicated that microwave techniques could give information related to changes in chemical or molecular structure that affect the dielectric constant and dissipation of energy at microwave frequencies. Some of the properties measured include polymerization, oxidation, esterification, distillation, and vulcanization.

Advantages. In comparison with ultrasonic inspection and x-ray radiographic inspection, the advantages of inspection with microwaves are as follows:

- Broadband frequency response of the coupling antennas
- Efficient coupling through air from the antennas to the material
- No material contamination problem caused by the coupling
- Microwaves readily propagate through air, so successive reflections are not obscured by the first one
- Information concerning the amplitude and phase of propagating microwaves is readily obtainable
- No physical contact is required between the measuring device and the material being measured; therefore, the surface can be surveyed rapidly without contact
- The surface can be scanned in strips merely by moving the surface or by scanning the surface with antennas
- No changes are caused in the material; therefore, the measurement is nondestructive
- The complete microwave system can be made from solid-state components so that it will be small, rugged, and reliable
- Microwaves can be used for locating and sizing cracks in materials if the following considerations are followed. First, the skin depth at microwave frequencies is very small (a few micrometers), and the crack is detected most sensitively when the crack breaks through the surface. Second, when the crack is not through the surface, the position of the crack is indicated by a detection of the high stresses in the surface right about the subsurface crack. Finally, microwave crack detection is very sensitive to crack opening and to the frequency used. Higher frequencies are needed for the smaller cracks. If the frequency is increased sufficiently, the incident wave can propagate into the crack, and the response is then sensitive to crack depth

Limitations. The use of microwaves is in some cases limited by their inability to penetrate deeply into conductors or metals. This means that nonmetallic materials inside a metallic container cannot be easily inspected through the container. Another limitation of the lower-frequency microwaves is their comparatively low power for resolving localized flaws. If a receiving antenna of practical size is used, a flaw whose effective dimension is significantly smaller than the wavelength of the microwaves used cannot be completely resolved (that is, distinguished as a separate, distinct flaw). The shortest wavelengths for which practical present-day microwave apparatus exists are of the order of 1 mm (0.04 in.). However, the development of microwave sources with wavelengths of 0.1 mm (0.004 in.) are proceeding rapidly. Consequently, microwave inspection for the detection of very small flaws is not suited for applications in which flaws are equal to or smaller than 0.1 mm (0.004 in.). Subsurface cracks can be detected by measuring the surface stress, which should be much higher in the surface above the subsurface crack.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Physical Principles of Microwaves

In free space, an electromagnetic wave is transverse; that is, the oscillating electric and magnetic fields that constitute it are transverse to the direction of travel of the wave. The relative directions of these two fields and the direction of propagation of the wave are shown schematically in Fig. 1. As the wave travels along the z -axis, the electric and magnetic field intensities at an arbitrary fixed location in space vary in magnitude. A particularly simple form of a propagating electromagnetic wave is the linearly polarized, sinusoidally varying, plane electromagnetic wave illustrated in Fig. 2. The magnitude of the velocity, v , at which a wave front travels along the z -axis is given by the relation $v = f\lambda$, where f is frequency and λ is wavelength. In free space, this velocity is the speed of light, which has the value 2.998×10^8 m/s and is usually designated by the letter c .

Fig. 1 Relative directions of the electric field intensity (E), the magnetic field intensity (H), and the direction of propagation (z) for a linearly polarized, plane electromagnetic wave

Fig. 2 Diagram of a linearly polarized, sinusoidally varying, plane electromagnetic wave propagating in empty space. λ , wavelength; z, direction of wave propagation; E, amplitude of electric field; H, amplitude of magnetic field

In microwave inspection, a homogeneous material medium can be characterized in terms of a magnetic permeability, μ ; a dielectric coefficient, ϵ ; and an electrical conductivity, σ . In general, these quantities are themselves functions of the frequency, f . Moreover, μ and ϵ must usually be treated as complex quantities, rather than as purely real ones, to account for certain dissipative effects. However, a wide variety of applications occur in which μ and ϵ can be regarded as mainly real and constant in value. The magnetic permeability, μ , usually differs only slightly from its value in vacuum, while the dielectric coefficient, ϵ , usually varies between 1 and 100 times its value in vacuum. The electrical conductivity, σ , ranges in value from practically zero ($10^{-16} \Omega \cdot \text{mm}$) for good insulators to approximately $10^7 \Omega \cdot \text{mm}$ for good conductors such as copper.

For an electromagnetic wave incident upon a material, a part of the incident wave is transmitted through the surface and into the material, and a part of it is reflected. The sum of the reflected energy and refracted energy (transmitted into the material) equals the incident energy. If the reflected wave is subtracted in both amplitude and phase from the incident wave, the transmitted wave can be determined. When the reflected wave is compared, in both amplitude and phase, with the incident wave, information about the surface impedance of the material can be obtained.

Plane electromagnetic waves propagating through a conductive medium diminish in amplitude as they propagate, falling to 37% of their amplitude at a reference position in distance, referred to as the skin depth, measured along the direction of propagation. The skin depth, δ , in a good conductor ($\sigma \gg \omega\epsilon$, where ω is the angular frequency) is given by the relation $\delta = (2/\mu\sigma\omega)^{1/2}$. The velocity, v , of an electromagnetic wave propagating in a nonconductor is given by the relation $v = 1/(\mu\epsilon)^{1/2}$. This velocity can be expressed relative to the velocity of electromagnetic waves in vacuum, the ratio being the

index of refraction, n , where $n = c/v = (\mu\epsilon/\mu_0\epsilon_0)^{1/2}$ with μ_0 and ϵ_0 being the magnetic permeability and dielectric coefficient of free space. The phase velocity of a plane harmonic electromagnetic wave in a conductive medium can be given as $v = \omega\sigma = (2\omega/\mu\delta)^{1/2}$, where δ is the skin depth. Therefore, the velocity, v , depends strongly on the frequency, ω , even if magnetic permeability, μ , and electrical conductivity, σ , do not themselves depend on ω . As a result, a conductive medium is said to be highly dispersive, because a wave packet, which comprises sinusoidal components of many different frequencies, disperses (spreads) as it propagates. In conductive media, the magnetic component of an electromagnetic wave does not propagate in phase with the electric component. Assuming $|\epsilon| \ll |\sigma|$, the surface impedance of a material is (Ref 2):

$$Z_s = \sqrt{\frac{\mu}{\epsilon - j(\sigma/\omega)}} \approx \sqrt{\frac{j\omega\mu}{\sigma}} \quad (\text{Eq 1})$$

where μ is the complex permeability, σ is the conductivity, ϵ is the complex permittivity, ω is the angular frequency, and $j = \sqrt{-1}$.

The skin depth, δ , of an electromagnetic wave propagating in a weakly conductive medium ($\sigma \ll \omega\epsilon$) is given approximately by the relation $\delta \simeq 2/\sigma \sqrt{\epsilon/\mu}$. In this case, the wavelength is approximately given by:

$$\lambda \simeq \lambda_0 \left(\frac{1}{n}\right) \left[1 - \frac{1}{8}(\sigma/\epsilon\omega)^2\right] \quad (\text{Eq 2})$$

where λ_0 is the wavelength of the wave in vacuum, n is the index of refraction of the medium. Equation 1 is sufficiently accurate for most materials having electrical conductivity low enough for practical microwave inspection involving transmission. The criterion for its validity is that the nonattenuative wavelength, λ_0/n , be short compared to the skin depth, δ .

Reflection and Refraction. The laws of reflection and refraction of microwaves at interfaces between mediums of differing, electromagnetic properties are essentially the same as those for the reflection and refraction of visible light. The angle of refraction is determined by Snell's law, $n_2 \sin \phi = n_1 \sin \theta$, where n_1 and n_2 are, respectively, the indexes of refraction of the two media; θ is the angle of incidence; and ϕ is the angle of refraction. The medium in which the incident ray occurs is arbitrarily designated by the subscript 1, and the other medium by the subscript 2.

For linearly polarized plane waves incident perpendicularly on an interface separating two dielectric mediums, the amplitudes of the reflected and transmitted waves, respectively, are given by:

$$E_{\text{max, reflected}} = [(n_2 - n_1)/(n_1 + n_2)] E_{\text{max, incident}} \quad (\text{Eq 3a})$$

$$E_{\text{max, transmitted}} = [2n_1/(n_1 + n_2)] E_{\text{max, incident}} \quad (\text{Eq 3b})$$

Analogous relations hold for the amplitudes of the magnetic field. For angles of incidence other than zero, the corresponding relations are more complicated and will not be quoted here. The amplitudes of reflected and refracted waves vary as a function of the angle of incidence for a typical choice of the ratio n_1/n_2 , as shown in Fig. 3. The shapes of the curves vary somewhat with the dielectric constant (Ref 3).

Fig. 3 Representative reflection of a linearly polarized plane electromagnetic wave at a dielectric interface with electric field parallel or perpendicular to the plane of incidence. (a) Wave entering dielectric. (b) Wave leaving dielectric

The curves in Fig. 3 show the amplitude reflection factor as a function of the angle of incidence when the polarization factor (direction of the electric field vector) is either parallel or perpendicular to the plane of the interface. The curves in Fig. 3(a) represent the conditions in which the microwaves are entering the material, and the curves in Fig. 3(b) are for waves leaving the material. In Fig. 3(a), the reflection factor increases steadily to unity at 90° for the perpendicular polarization factor. The reflection factor for the parallel polarization decreases to zero at the Brewster angle and then increases to total reflection as a function of increasing angle of incidence. In Fig. 3(b), the same occurrence takes place except that the unity reflection factor for both polarization factors occurs at the critical angle of incidence rather than at 90° . The critical angle for reflection, from Snell's law, is equal to $\arcsin(1/\epsilon^{1/2})$, where ϵ is the dielectric constant of the material. The Brewster angle for the case of reflection is equal to the $\arctan(1/\epsilon^{1/2})$. The scattering cross section oscillates with decreasing magnitude as the ratio of the circumference to wavelength varies from 0.3 to 10. Ratios from 0.3 to 10 are in the resonance region. The maximum scattering occurs when the circumference equals the wavelength. In the optical region, the scatter cross section equals the physical cross section, and $\sigma/\pi r^2 \approx 1$, where r is the radius of the sphere. Thus, scattering is proportional to physical cross section (πr^2).

Absorption and Dispersion of Microwaves. Microwaves are also affected during their propagation through a homogeneous nonmetallic material, primarily by the interaction of the electric field with the dielectric (molecular) properties of the nonmetallic material. The storage and dissipation of the electric field energy by the polarization and conduction behavior of the material are the basic factors under consideration.

Polarization and conduction are the cumulative results of molecular-charge-carrier movement in the nonmetallic material. Polarization involves the action of bound charges in the form of permanent or induced dipoles. Conduction refers to whatever small amount of free charge carriers (electrons) is present. As a microwave passes through the material, the dipoles oscillate because of the cyclic nature of the force on them from the electric field. The dipole oscillation alternately stores and dissipates the electric field energy. Conduction currents only dissipate the energy, that is, convert it to heat.

The dielectric properties of a nonmetallic material are normally expressed in terms of the dielectric constant (permittivity) and loss factor. The dielectric constant is related to the amount of electric field energy that the dipoles in a material temporarily store and release during each half cycle of the electric field change. Materials with a high dielectric constant have a great storage capacity. This reduces the electric field strength, the velocity, and the wavelength. The loss factor, or loss tangent, expresses the dissipation of energy caused by both conduction and dipole oscillation losses. In other words, the dielectric constant measures the energy storage, while the loss factor measures the dissipation of electromagnetic energy by nonmetallics.

Standing Waves. Interference conditions usually prevail when microwaves are used for nondestructive inspection because of the wavelengths and velocities involved, the coherent nature of the microwaves used, the high transparency of most nonmetallic materials, and the fact that the thicknesses of the nonmetallic materials are within several wavelengths. The familiar standing wave is the usual wave pattern resulting during nondestructive inspection. A standing wave (Fig. 4) is produced when two waves of the same frequency are propagating in opposite directions and interfere with each other. The result is the formation of a total field whose maximum and minimum points remain in a fixed or standing position. Both component waves are still traveling, and only the resultant wave pattern is fixed. A simple way to form standing waves is to transmit a coherent wave normal to a surface. The incident and reflected waves interfere and cause a standing wave. The standing wave wavelength and peak amplitude change along the standing wave pattern and are related to the velocity and attenuation experienced by the wave in a given medium. The technique by which standing waves are formed with microwave radiation is used to make accurate measurements of thickness where conventional caliper methods are especially difficult. The technique involved is discussed in the section "Thickness Gaging" in this article.

Fig. 4 Pattern of a standing wave formed by interference of an incident wave and a reflected wave

Scattering of Microwaves. Microwaves reflect from inhomogeneities by a process known as scattering. The scattering is generally used to describe wave interaction with small particles or inhomogeneities. The term reflection is generally used to describe wave interaction with surfaces that are large compared to wavelength. When the surface is not smooth on a scale commensurate with the wavelength of the microwaves used, the reflected wave is not a simple single wave, but is essentially a composite of many such waves of various relative amplitudes, phases, and directions of propagation. This effect is greatest when the wavelength is comparable to the dimensions of the irregularities. Under these

circumstances, the radiation is said to be scattered. The scattering behavior of metal spheres having differing ratios of circumference to the wavelength of incident microwave radiation is shown in Fig. 5. The scattering cross section is proportional to the amplitude of the wave scattered in the direction back toward the source of the incident wave.

Fig. 5 Microwave scattering by metal spheres of various sizes

The scattering is small for values of the ratio of the circumference to the wavelength less than 0.3, and scattering varies as the fourth power of this ratio. Ratios below 0.3 lie in what is known as the Rayleigh region.

Mathematically, the dielectric constant and loss factor are expressed in combined forms as a complex permittivity:

$$\epsilon^* = \epsilon' - j\epsilon'' \quad (\text{Eq 4})$$

where ϵ^* is the complex permittivity or complex dielectric constant, ϵ' is the permittivity or dielectric constant, j is the phasor operator $[(-1)^{1/2}]$, and ϵ'' is the loss factor. Equation 4 shows that the dielectric constant is 90° out of phase with respect to the loss factor. The loss tangent is equal to the ratio of ϵ''/ϵ' . Wave velocity and attenuation are related to dielectric properties and therefore serve as a means of measurement.

The dielectric properties of a nonmetallic material are frequently affected by other material properties of industrial importance. The degree of correlation depends on the frequency of the electromagnetic wave, and sensitive measurements can often be made with microwaves.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Special Techniques of Microwave Inspection

The following general approaches have been used in the development of microwave nondestructive inspection:

- Fixed-frequency continuous-wave transmission
- Swept-frequency continuous-wave transmission
- Pulse-modulated transmission
- Fixed-frequency continuous-wave reflection
- Swept-frequency continuous-wave reflection
- Pulse-modulated reflection
- Fixed-frequency standing waves
- Fixed-frequency reflection scattering
- Microwave holography
- Microwave surface impedance
- Microwave detection of stress corrosion

Each of these techniques uses one or more of the several processes by which materials can interact with microwaves, namely, reflection, refraction, scattering, absorption, and dispersion. These techniques will be briefly described from the standpoint of instrumentation and are grouped to four areas:

- Transmission
- Reflection
- Standing wave
- Scattering

Transmission Techniques

The basic components of the transmission technique are shown schematically in Fig. 6. A microwave generator feeds both a transmitting antenna and a phase-sensitive detector (or comparator). The transmitting antenna produces the electromagnetic wave that is incident on one face of the material to be inspected. At the surface, the incident wave is split into a reflected wave and a transmitted or refracted wave. The transmitted wave goes through the material into the receiving antenna. All of the transmitted wave will not pass through the second face of the material because some of it will be reflected at the second surface. The microwave signal from the receiving antenna can be compared in amplitude and phase with the reference signal taken directly from the microwave generator.

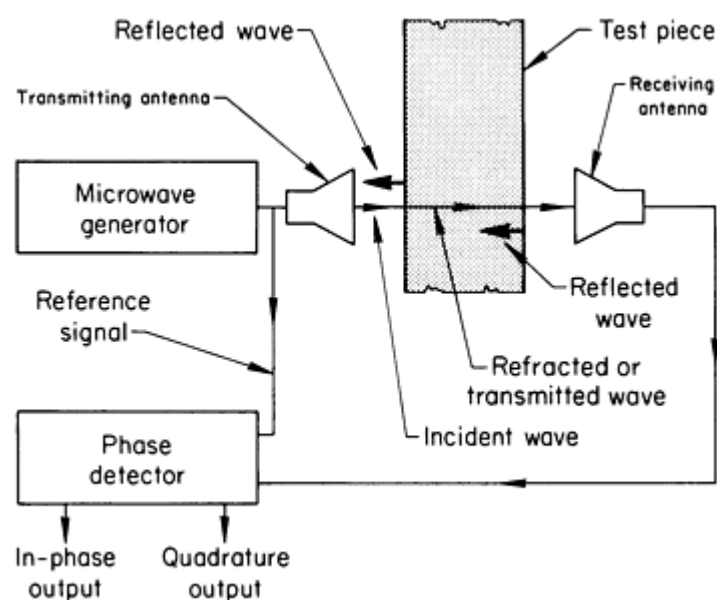

Fig. 6 Diagram of the basic components of the transmission technique used for microwave inspection

The reference signal can be taken to be of the form $V_{\text{ref}} = V_0 \cos \omega t$. The received signal, V_{rec} , is then of the form:

$$V_{\text{rec}} = V' \cos (\omega t + \phi) = (V' \cos \phi) \cos \omega t - (V' \sin \phi) \sin \omega t \quad (\text{Eq 5})$$

Because it is the coefficient of the term that varies in phase with the reference signal, the quantity $V' \cos \phi$ is referred to as the in-phase component, and the quantity $V' \sin \phi$ is termed the quadrature component. Standard electronic phase-sensitive detectors are available that can detect each of these components separately. The transmission technique can have three variations:

- Fixed-frequency continuous wave
- Variable-frequency continuous wave
- Pulse-modulated wave

Fixed-Frequency Continuous-Wave Transmission. In this technique, the frequency of the microwave generator is constant. It is used either when the band of frequencies required for the desired interaction is very narrow or when the band of frequencies is so broad that the changes of material properties with frequency are very small and therefore not especially frequency sensitive. The fixed-frequency continuous-wave transmission technique is the only one of the transmission techniques in which both components (in-phase and quadrature-phase) can be detected with little mutual interference. When separation (the ability to separate the components) is important, this technique is generally used.

Swept-Frequency Continuous-Wave Transmission. Some microwave interactions are frequency sensitive in that their resonant frequency shifts with changes in material properties. For others, the response as a function of frequency over substantial bandwidth must be used. The swept-frequency continuous-wave transmission technique provides for a transmission measurement over a selected range of frequencies. The fixed-frequency microwave generator shown in Fig. 6 is replaced with a swept-frequency generator whose frequency is programmed to vary automatically. With currently available generators, a frequency band of one octave or more can be electronically swept (from 1 to 2 GHz, for example). Broad band amplifiers of low noise and high gain also make it possible to detect transmitted signals through materials having very high attenuation. Multioctave generators from 100 kHz to 4 GHz or 10 MHz to 40 GHz are available. Vector network analyzers provide broadband amplitude and phase.

Pulse-Modulated Transmission. Although phase measurements can be made on the transmitted wave, they are only relative to the reference wave. There is no simple method for tagging a particular sine wave crest relative to another to measure transmission time. Therefore, when a measurement of the time of transmission is required, the pulse-modulated technique is used. To produce the pulse modulation, the microwave generator is gated on and off. The phase-sensitive detector in the receiver is usually replaced by a peak-value detector. Thus, the receiver output consists of pulses that are delayed a finite time relative to the transmitted pulse. An oscilloscope with an accurate horizontal-sweep rate can be used to display these pulses. Swept-frequency measurements give group delay information. The time domain features of vector network analyzers can also be useful.

Reflection Techniques

The reflection techniques are of two types: single antenna and dual antenna. The single-antenna system, in which incident and reflected waves are both transmitted down the waveguide between the microwave generator and the antenna, is shown schematically in Fig. 7(a). The phase detector is set so that it compares the phase of the reflected wave with that of the incident wave. This gives two output signals that are respectively proportional to the in-phase and quadrature components in the reflected wave. Such a system works well only for normal or near-normal incidence.

Fig. 7 Diagram of the single-antenna and dual-antenna reflection systems used for microwave inspection

The dual-antenna reflection system (Fig. 7b) operates at any angle of incidence for which there is appreciable reflection. A comparison of Fig. 7(b) with Fig. 6 shows that the dual-antenna reflection equipment is essentially the same as that used for transmission measurements. In the transmission technique, the reflected wave is not used. In the reflection technique, the transmitted wave is ordinarily not used except as a reference.

The boundary conditions must be complied with at the surface of the material. Therefore, the reflected wave, in principle, has the same information about the bulk microwave properties of the material as the refracted wave. However, the wave reflected from the first surface does not contain any information about the inhomogeneous properties of the material within the sample being tested. There are further reflections from any internal discontinuities or boundaries, which ultimately add to the surface-reflected wave when refracted at the surface. In this manner, properties beneath the surface are sensed. If the component being inspected is a plate that is backed with a layer of conductive material, the wave reflected from this metal face traverses the material twice, and it too adds to the surface-reflected wave to provide information about the interior of the material.

Fixed-Frequency Continuous-Wave Reflection. The simplest microwave reflectometer is based on the fixed-frequency technique. The microwave signal is incident on the material from an antenna; the reflected signal is picked up by the same antenna. Both the in-phase and quadrature-phase components of the reflected wave can be determined. In practice, most such techniques have used only the amplitude of the reflected signal. The dual-antenna reflection technique (Fig. 7b) can also be used at a fixed frequency. The fixed-frequency continuous-wave technique has two limitations. First, the depth of a flaw cannot be determined, and second, the frequency response of the material cannot be determined. For these reasons, a swept-frequency technique may be more useful.

Swept-Frequency Continuous-Wave Reflection. When the interaction between a material and microwaves is frequency sensitive, a display of reflection as a function of frequency may be valuable. Because phase-sensitive detection over a wide range of frequencies is difficult, only the amplitude of the reflected signal is usually used as the output in swept-frequency techniques. However, phase-sensitive detection over a wide range of frequencies has recently been simplified with the use of vector network analyzers.

Depth can be measured with a swept-frequency technique if the reflected signal is mixed with the incident signal in a nonlinear element that produces the difference signal. The difference frequency, then, is a measure of how much farther the reflected signal has traveled than the incident signal. Thus, not only can the presence of an internal reflector be determined but also its depth. Depth can also be measured on a vector network analyzer utilizing time domain techniques.

Another application of this technique employs a slow sweep of frequency to identify specific layers of several closely spaced layers of material. The reflection at even multiples of one-fourth wavelength is larger than at odd multiples of one-fourth wavelength. The reflected signal identifies specific frequencies for which the layer spacing is at even or odd integral multiples of the quarter-wavelength. This same effect is used, for example, to reduce reflection from lenses by coating them with layers of dielectric.

Pulse-Modulated Reflection. The depth of a reflection, in principle, can also be determined by pulse modulating the incident wave. When the reflected time-delayed pulse is compared in time with the incident pulse and when the velocity of the wave in the material is known, the depth to the site of the reflection can be determined. In both frequency and time domain modulation, the nature of the reflector is determined by the strength of the reflected signal. The limitation of pulse modulation is that the pulses required are very narrow if shallow depths are to be determined. For this reason, the use of frequency modulation has been developed and used.

Standing Wave Techniques

A standing wave is obtained from the constructive interference of two waves of the same frequency traveling in opposite directions. The result is a standing wave in space. If a small antenna is placed at a fixed point in space, a voltage of constant amplitude and frequency is detected. Moving the antenna to another location would give a voltage of a different constant amplitude with the same frequency. The graph of the amplitude of the voltage as a function of position (distance) along a pure standing wave is shown in Fig. 8. One antenna is needed to produce the incident wave, which can interact with the reflected wave to produce the standing wave. Another antenna or probe is needed to make measurements along the standing wave. Thus, the dual-antenna system shown in Fig. 7(b) could be used to both make and measure microwave standing waves. The receiving antenna must not interfere with the incident wave. A single antenna fed through a circulator can also be used to separately transmit the incident wave and the reflected wave.

Fig. 8 Relation of electromagnetic wave amplitude (detector response) to the distance along a standing wave

Scattering Techniques

The dual-antenna system diagrammed in Fig. 7(b) must be used for scattering measurements because the angles of the diffused or reradiated waves can be over a solid angle. To measure all of the scattered radiation, the entire sphere around the irradiated object or material should be scanned and the detected signal graphed as a function of position.

Microwave Holography

When two electromagnetic waves (Fig. 2) occupy the same space, the resulting electromagnetic wave is the vector sum of the two. If the two waves have the same source, they will have the same frequency and will add or subtract as vectors according to their relative phase angles. These additions and subtractions will cause an interference pattern, which is a plane of interference composed of places where they add and places where they subtract. Wave front reconstruction is discussed in Ref 4, 5, 6, 7, and 8.

When the electromagnetic waves are in the infrared through ultraviolet range of frequencies and when a photographic film or plate is used at the plane of interference, a hologram is produced on the film. This hologram is a picture of the interference pattern. When laser light passes through the hologram, the result is a three-dimensional projection of the object from which the hologram was made. The image projected in this manner is sometimes called the hologram.

For electromagnetic waves of microwave frequencies (300 MHz to 300 GHz), the interference detector, instead of being a photographic film, is a microwave receiving antenna feeding a receiver in which the peak amplitude of the received signal is detected. This gives a voltage proportional to the magnitude of the vector sum of the wave reflected from the object and a reference signal derived directly from the source of the incident microwave irradiating the object. The microwave holographic system is illustrated in Fig. 9. When the antenna probe scans the plan of interference, the interference pattern could be drawn out with the voltage from the detector. When the voltage is amplified to feed a lamp or an oscilloscope, the interference pattern can be visually observed or photographed. The photograph is then a microwave hologram from which a three-dimensional visual image of the object can be projected using light. Microwave holography is discussed in more detail in the section "Microwave Holography Practice" in this article. Additional information is available in the articles "Optical Holography" and "Acoustical Holography" in this Volume.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Instrumentation

The high frequencies of microwaves do not allow the use of standard electronic circuits (which possess discrete inductance, capacitance, and resistance). At microwave frequencies, these quantities become distributed along the propagation path. Therefore, microwave circuit design and description are handled from a wave standpoint, rather than from the conduction of electrons through wires and components.

Hollow metal tubes (typically, rectangular in cross section) called waveguides are normally used to convey microwaves between two parts of a circuit. Sometimes the microwaves are conveyed, as a wave, along coaxial or parallel conductors (Ref 3).

Microwave energy is conveyed through a waveguide in electromagnetic patterns called modes. The patterns consist of repetitive distributions of the electrical and magnetic fields along the axis of the waveguide. A classic transverse electromagnetic (TEM) wave (Fig. 2) cannot propagate in a waveguide. Modes are identified as either transverse electric (TE) or transverse magnetic (TM), referring to whether the electric or the magnetic field is perpendicular to the waveguide axis, or direction of propagation. High-order modes produce complicated patterns, while lower-order modes produce relatively simple patterns. Practically all microwave nondestructive inspection (NDI) circuits use the lowest-order transverse electric mode ($TE_{1,0}$) (Ref 3).

The waveguide pattern for the $TE_{1,0}$ mode is shown in Fig. 10. The electric field is represented by the solid lines that are vertical in the waveguide. The intensity of the electric field varies sinusoidally along and across the waveguide, with a peak intensity in the middle of the waveguide and zero intensity at either sidewall (end view, Fig. 10). A uniform (constant) electric field exists in the B (height) direction, and a sinusoidal variation occurs every one-half wavelength along the length of the waveguide (front view, Fig. 10). A top view of the waveguide shows that the magnetic field is in the form of loops, spaced at intervals of one-half wavelength.

Fig. 10 Diagrams showing the lowest-order transverse electric mode ($TE_{1,0}$) in a waveguide

Each mode has a cutoff frequency below which it cannot be propagated down a given size of waveguide. For the commonly used $TE_{1,0}$ mode, the cutoff frequency is equal to the free-space velocity divided by twice the A dimension. This means that the A (width) dimension of the waveguide must be at least one-half the free-space wavelength for the $TE_{1,0}$ mode to propagate. Therefore, large waveguides imply low frequencies, and small ones imply high frequencies.

In the past, microwaves were mainly generated by special vacuum tubes called reflex klystrons. Klystrons generate microwave radiation by the synchronized acceleration and deceleration of electrons into bunches through a resonant cavity. The microwave radiation, frequently emitted through a mica window, is virtually monochromatic and phase coherent. Currently, microwaves are also generated over the range of 300 MHz to 300 GHz by solid-state or semiconducting devices. The advantage of these sources is that their outputs are single frequencies that are coherent. The frequency can also be varied over a wide range.

Microwave energy can be detected by devices such as special semiconductor diodes, bolometers (barretters), or thermistors. Phase-sensitive detectors can also be used. The diode, the most common detector used for nondestructive inspection, generates an electromotive force proportional to the microwave power level impinging on it. Another type of detector operates on the principle of converting the microwave power to heat (barretters and thermistors). For many years, the evapograph has been used to record an infrared image on a thermosensitive layer (Ref 9). The infrared radiation causes localized heating on the heat-sensitive layer so that the infrared image is recorded. In 1967, this same technique was reportedly being used to observe and record microwave electromagnetic wave interference patterns (Ref 10).

The experimental setup used is illustrated in Fig. 11. The microwave image is produced on the evaporated-oil membrane. The membrane is composed of a thin plastic sheet with two coatings. The coating that receives the microwave energy is a thin, vacuum-deposited layer of a low-conductivity metal such as bismuth or lead. This first layer absorbs a fraction (10 to 50%) of the incident microwave power pattern. This locally produced heat profile is transmitted through the plate sheet to the second layer on the other side of the plastic membrane. The second layer is a thin film of hexadecane ($C_{16}H_{34}$, with melting point of 20 °C, or 68 °F) or similar oil, which was deposited from a vapor and is held in the equilibrium state between condensation and reevaporation. The local heat caused by the incident microwave power causes reevaporation of the oil film. When the oil film is illuminated with light, as shown in Fig. 11, the oily film presents a uniform interference color. Under the microwave heating, the oil coating presents a microwave interference pattern seen as a colored visual image on the oil film. This colored visual image is also a microwave hologram. Good holograms have been obtained with a microwave energy of 80 mW/cm² (520 mW/in.²) in a few minutes (Ref 9).

Fig. 11 Experimental setup used for microwave thermography

A newer microwave liquid crystal display (MLCD) has made it possible to obtain real-time two-dimensional color display of microwaves having frequencies up to and above 300 GHz (Ref 10). Figure 12 illustrates the basic operating mechanism of the MLCD. The display consists of an absorbing layer with a typical resistivity of $5 \text{ k}\Omega/\text{cm}^2$ and a liquid crystal layer, both bonded to a flexible Mylar plastic sheet. The liquid crystal and resistive layers are 0.025 mm (0.001 in.) thick, while the Mylar support is 0.075 mm (0.003 in.) thick. Absorbed power as low as $1 \text{ mW}/\text{cm}^2$ ($6.5 \text{ mW}/\text{in.}^2$) will form display patterns. The absorbing layer converts electromagnetic energy into heat, and the liquid crystal layer selectively reflects light according to its temperature. The above mechanism produces two-dimensional color displays, electromagnetic field patterns, and interference field patterns with incident microwave radiation as low as $1 \text{ mW}/\text{cm}^2$ ($6.5 \text{ mW}/\text{in.}^2$).

Fig. 12 Schematic of a microwave liquid crystal display. A resistivity layer provides electromagnetic energy-to-heat conversion, a liquid crystal layer provides pattern definition, and a Mylar section provides support and protection from liquid crystal contamination.

Metal horns are usually used to radiate or pick up microwave beams. The directionality of the radiation pattern is a function of its aperture size in terms of number of wavelengths across the aperture. Horns with aperture dimensions of several wavelengths produce fairly good directionality. Most close-up NDI applications utilize even smaller horns, regardless of their larger beam spread.

Most of the microwave equipment used in the past for nondestructive inspection operated at frequencies in the vicinity of 10 GHz (X band). The free-space wavelength at 10 GHz is 30 mm (1.18 in.). A few applications have used frequencies as low as 1.0 GHz and as high as 100 GHz. The waveguides used for nondestructive inspection at 10 GHz are typically 25 mm (1 in.) wide and 13 mm ($\frac{1}{2}$ in.) high, and horn sizes range from $25 \times 25 \text{ mm}$ ($1 \times 1 \text{ in.}$) in aperture to 127 mm (5 in.) or more. The currently available solid-state sources from 1 to 300 GHz should make microwave NDE readily accomplished in this range.

One of the developing areas of great interest to those wanting to use microwave frequencies for NDE is that in solid-state and vacuum-tube sources and transmitters. The information in Fig. 13(a) and 13(b) gives the status of solid-state devices as of October 1983. No more recent information in summary form was found up to October 1988. The solid-state sources available in 1983 are listed by categories in Fig. 14. In Fig. 13(a) and 13(b), the numbers are the efficiencies (in percent) of power output divided by the input dc power. Efficiency values as high as 30% are obtained with an output of 20 W at 5 GHz using a GaAs, impact avalanche transit time (IMPATT) diode. The IMPATT diode has a negative resistance region,

which comes from the effects of phase shift introduced by the solid-state sources, that closely follows the $1/f$ and the $1/f^2$ slopes shown in Fig. 13(a) and 13(b). The transition from the $1/f$ to the $1/f^2$ slope falls between 50 and 60 GHz. The transition for silicon impact avalanche transit time (Si IMPATT) diodes is between 100 and 120 GHz. As shown in Fig. 13(b), in the 40 to 60 GHz region, the GaAs IMPATTs show higher power and efficiency, while the Si IMPATTs are produced with higher reliability and yield (Ref 11).

Fig. 13 Plots of continuous wave power versus frequency to obtain efficiency (in %) of various solid-state devices. (a) Efficiency data for InP and GaAs Gunn diodes; and GaAs and Si IMPATT diodes. Data obtained from Hughes, MA/COM, Raytheon, TRW, Varian. (b) Efficiency data for power and low noise FETs. Data obtained from Avantek, Hughes, MSC, Raytheon, TI. Source: Ref 11

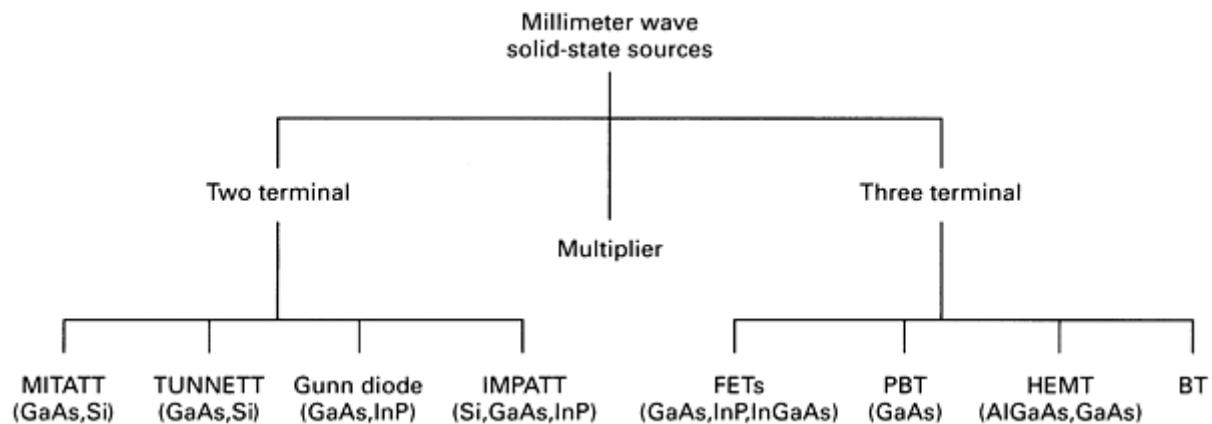

Fig. 14 Solid-state microwave sources by categories. HEMT, high electron-mobility transistor

The Gunn diode oscillators have better noise performance than the IMPATT's. They are used as local oscillators for receivers and as primary source where continuous-wave (CW) powers of up to 100 mW are required. Indium phosphide Gunn devices show higher power and efficiency than gallium arsenide Gunn devices.

The performance in power and low noise for GaAs field-effect transistors (FETs) is shown in Fig. 13(b). Again, the number by the data points is the efficiency associated with that power. Higher powers can and will be achieved by using optimized inpackage matching circuitry.

The noise figure of the low-noise GaAs-FET devices ranges from 14 to 7 dB over the frequency range of 3.5 to 60 GHz. Peak powers 3 to 6 dB higher have been obtained from power GaAs FETs, while 5 to 10 dB increases in power are possible with IMPATTs. The power combining of IMPATT devices was also demonstrated successfully by 1983. Peak powers of several hundred watts were obtained in the X band (8 to 12.5 GHz, as shown in Table 2). Broadband CW combiners in the U band (46 to 56 GHz) have been reported that deliver several watts of power (Ref 11).

The state-of-the-art performance for various microwave vacuum tubes is shown in Fig. 15(a) and 15(b). Again, the numbers by the data points are the efficiency in percent. The parenthetical letter represents the company that supplied the data and developed the device. The devices represented in Fig. 15(a) are the traveling wave tube (TWT), the helix TWT, the backward wave oscillator (BWO) tube, the gyrotron, the orotron, the extended interaction amplifier (EIA), and the extended interaction oscillator (EIO). The devices in Fig. 15(b) include the crossed-field amplifier (CFA), TWT, klystron, and gyrotron. Power levels from these devices cover the range of 1 to 3 kW over the frequency range of 5 to 270 GHz. The devices in Fig. 15(b) can supply almost 5 MW peak power at 1 GHz and 1.5 kW peak power at 300 GHz (Ref 11).

Fig. 15 Plots of power versus frequency to obtain efficiency (in %) of various microwave vacuum tubes. (a) Continuous-wave power. (b) Peak power. Source: Ref 12

Impressive power and voltage gain values are also available. Over 50 dB of gain is available in a 93 to 95 GHz TWT at an average output level of 50 W (Ref 11). The most impressive power achievements have been made with the gyrotrons (Ref 11). Many researchers are examining the cyclotron resonance principle to build amplifiers (Ref 11). Recent developments in the helix plane circuit promise to provide ultralow-cost, high-average-power TWTs (Ref 11). Increased activity from 1983 through 1987 by tube designers has resulted in TWTs exceeding 1 kW continuous wave and 100 W continuous wave at 100 GHz (Ref 12). Gyrotrons in 1987 could generate close to 200 kW of continuous wave at 140 GHz (Ref 12). Although these large powers are not usually used in NDE, developments such as these benefit the whole field of

microwave NDE. The sizes of these vacuum-tube amplifiers prevent their use for most NDE applications. All of the continuing developments in solid-state sources and transmitters are usable for microwave NDE.

In the early development of microwaves, systems consisted of a large number of devices performing specific single functions. The system engineer became a master of optimizing interfaces and writing device specifications with adequate margin to overcome interactions. This led to reduced overall system performance. The need for improvement led to the supercomponent concept. The microwave supercomponent was thought to be the answer to the problem of the complex and costly device interfaces. The supercomponent was defined as a stand-alone device that contains multiple functions of a generic nature (sources, amplifiers, mixers, and so on) and support functions such as switches, isolators, filters, attenuators, couplers, control circuits, and supply circuits, all of which are tightly packaged and combined to meet a single subsystem specification. One of the earliest microwave supercomponents was the combination of a TWT with a solid-state power supply in mid-1960. This combination eliminated the need to adjust this interface after the device left the factory (Ref 13).

The concept of supercomponents is best utilized when the system designer works actively with the manufacturer of the supercomponent. The designer should keep in mind that he may be dealing with a supercomponent engineer who is more skilled in individual devices than in system work. Therefore, simply writing a specification and submitting it will often not produce the desired results. Good communication is necessary between the system designer and the supercomponent engineer to ensure that both understand each other's needs so that they can jointly arrive at the best combination of performance and cost. Most companies that are truly dedicated to supplying supercomponents are continuously training engineers who have the necessary broad background to work successfully at producing supercomponents.

The supercomponent or subsystem concept has and is maturing rapidly. It has progressed beyond a risky, expensive strategy to one that offers solid ground for improvement of microwave NDE equipment in terms of size, weight, cost performance, reliability, and maintainability. For some NDE applications, the use of supercomponents may mean the difference between successful and mediocre operation. Other information on supercomponents can be found in Ref 14 and 15.

Microwave instrumentation for nondestructive inspection can be set up for reflectometry through transmission and scattering techniques. Usually, the single-frequency design is used, but swept-frequency systems have been constructed for certain applications.

Some applications require the use of through transmission or wave-scattering systems involving a separate transmitter and receiver. As with ultrasonics, through transmission is performed by placing the transmitter on one side of the material and the receiver on the opposite side (see the article "Ultrasonic Inspection" in this Volume). Scattering setups orient the receiver horn at some oblique angle to the transmitted beam. The receiver is sometimes placed against a side surface (for example, the side of a block) so that its direction is oriented 90° with respect to the polarization of the transmitted beam. If measurable scattering sites exist in the material, they can frequently be detected by scanning the obliquely oriented transmitter and receiver.

Microwave flaw detectors, based on swept-frequency heterodyning principles, can be used to measure flaw depth. This type of flaw detector transmits a signal whose frequency sweeps from a maximum to a minimum value at a specified repetition rate. A discontinuity in the material under test reflects a portion of this energy back to the reflectometer. The reflected energy interferes with the transmitted energy by a process known as heterodyning. The heterodyning action produces a beat frequency equal to the instantaneous difference between the frequencies of the transmitted and delayed received waves. This difference in frequency, caused by timing differences between the waves, is proportional to the distance to the flaw.

Swept-frequency approaches are also used for microwave thickness gaging and density determinations. The frequency that yields maximum power reflection is related to either density or thickness.

The pulse-echo system, as used in ultrasonic and many radar designs, cannot be applied to microwave flaw detection or thickness gaging, because the wave velocities are too great and the distances too short. The necessary electronic resolving powers, well into the picosecond (10^{-12} s) range, are not available for accurately measuring flaw depth. This is one major reason why frequency-modulated and standing wave designs are used. Another potential problem with pulse-echo resolving methods is that the frequency of such short-duration pulses would be too high for desirable propagation behavior in nonmetallic materials.

Microwave instruments for nondestructive inspection based on Doppler techniques are used for industrial in-motion applications, particularly in Europe. The Doppler principle is based on a frequency shift in a wave that is reflected from a moving target. The amount of frequency shift is proportional to the velocity of the target.

Thickness Gaging

Thickness measurements can be made with microwave techniques on both metallic and nonmetallic materials. For metals, two reflected waves are used, one from each side of the spectrum, as shown in Fig. 16. The measurement is made using the standing wave technique. When the wave is incident on a metal (electrically conductive), most of the wave is reflected; only a small amount is transmitted (refracted). The transmitted wave is highly attenuated in the metal within the first skin depth. For nonmetallic materials (electrically nonconductive), the reflected wave is much smaller than the incident wave, so that any standing wave that does develop does not have a large amplitude.

Fig. 16 Diagram of a reflectometer for determining metal thickness using microwave techniques. Arms A and B differ in length by an integral number of half-wavelengths for detector output null.

As shown in Fig. 17, the distance between the minima of the standing wave is equal to one-half wavelength; that is, when a detector antenna moves a distance of one-half wavelength along a standing wave, the amplitude changes. Therefore, with a reflectometer (shown schematically in Fig. 16), the thickness can be measured by forming a standing wave in the detector arm of a hybrid tee, a standard microwave device. The wave from the generator is split by the hybrid tee into two waves of equal amplitude. Each of these waves travels down separate waveguides, is reflected from the metal surface, and travels back through the waveguide to the hybrid tee. The hybrid tee then recombines the two reflected waves, directing them into the detector. One arm of the system has been changed in length to allow the sample to be inserted. When the difference between the respective roundtrip distances traveled by the two waves is one-half wavelength, the two waves interfere destructively, and a minimal voltage is read on the detector. The frequency of the generator can be adjusted so that a minimal voltage is obtained for any given thickness of specimen. The specimen thickness can then be calculated because the wavelength is known and the distance to one side of the sample is measured or calibrated.

Fig. 17 Response of a detector moved along the path of interfering waves for large amplitude difference and amplitudes nearly equal

The reflectometer shown in Fig. 16 can also be adapted to measure the thickness of an electrically nonconductive material if one side is coated with a thin film of a conductive material. The difference between the two arm lengths would then be a distance equivalent to twice the thickness of the nonconductive material. If the velocity of the wave in the material and the frequency are known, the thickness can be computed.

If the dielectric material whose thickness is being measured also has absorption, the reflected wave is reduced in amplitude such that a smaller-amplitude standing wave is obtained. The smaller-amplitude standing wave decreased the accuracy of the measurements of the position of the minimum. A comparison of the standing waves for low and high absorption is given in Fig. 18.

Fig. 18 Relation of the amplitude of reflected microwaves and the ratio of material thickness to wavelength.
Source: Ref 3

The range over which the simple thickness meter shown in Fig. 16 can be used unambiguously is approximately one-fourth of the wavelength of the microwaves in the material being measured. If the thickness varies more than one-fourth wavelength, ambiguous results will be obtained. The nominal thickness of most materials can usually be estimated or is known within manufacturing tolerances to within plus or minus one-eighth wavelength, so that the ambiguity can be resolved.

A diagram of another simple microwave thickness gage is shown in Fig. 19. This single-side gage has a direct waveguide to the testpiece, which must be backed by a thin metallic coating. The standing wave that is set up in the waveguide is detected by a probe in the waveguide itself. If the frequency were fixed and the probe were movable, it would trace out a curve similar to those shown in Fig. 18. In practice, however, the probe is fixed and the frequency is swept. A material of known thickness is inserted, and the center frequency and frequency sweep width for the microwave generator are adjusted until a single one-half wavelength standing wave is observed on the oscilloscope. The sawtooth output from the microwave generator is proportional to the instantaneous frequency shift, so that horizontal position on the oscilloscope display is proportional to frequency.

Fig. 19 Diagram of a single-side microwave thickness gage. See text for discussion.

Also observed on the oscilloscope is the output signal from the frequency meter, which occurs as a sharp peak when the frequency of the oscillator passes through the frequency to which the meter is set. This absorption peak appears superimposed on the standing wave as a pulse (Fig. 20). When the equipment is properly set, the peak is not seen except at the null of the standing wave, as shown in Fig. 20(a). When the material of known thickness is replaced by one that is thinner, the peak appears on the standing wave, as shown in Fig. 20(b). When the material is greater than the known thickness, the display is as shown in Fig. 20(c). By observing the movement of the peak with respect to the standing wave, the material can be calibrated in thickness relative to the known thickness.

Fig. 20 Scope display and standing wave relationship for a single-sided microwave thickness gage. See also Fig. 19.

The use of a microwave thickness gage in a variety of production operations has demonstrated its suitability for nondestructive inspection and quality control of dielectric components. The data for the graph in Fig. 21(a) was obtained from polyethylene coating on common aluminum foil wrapping material. Measurements were made on coatings of thicknesses of 25, 38, 44, and 51 μm (0.0010, 0.0015, 0.00175, and 0.0020 in.). The data for Fig. 21(b) were obtained from a fiberglass-reinforcement resin plate used for fabricating boat hulls. The data for Fig. 21(c) were obtained from

aluminum-backed thick polyurethane foam used as a thermal insulation blanket for space vehicles. All the data in Fig. 21 were taken with a simple amplitude-sensitive reflectometer operating at 9.4 GHz. An antenna (a 25 mm, or 1 in., square horn) was used to obtain the data in Fig. 21(b) and 21(c). The data in Fig. 21(a) were obtained with an antenna known as a short-field probe (Ref 16).

Fig. 21 Readings of an amplitude-sensitive reflectometer as a function of film thickness for (a) polyethylene, (b) fiberglass plate, and (c) polyurethane

Detection of Discontinuities

Discontinuities such as cracks, voids, delaminations, separations, and inclusions predominantly reflect or scatter electromagnetic waves. Wherever these types of flaws occur, there is a more or less sharp boundary between two materials having markedly different velocities for electromagnetic waves. At these boundaries, which are usually thin compared to the wavelength of electromagnetic radiation being used, the electromagnetic wave is reflected, refracted, or scattered. The reflected or scattered radiation has appreciable amplitude only if the minimum dimension of the discontinuity is larger than about one-half the wavelength of the incident radiation in the material being tested.

Porosity and regions of defective material such as departures from nominal composition do not produce strong reflection or scattering. They do influence the attenuation and the velocity of the electromagnetic wave. When there is absorption, the transmitted wave has an exponential decay with respect to the distance traveled.

Continuous-wave reflectometers are those in which the amplitude of the standing wave is measured by a detector in a combination send-receive, slotted microwave coaxial transmission line. They can be used to detect discontinuities in such components as glass-filament solid-rocket motor chambers using a frequency of 12.4 to 18.0 GHz (Ref 17).

Reflections from internal discontinuities change the amplitude of the standing wave measured by the detector and give a change in the output. When the material is scanned and the reflectometer signal is recorded by intensity modulating a pen recorder, the discontinuities can be observed as light or dark areas. This type of C-scan, when connected with level-sensing equipment, can be used to record only variations above or below a certain level, thus showing only the discontinuities. A diagram of a continuous-wave microwave system that incorporates a slotted coaxial transmission line is shown in Fig. 22.

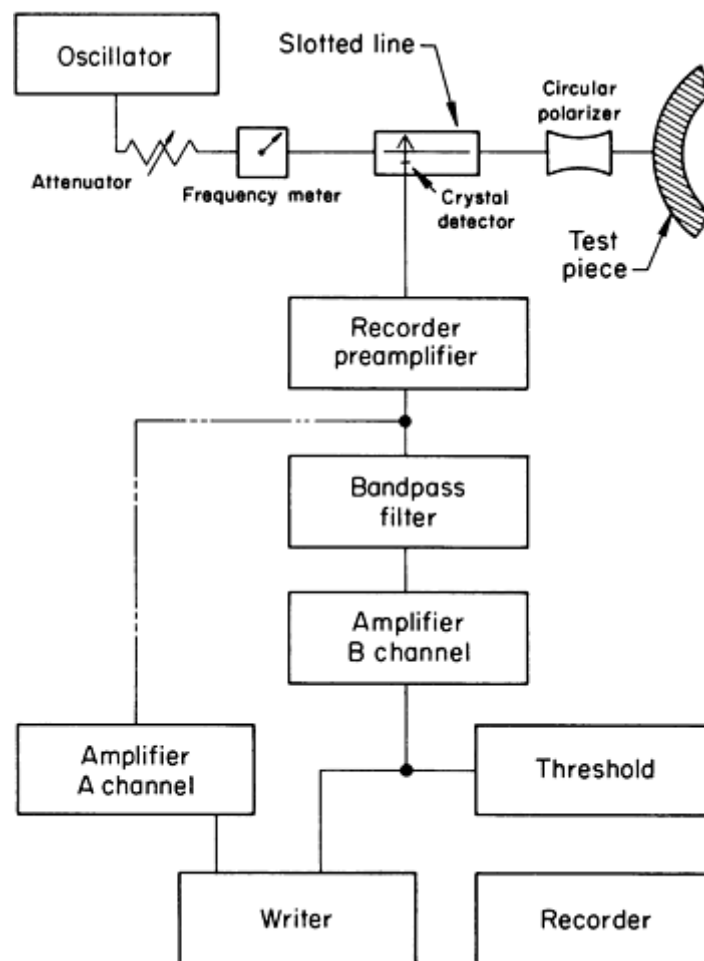

Fig. 22 Diagram of a continuous-wave microwave system used to detect discontinuities

The detection of voids depends on a change in the wave reflected into the antenna resulting from the added reflection from the discontinuity caused by the void. The system shown in Fig. 22 can be modified for these measurements by substituting a directional coupler for the slotted line. This coupler allows the output signal to be proportional only to the amplitude of the reflected signal. The reflected signal from components such as a rocket-motor chamber consists of a large reflection from the outer surface of the case plus smaller ones from the glass insulation and the insulation/propellant interfaces. At any void or unbonded area, an additional reflection occurs that increases the overall reflection into the antenna. A standing wave can be set up by the reflection in the material so that, at some frequencies, complete cancellation occurs for reflections that are one-fourth wavelength apart. Because of this possibility, frequencies should be carefully chosen. Several frequencies are used to ensure that no cancellation will occur.

In the frequency-modulated reflectometer, a linear sweep is made of the entire frequency range of two generators: 1 to 2 GHz and 12.4 to 18 GHz (roughly the L band and the K_u band, respectively, per Table 2). A separate system is used for each band; each band is swept at a rate of 40 sweeps per second. Figure 23(a) shows the basic components of the frequency-modulated reflectometer (Ref 18). A graph of the signal at the detector as a function of time is shown in Fig. 23(b). The transmitted signal from the antenna is reflected back into the antenna and the detector from targets 1 and 2. The reflected signals also vary in frequency, as do the transmitted signals, but at the detector they are

displaced in time, as shown by the dashed lines in Fig. 23(b). Therefore, at any instant of time, there are three signals at the detector: the first from the transmitted wave, the second from target 1, and the third from target 2.

Fig. 23 Setup and signal response of a frequency-modulated microwave reflectometer. (a) Schematic showing components of a frequency-modulated microwave reflectometer. (b) Paths of transmitted and reflected signals at detector in relation to frequency and time

Each of these signals is of a different frequency, corresponding to the different propagation times involved. The frequency difference, Δf , is equal to the rate of sweep (in hertz) times the delay (in seconds). The phase of the reflected signal, ϕ , relative to the reference (transmitted) signal is $40\pi f/c$. Both the frequency and the phase of the reflected signals are proportional to the distance to the respective reflectors. Small changes in the position of the reflector cause relatively large changes in phase, which in turn cause large changes in the shape of the signal obtained at the crystal detector. As the reflector moves through a distance equal to phase shifts of 0° , 90° , 180° , and 270° , the output of the detector, $e(\Delta f)$, is a function of the frequency difference and changes in shape as shown by the curves in Fig. 24.

Fig. 24 Theoretical indications of reflections, $e(\Delta f)$, produced by a frequency-modulated microwave reflectometer during phase shifts of 0° , 90° , 180° , and 270° as functions of frequency shift of the modulation Δf

The arrangement of equipment for a frequency-modulated microwave reflectometer using L-band frequencies is shown schematically in Fig. 25. In this setup, separate antennas are used for sending and receiving. The detector senses both the transmitted signal and the reflected signals. These are mixed in the detector to produce a difference frequency equal to the reflected wave, f , minus the reference frequency, f_0 , generated by the swept oscillator. A separate beat frequency is developed for each reflected signal. For two discrete reflectors, the output signal of the crystal detector consists of two frequencies, one for each target.

Fig. 25 Schematic of components of a frequency-modulated microwave reflectometer using L-band frequencies. Dimensions given in inches. Source: Ref 18

To determine the number of reflected objects and their locations, the signal from the detector passes through a cross-correlation spectrum analyzer. The readout of the signal processor is a plot of the amplitude of the detector signal as a function of frequency. To accomplish this, the signal is cut into many segments of equal duration. If the spacing of these segments corresponds to one of the frequency components of the signal, an output results. The spacing of these segments is varied by the long, saw-tooth voltage, A, so that all the possible frequencies in the signal are swept. Therefore, the output contains a voltage for each of the frequency components of the signal. Each component is displayed as a dot on an oscilloscope. The vertical displacement of this dot is proportional to the amplitude reached by the integrator for that particular frequency in the integration time. The K-band equipment is similar to that shown in Fig. 25 for the L band except that a waveguide is used rather than a coaxial cable.

Frequency-modulated reflectometers typically operate in the range of frequency bands given in Table 3. Sources are now available to frequencies beyond 200 GHz. These would produce resolution to 1 mm (0.04 in.). Application of these higher frequencies to inspection and measurement has been limited by the relatively high price of the microwave sources.

Table 3 Frequency bands of frequency-modulated reflectometers

Frequency, GHz	Type	Resolution in air		Resolution in plastics ^(a)	
		mm	in.	mm	in.
0.5-1.0	Coaxial cable	300	12	150	5.9
1.0-2.0	Coaxial cable	150	5.9	75	3.0
2.0-4.0	Coaxial cable	75	3.0	37	1.5
4.0-8.0	Coaxial cable	37	1.5	18	0.71
8.0-12.4	Waveguide	34	1.3	17	0.67
12.4-18.0	Waveguide	28	1.1	14	0.55
18.0-26.0	Waveguide	19	0.75	10	0.39

26.0-40.0	Waveguide	11	0.43	5.5	0.22
-----------	-----------	----	------	-----	------

(a) This assumes a refractive index of 2.

Applications have been used in penetrating rock, soil, and thick solid propellant samples in the low bands; concrete in the medium bands; and plastics and composite materials such as filament-wound glass, Kevlar, and honeycomb in the higher bands.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Microwave Detection of Surface Cracks In Metals

When an electromagnetic wave is incident on a metallic surface that has slits or cracks, the metallic surface reradiates (reflects) a signal because of induced current. Under the proper conditions, the reflected wave combines with the incident wave to produce a standing wave. The reflection from a surface without a crack is different from that surface with a crack and depends on the direction of the incident wave polarization relative to the crack. When the crack is long and narrow and the electric field is perpendicular to the length of the crack, the reflected wave (and therefore any standing wave) is affected by the presence of the crack. The amount of change is used to determine the size and depth of the crack.

Standing Wave System. The most sensitive means of detecting the small crack-related changes in the standing wave is to use the standing wave in a resonant cavity (Ref 19). Such a resonant system is also sensitive to variables other than surface cracks. However, a nonresonant standing wave system can be used. One such system is shown in Fig. 26. The detection head with the test specimen forming one end of the system is shown in Fig. 26(a). The excitation is fed into two slots, while the receiver is fed from two other slots. A diagram of the microwave circuit is shown in Fig. 26(b). The test specimen is mounted so that it can be rotated.

Fig. 26 "Nonresonant" standing-wave system that can be used for detecting cracks in metal parts. Dimensions given in inches. Source: Ref 19

In the system described above and shown in Fig. 26, the test surface acts as a short for one end of the waveguide section. In order that the only waves present in the waveguide section are those incident on and reflected from the test specimen, the opposite end of the waveguide section is made nonreflective by using a matching horn and absorbing material. The exciter slots are so arranged that the cylindrical transverse electric ($TE_{1,1}$) standing wave is set up by the reflections from a flat (crack-free) specimen.

The goal of the design is to have none of the transverse magnetic ($TM_{1,1}$ or $TM_{2,1}$) modes excited when the test specimen is crack free. The presence of a crack in the surface of the test specimen disturbs the flow of current in the end required by the transverse electric mode so that the higher-order transverse magnetic modes will be excited. Because the higher modes are specifically caused by the currents due to the crack in the end plate, when the end plate is rotated these modes will also rotate past the receiver slots. With the $TM_{1,1}$ mode, a receiver output shows two peaks for a 360° rotation; with the $TM_{2,1}$ mode, four peaks are obtained from a full rotation. A crack at the exact center of the test surface does not produce a signal.

A suitable operating frequency was found by sweeping the frequency while the specimen, with a groove 20.3 mm (0.8 in.) long and 0.76 mm (0.030 in.) deep, was being rotated. The correct value is indicated by a zero-dc level and a signal response to rotation of the groove that established the reference signal level. The microwave circuits were then tuned to this frequency. For the groove that was 20.3 mm (0.8 in.) long and 0.25 mm (0.010 in.) deep, a frequency of 15.965 GHz was used.

The influence of burrs was studied with a burr 0.0089 mm (0.00035 in.) high on a groove 0.08 mm (0.003 in.) deep. The average signal with the burr had a peak-to-peak value of 15 μ V, while the average signal without the burr was 6 μ V.

Variations of signal outputs from fatigue cracks are shown in Fig. 27. The fatigue cracks were much smaller than the notches used for calibration, being approximately 3.2 mm (0.125 in.) long and 1.25 μ m (50 μ in.) wide. The fourfold variation shown in Fig. 27(a) was caused by the asymmetry of the interfaces between the sample holder and the sample. The presence of one crack gave the results shown in Fig. 27(b). When a second crack was added, the results in Fig. 27(c) show that the two outside variations were increased in value. The peaks shown in Fig. 27(c) were probably caused by a mixture of the two TM modes rather than higher transverse magnetic modes.

Fig. 27 Signal outputs from the standing wave crack detection system in Fig. 26 for side-notched specimens. (a) Crack-free specimen. (b) Fatigue crack in one specimen. (c) Fatigue crack in two specimens. The rotating specimen holder was designed so that two specimens could be inspected at the same time.

Chemical Composition of Dielectric Materials

In many cases, chemical changes in dielectric materials, such as plastics, can be detected or even continuously monitored by microwaves, and the results of chemical changes can be measured. The criterion is that the chemical change must affect the dielectric properties (dielectric constant and/or loss tangent) of the material for electromagnetic frequencies in the microwave region. Some of the chemical or molecular-level applications that have been successfully investigated include polymerization, degree of cure, oxidation, esterification, distillation, vulcanization, evaporation, and titration (end points).

Microwave techniques have been used to measure specific gravity, homogeneity during blending, and vibration (or displacement). Several investigators have measured the glass-to-resin ratio of some aerospace composites (Ref 17). Studies such as these can be made with either a through transmission system or a reflectometer because the changes in chemical composition cause a change in the velocity of propagation. The changes in propagation velocity change the amount and angle of the reflected and transmitted energy.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Moisture Analysis Using Microwaves

The free (unbound) moisture content of many dielectric materials can be accurately measured with microwave techniques. Microwaves are strongly absorbed and scattered by water molecules because water exhibits a broadband rotational relaxation in the microwave region. Because many completely dry host materials are transparent in the same frequency range, a moisture-measuring technique is possible. This technique has found widespread use on both a continuous-process and laboratory-sample basis, especially for plastic and ceramic materials. Moisture measurement of polyethylene powder using microwaves has been done by through-transmission techniques at a frequency of 9.4 GHz (Ref 16). Measurements similar to those for the plastic powders can also be obtained for solid shapes, slurries, and liquids. The technique (as described here) is not applicable for gases.

Because water is a polar molecule, its dielectric properties are a function of temperature. Therefore, if substantial material temperature changes occur, compensation is necessary in the instrument calibration. For example, a decrease in temperature of 12 °C (22 °F) will normally cause an error of $\pm 0.2\%$ in the moisture readout. The effect is more pronounced in materials having a high moisture content. Fortunately, the product temperature of most plastic-process lines is kept reasonably constant at a given location. The temperature effect is even less of a problem with plastics because they are relatively dry at the point of measurement.

Microwave Measurement of Material Anisotropy

The directionally dependent properties of some materials can be measured by the use of linearly polarized microwaves. Measurements of anisotropy, on both the molecular scale and macroscopic scale, are made by rotating the sensing head relative to the material under test and observing the signal as a function of polar angle. Certain linearly oriented polymers can be used as examples of molecular-level measurements; wood and fiberglass-resin structures are examples of the

macroscopic level. The direction of glass fibers can be readily determined. The direction of the fibers in paper can also be detected with linearly polarized microwaves and antenna rotation.

Fiber-matrix composites have also been measured for directionality. One instance was a multiple-ply composite having a fiberglass-resin matrix and unidirectional boron filaments. The boron filaments, approximately 0.13 mm (0.005 in.) in diameter, contained a tungsten-fiber center (0.013 mm, or 0.0005 in., in diameter) onto which the boron had been deposited. Being electrically conductive, the overall composite acted on the microwaves very much like a diffraction grating. Alignment shifts of only a few degrees were detected easily by monitoring either the reflected or the transmitted microwave component. When the boron filaments were perpendicular with respect to the polarization of the microwave beam (electric field vector), a maximum amount of energy was transmitted (or a minimum amount of energy reflected). When the boron filaments and the polarization were parallel, the reverse was true. By continuously rotating the sample, a sinusoidal pattern of filament direction versus signal amplitude was obtained.

Microwave Inspection

Stress-Corrosion Microwave Measurements

Materials such as aluminum, magnesium, and titanium are subject to stress-corrosion cracking or fatigue when they are under stress in a corrosion-producing environment. Cracks and fatigue can appear at stress values much less than the normal yield in a corroded material. Early fatigue may occur at less than rated load in a structure that has corroded materials. For reliable structures that may be constructed from corroded materials or from materials corroded after construction, it is necessary to have a method for detecting corrosion-prone and corroded areas of materials.

Several mechanisms have been suggested to explain stress-corrosion cracking and fatigue (Ref 20). Three of them are electromechanical, mechanical, and surface energy. Similarities among these mechanisms suggest an approach to the detection of corroded or corrosion-prone areas of the above materials.

All of these theories suggest that corrosion and the subsequent cracking begin at crystal lattice imperfections. The imperfections considered are dislocations, vacancies, and impurities. It was assumed that if the existence of these imperfections could be detected by a nondestructive method, then that method could be used to evaluate the stress-corrosion susceptibility of materials and structures so as to eliminate corrosion-prone or corroded materials.

The correlation between electrical resistivity and dislocation density has been discussed by many authors (Ref 21, 22, 23, 24). It has also been found that the concentration of impurities varies the electrical resistivity of a material. It is further mentioned that there is a difference in the surface resistivity between dislocations caused by vacancies and impurities. Surface resistivity can be measured with high-frequency electromagnetic waves because they penetrate to a depth of only 10 to 0.1 μm (400 to 4 $\mu\text{in.}$) or less into the surface and because the wave reflected from the surface has its phase changed from that of the incident wave by the action of the surface impedance, which includes the resistance of the material. Any protective coating such as paint or oxides on the surface of the metal will allow most of the energy in the electromagnetic wave to pass through them and to be reflected from the conductive surface, if the frequency used is in the microwave region or below. However, the higher the frequency, the greater will be the magnitude of the change in the surface impedance caused by imperfections. Therefore, although frequencies from microwaves through the ultraviolet can be used, less interferences from surface coatings coupled with a relatively high sensitivity will be found in the microwave region from 1 to 100 GHz.

Therefore, a measurement of the microwave surface impedance by means of a comparison of the reflected wave with the incident wave should yield a measure of the imperfection density. A microwave system for measuring the surface impedance of a metal can be adapted and calibrated for the determination of the corrosion-prone areas in materials. Measurements of resistivity have been made on many metals and alloys, including aluminum, showing the resistivity to be dependent on the dislocation density (Ref 21, 22, 23, 24). Also, a difference in resistivity of dislocations related to vacancies and impurities has been measured (Ref 21, 22, 23, 24). The imperfection densities have been determined with an electron microscope, and good agreement has been obtained between the experimental and theoretical values for the resistivity of dislocations (Ref 21, 22, 23, 24). For aluminum, the average dislocation resistance was found to be $7 \times 10^{-19} D \cdot \Omega \cdot \text{cm}^3$, where D is the dislocation density of $D \cdot \text{cm}^{-2}$ (Ref 21, 22, 23, 24). The vacancy resistivity was also found to

be $1.4 \times 10^{-6} \Omega \cdot \text{cm}$ per atomic percent vacancies (Ref 21, 22, 23, 24). Investigators have made measurements on surface properties of metals, such as surface impedance, skin depth, and conductivity (Ref 25). Most of these investigations have been conducted to determine the electrical properties of metals rather than to measure the density of their imperfections. One investigation was made using microwaves to study the development of early surface damage during the fatigue of high-strength aluminum alloys (Ref 25). The microwave measurements were related to the fatigue period for the test parameters rather than to the material parameters, such as the density of imperfections.

A vector network analyzer can be used to obtain magnitude and phase information of the reflected wave. The interval processing capabilities of present-day vector network analyzers provide the data in a variety of formats.

The basic concepts of the microwave method of measuring surface impedance are shown in Fig. 28. The output from a microwave generator is fed through a circulator and through a coupling device such as an antenna to provide an electromagnetic wave incident upon the surface whose impedance is to be determined.

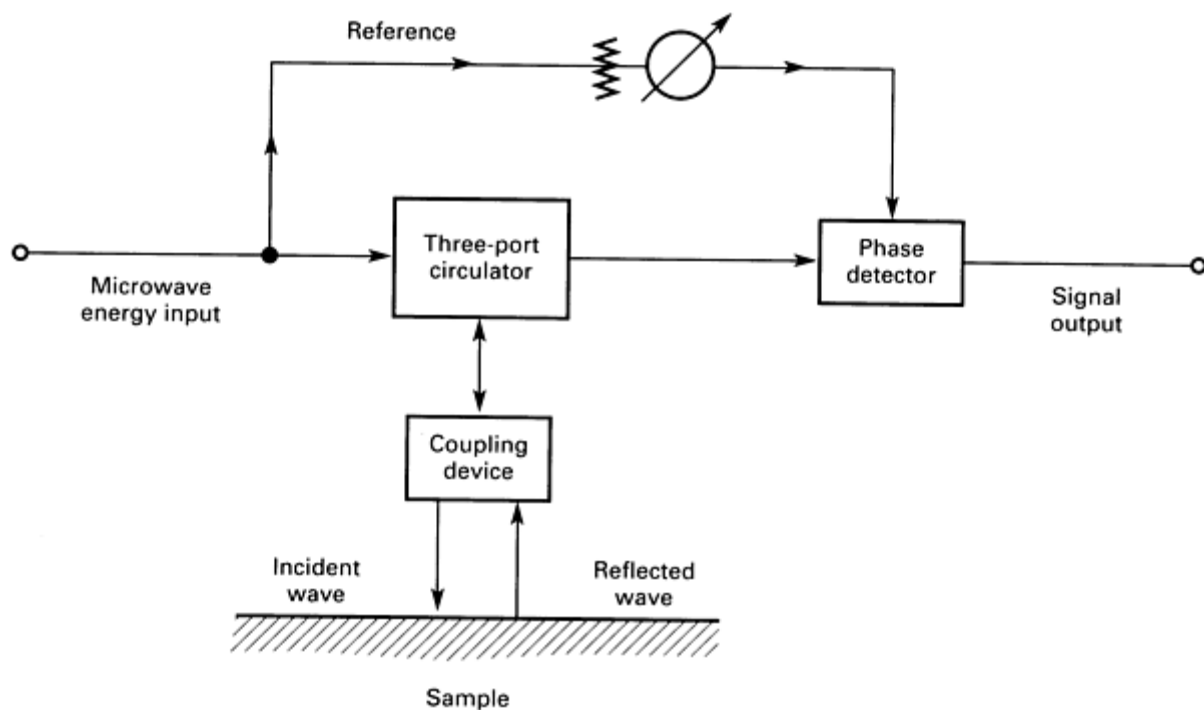

Fig. 28 Basic microwave surface impedance measurement technique

A small part of the incident wave is transmitted into the surface of the material, and the remainder is reflected. Therefore, the reflected wave contains the information about the impedance of the surface. If the reflected wave is compared in both amplitude and phase with a reference signal taken directly from the microwave generator, the output of this amplitude-sensitive phase detector will be information about the surface impedance of the material. The surface impedance of a material having a complex permeability μ , conductivity σ , and permittivity ϵ is, at the angular frequency ω , given in Eq 1 (Ref 2). Because all three terms can be complex at microwave frequencies, the impedance is complex, having both real and imaginary parts.

A highly sensitive but slowly scanning method for measuring surface impedance is shown in Fig. 29. The microwave energy delivered to the system is generated by the source. Frequency control is provided by a dc voltage, giving a convenient method of sweeping the frequency. The precise frequency is then determined by a frequency counter or wavemeter, and a calibrated attenuator is used to control the amount of power passing down the waveguide to the cavity. Isolation between the system and the source can be obtained by the use of a ferrite isolator, which allows power to pass through the isolator in one direction only. A ferrite three-port circulator is an ideal device for this type of measurement. It is a wide absorption cavity and provides isolation between the detector and the klystron.

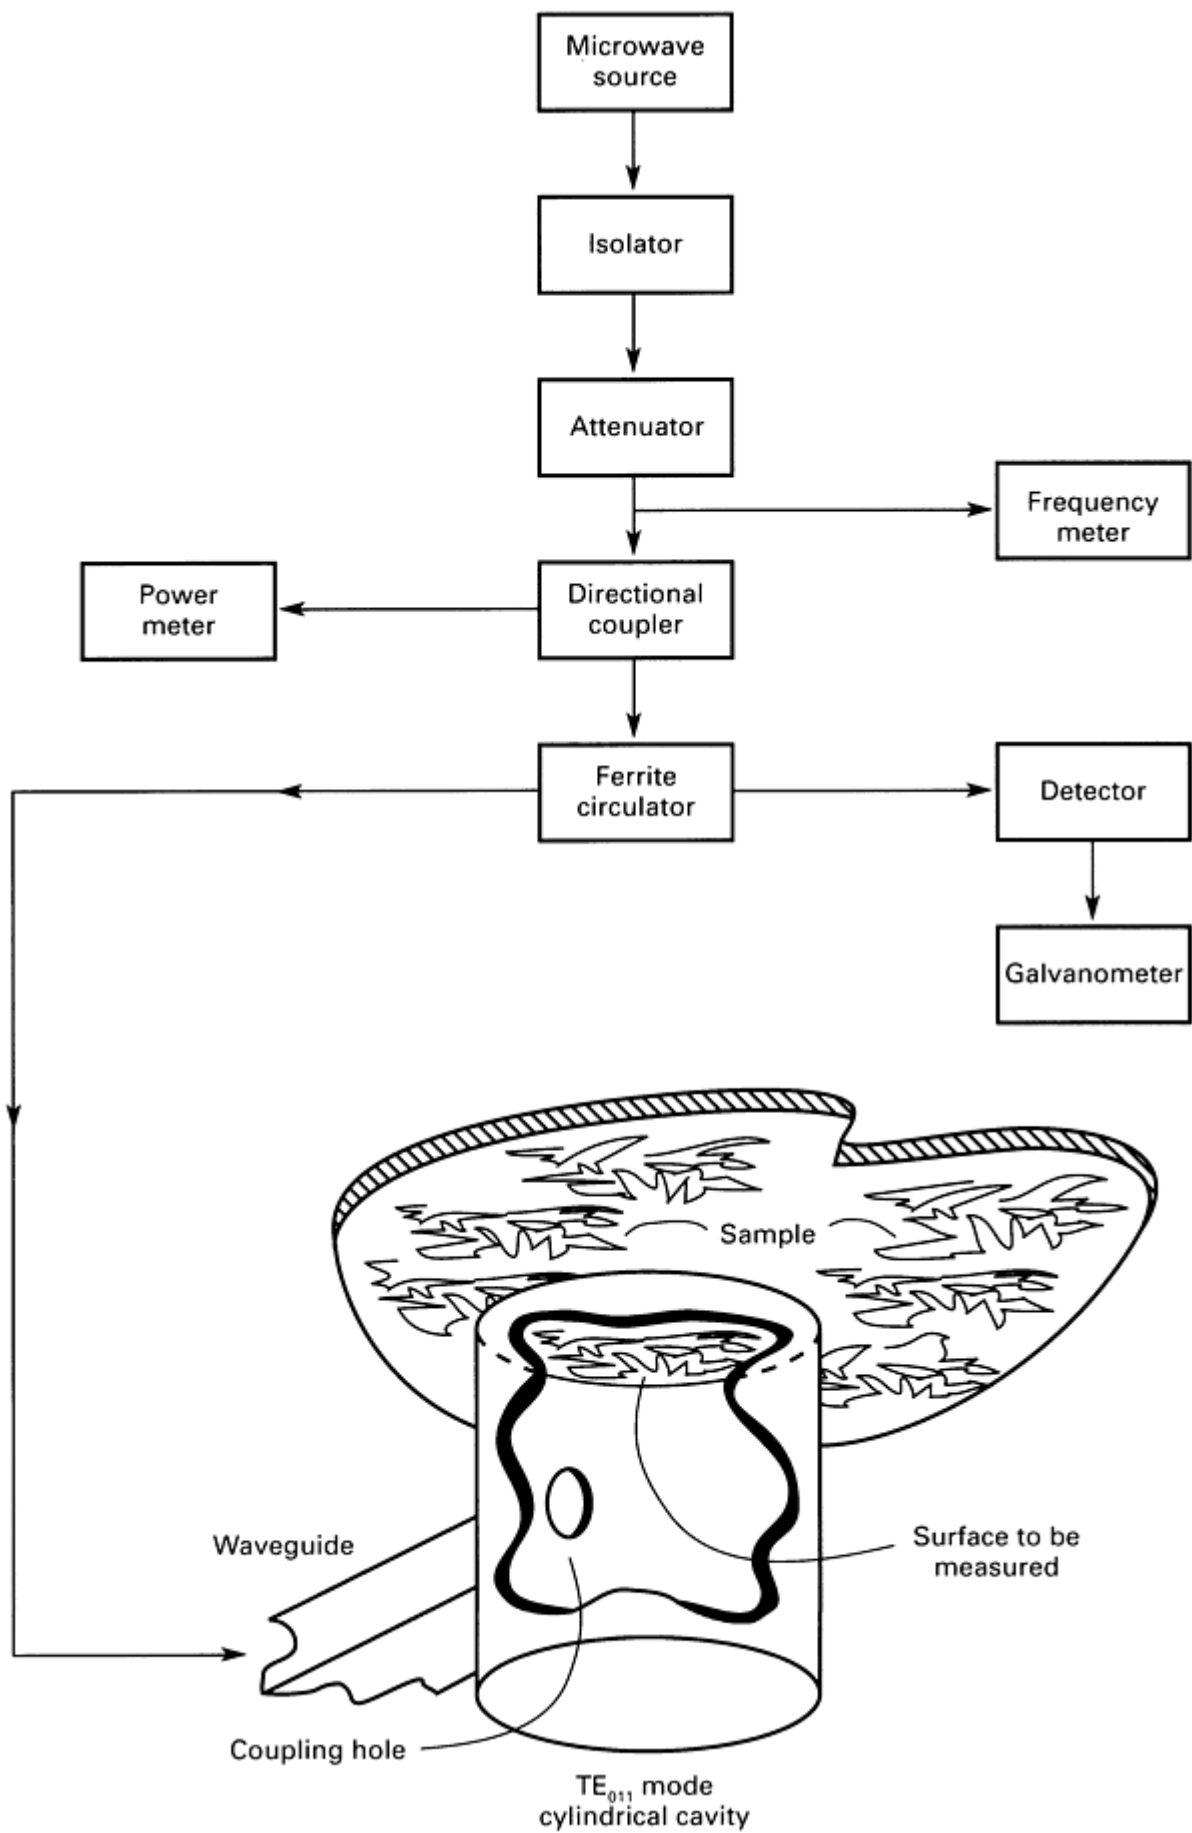

Fig. 29 Typical microwave measurement circuit

The cavity shown in the simplified circuit in Fig. 29 is an absorption-type cavity. Its distinguishing feature is that only one port is provided for coupling energy into and out of the cavity. Another type of cavity that has obtained prominence is the transmission cavity, in which there are two coupling ports. Energy is transmitted through the transmission cavity. When using the absorption cavity, one end or a side, depending on whether the cavity is circular or rectangular, is replaced by a sample to be measured. In this manner, the difference in skin depth or depth of penetration of the electromagnetic energy of the sample and a standard sample can be measured in terms of a change in quality factor. The frequency can be swept through the center frequency of the cavity and the detected output recorded on a chart recorder or other recording instrument. A curve identical to a parallel resonant-circuit frequency-response curve will be measured directly. The quality factor Q is defined as (Ref 25):

$$Q = \frac{f_0}{\Delta f} \quad (\text{Eq 6})$$

where f_0 is the resonant frequency and Δf is the frequency difference between half-power frequencies or bandwidth.

A relation for the skin depth of an unknown sample in terms of the skin depth of a standard sample and the difference in their quality factors for a circular cavity has been derived (Ref 1):

$$S_x = S_a + \frac{2V'}{S'_a} \left(\frac{1}{Q_x} - \frac{1}{Q_a} \right) \quad (\text{Eq 7})$$

where S_x is the skin depth of the unknown sample, S_a is the skin depth of the standard sample, Q_x is the quality factor of the unknown sample, Q_a is the quality factor of the known standard, and $2V'/S'_a$ is the constant depending on cavity and frequency.

The skin depth, S_x , for a good conductor has been derived in terms of the frequency, permeability, and conductivity (Ref 25):

$$S_x = \left(\frac{2}{\omega \mu \sigma} \right)^{1/2} \quad (\text{Eq 8})$$

where ω is the angular frequency, μ is the permeability, and σ is the conductivity ($=1/\text{resistivity}$).

Because resistivity, ρ , and conductivity are reciprocal, the preceding has shown that the resistivity, and therefore a measure of the imperfection density, can be obtained from microwave measurements. It should be stressed that only the resistivity at or near the surface can be measured for a good conductor and that this is the region where stress-corrosion fatigue begins.

As shown in Fig. 28 and 29, the phase detection required to obtain the amplitude and phase of the surface impedance is accomplished at microwave frequencies. This will improve the signal-to-noise ratio, but the two output voltages, one proportional to the magnitude and one proportional to the phase, are expected to be of very low level and essentially direct current. Additional gain at direct current will be required, which can cause drift in the output. A much preferred situation would be one in which ac amplification is used.

To use ac amplification, the signal must be either amplitude, frequency, or phase modulated. Such modulation can be provided in two ways:

- Modulate the microwave source
- Modulate the effect being measured (in this case, the surface impedance)

Modulation of the microwave source is readily accomplished. If the modulation frequency is made high enough, the signal-to-noise ratio will be improved because the noise output of the phase detector diodes is lower at higher modulation

frequencies than it is at direct current. Additional signal-to-noise improvement will be obtained if the demodulated output is again phase detected with the original modulation as the reference.

Modulation of the surface impedance can be accomplished with the electroreflectance effect in nonferromagnetic materials (Ref 26). When this is done, the modulation will be proportional only to the surface impedance. Therefore, the component of the reflected signal that is proportional to the surface impedance can be readily separated from the other effects. Additional signal-to-noise improvement can be obtained when phase detection is used at the modulation frequency.

The electroreflectance effect is understood to be caused by a change in the energy bands in the surface of the material, which in turn is caused by an electric field also in the surface (Ref 26). In metals, it is very difficult to use externally applied high electric fields to accomplish this modulation. However, when an electrolyte is used, it is possible to obtain large fields at the surface of the sample with small applied voltages because a dipole layer is formed in the electrolyte at the interface between the electrolyte and the sample.

In experiments in which light has been used to measure the reflectance, the metal sample was placed in a fused-quartz cell (Ref 26). A 35-Hz modulating voltage of only 2-V peak was applied between the sample and a platinum electrode, which are immersed in the KCl-H₂O electrolyte. The reflected light was detected by photomultiplier tubes. The output of the photomultiplier tubes was a 35-Hz voltage proportional to the change in reflectance. After this 35-Hz signal was phase detected, using the original modulation as a reference, a dc voltage was obtained that is also proportional to the change in reflectance caused by the modulating electric field. No information was found on the phase angle of the 35-Hz signal relative to the modulation.

Experiments need to be conducted to show that the changes in the reflectance are caused by changes in the optical and microwave constants of the materials and that the electrolyte may act as a sensitive probe for the reflectivity of the metal. Therefore, by moving the probe while the whole surface is illuminated by microwave electromagnetic waves, the whole surface can be scanned. The larger problem is the manner in which the electroreflectance can be used in practical systems.

To modulate the surface impedance of a ferromagnetic material, the technique of magabsorption can be used (see the article "Magabsorption NDE" in this Volume). For magabsorption, a magnetomotive force is applied to the surface of the material by means of a low-frequency, many-turn coil. The microwave signal, reflected from the surface of the material inside of the magabsorption coil, will be amplitude modulated at a fundamental frequency twice the modulation frequency. The Lissajous figure obtained by applying the detected reflected microwave signal (the magabsorption signal) can be used to determine the surface impedance of the material. Changes will indicate the areas that are stress-corrosion prone or already corroded or fatigued.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Microwave Eddy Current Testing

Microwave crack detection can be thought of as detection by microwave eddy currents (Ref 27). The use of microwave frequencies produces some distinct differences between microwave and conventional eddy current testing (Ref 27) (see the articles "Eddy Current Inspection" and "Remote-Field Eddy Current Inspection" in this Volume). Three of the major differences are as follows:

- Because the skin depth at microwave frequencies is very small (typically a few micrometers), a crack must break through the surface of the metal in order to be detected
- Radiating and nonradiating probes can be used at microwave frequencies
- If the crack is open, energy storage within the crack begins to dominate the crack response as the frequency is increased. This means that a microwave crack detection system is very sensitive to crack opening. Eventually, if the frequency is increased enough, a wave can propagate within the crack, and the crack response also becomes very sensitive to crack depth

In eddy current testing at lower frequencies there are two distinct approaches. The first is the single-coil system in which the induced eddy currents change the impedance of the coil by a factor of ΔZ . The second approach is the introduction of a second sensor (an induction coil or a Hall-effect device) that senses both the applied field and the secondary field arising from induced eddy currents. Numerous variations of these two basic schemes have been explored at low frequencies and at microwave frequencies. The microwave version of the low-frequency single-coil system will be considered first.

One method that has been applied to the analysis of microwave eddy current sensors for calculating the change in the probe impedance, ΔZ_c , caused by a crack is based on the Lorentz reciprocity theorem (Ref 28). Basically, the reciprocity theorem relates the change in impedance produced by the flaw to an integral of certain magnetic fields on the surface of a volume that encloses the flaw (Ref 27). The basic equation used for analysis of microwave eddy currents is (Ref 27):

$$\Delta Z_c = \frac{1}{I \cdot I'} \int \int_{S_F} [(\mathbf{n} \times \mathbf{E}') \cdot \mathbf{H} - (\mathbf{n} \times \mathbf{E}) \cdot \mathbf{H}'] dS \quad (\text{Eq 9})$$

where I is the probe current without a flaw, I' is the probe current with a flaw, S_F is the surface including the flaw, \mathbf{H} is the magnetic field without a flaw, \mathbf{H}' is the magnetic field with a flaw, \mathbf{E} is the electric field without a flaw, \mathbf{E}' is the electric field with a flaw, and \mathbf{n} is the unit vector normal to the surface S_F . Equation 9 shows that the change in probe impedance is not influenced by the electromagnetic fields that are perpendicular to the surface S_F (Ref 27).

Equation 9 can be simplified by making realistic assumptions. First, the radiation fields can be neglected as long as the probe and the flow are much smaller than a wavelength. It should be assumed that the flow is rectangular with depth a and width Δu and that $a \ll \Delta u$.

If the ratio of flaw depth to skin depth is much larger than unity, as is typical at microwave frequencies, then:

$$\Delta Z_c = \left(\frac{H_0}{I} \right) [jka(\pi a/2 + \Delta u)\eta_0 - Z_s \cdot \Delta u] \quad (\text{Eq 10})$$

where k is 2π divided by the free-space wavelength ($ka \ll 1$), H_0 is the complex amplitude of the magnetic field tangent to the metal surface, η_0 is the intrinsic impedance of free space or 120π , and Z_s is the surface impedance. From Eq 10, if Δu is small and H_0/I is real, then ΔZ_c is essentially inductive.

If the frequency is high enough so that the flaw depth divided by the skin depth is much greater than unity, the change in impedance is:

$$\Delta Z_c = \left(\frac{H_0}{I}\right)^2 \left[2Z_s \left(a - \frac{\Delta u}{2} \right) + jka\eta_0 \cdot \Delta u - 1.56/\sigma \right] \quad (\text{Eq 11})$$

where σ is the conductivity of the surface. Equation 11 shows that if the slot width is small and H_0/I is real, then ΔZ_c will have both resistive and inductive components. If the slot width is not small, then ΔZ_c becomes predominantly inductive at high frequencies.

Research on microwave crack detection has been ongoing since the late 1960s (Ref 19, 29, 30, and 31). The block diagrams of three microwave crack detection systems are given in Fig. 30, 31, and 32.

Fig. 30 Microwave crack-detection system. Source: Ref 29

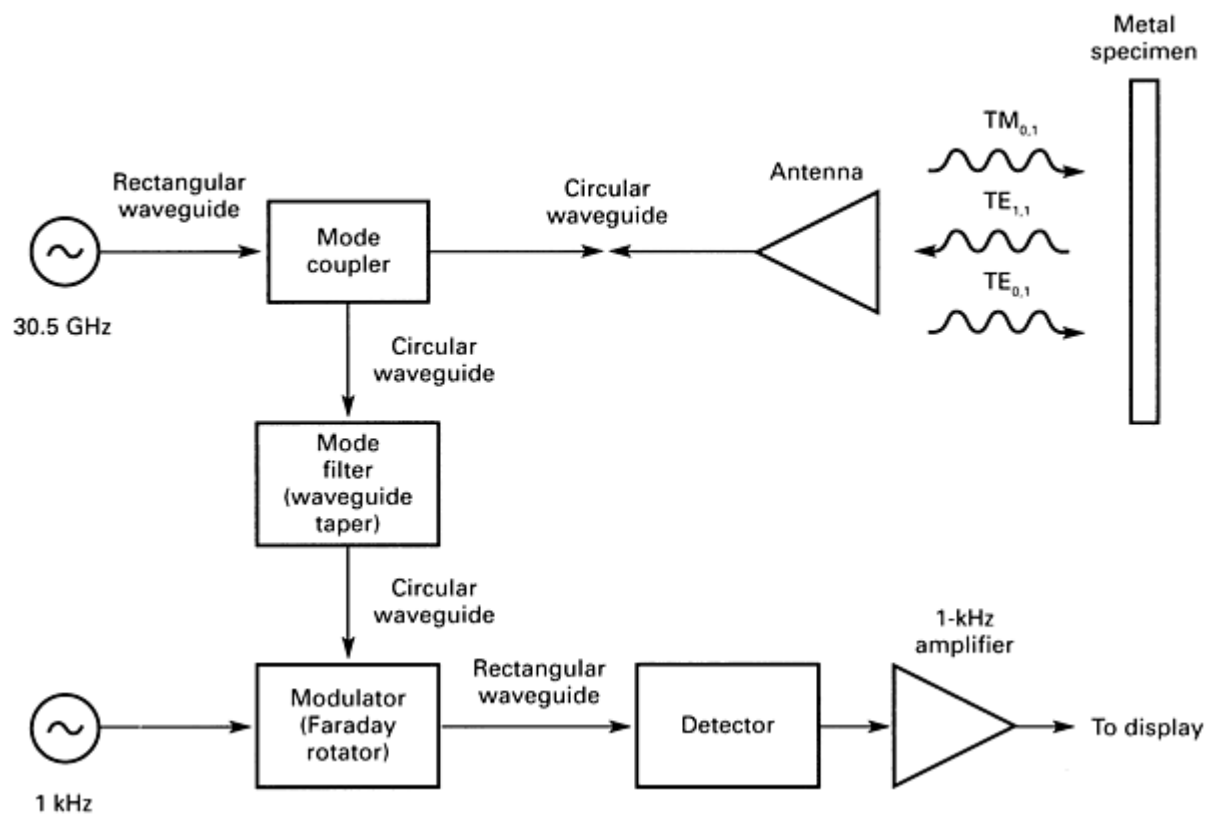

Fig. 31 Mode-converting crack-detection system. Source: Ref 30

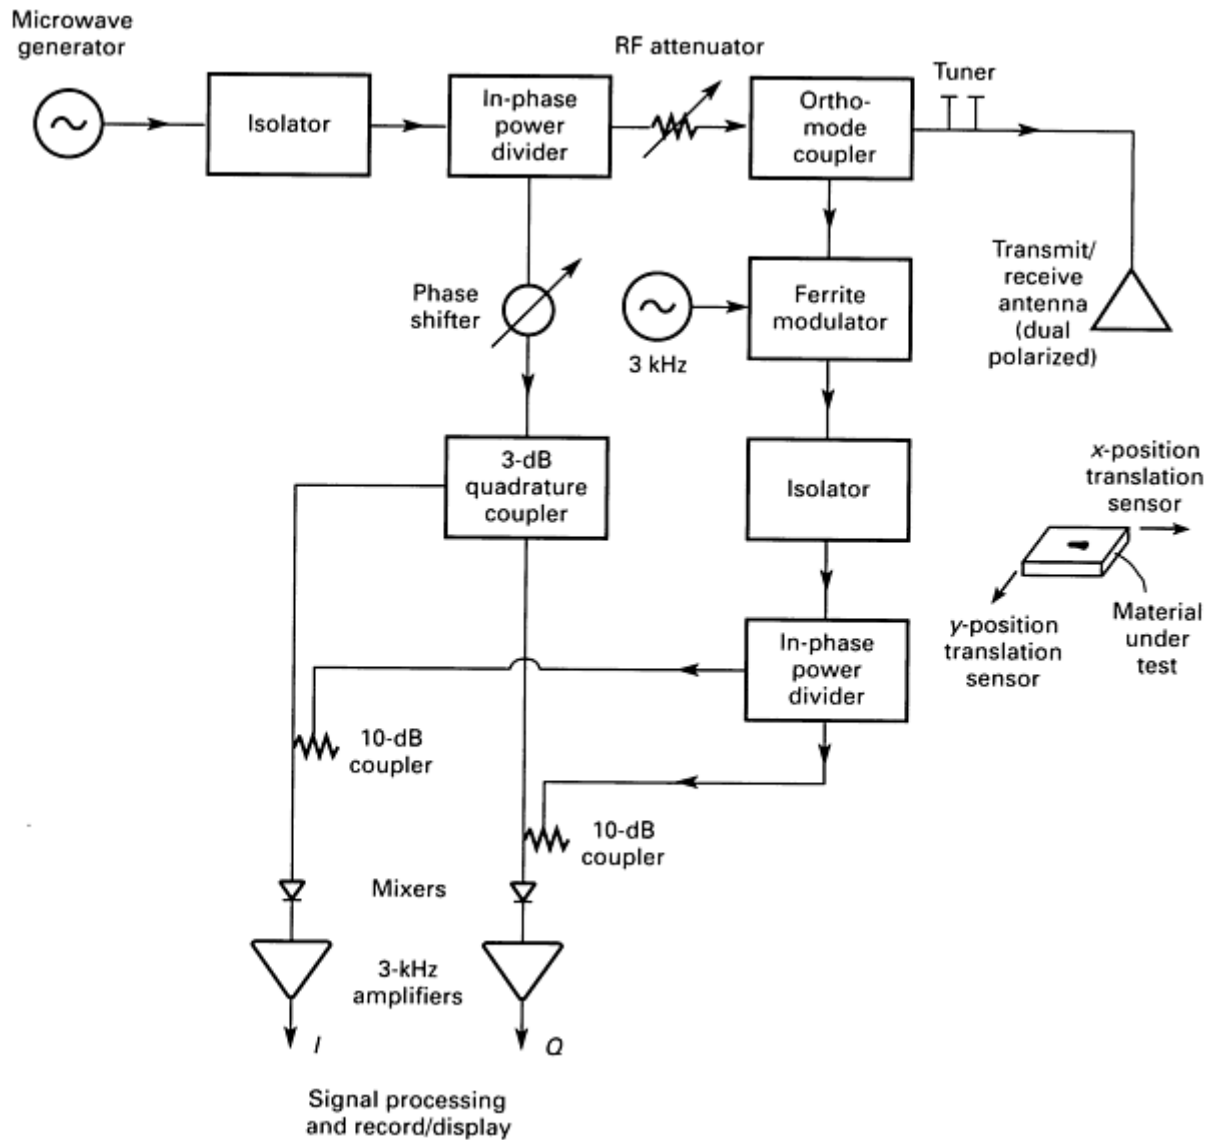

Fig. 32 Microwave system for measuring cross-polarized backscatter using homodyne detection. Source: Ref 31

An earlier microwave crack detection scheme is shown in block diagram form in Fig. 30. It is a basic reflectometer with two additional features. The first one is a microwave bridge to null out the background signal (that is, the surface reflection). The second is a rotating waveguide joint that provides polarization of the incident wave. This effectively tags the signal scattered by the crack because the crack is a polarizing filter that scatters maximum when the incident electric field is perpendicular to the length of the crack (Ref 29). This is a type of mode conversion in which the crack converts a fraction of the incident wave (a mode) into an orthogonally polarized wave (an independent mode).

Another system of mode conversion is used in the microwave crack detection system given in Fig. 31. The diameter of the circular waveguide connecting the mode coupler to the horn antenna is chosen so that either the TM_{01} or the TE_{01} circular waveguide mode is excited and radiated. The horn is placed close to the sample so that the incident fields at the sample surface are essentially those of the waveguide mode. A crack in the surface converts some of the incident energy to the TE_{11} mode, which is separated from the other modes with a tapered waveguide and a Faraday-rotor modulator.

The block diagram of the third microwave eddy current detection system is given in Fig. 32. It also uses mode conversion but without polarization modulation (Ref 31). A linearly polarized incident wave is partially converted to orthogonal polarization when the incident polarization is at an angle of 0 to 90° relative to the slot (crack) (Ref 31). The homodyne detection system provides outputs that are in-phase (I) and quadrature-phase (Q) and that can be displayed in the same way as the conventional (low-frequency) eddy current system.

The antenna used in the system was a lens-focused horn with a beam width at its focal point of about 3.5 mm (0.14 in.) at the operating frequency of 100 GHz. This is an example of a radiating probe that searches for flaws in the far field.

The results from the three systems reported indicate that the crack is detectable provided that the crack is open, the crack has a high Q , and the crack length is larger than one-half wavelength (Ref 31). In practice, one would vary the frequency until the crack signal is normal to the lift-off circle. Knowing the frequency and having a model for the electromagnetic propagation within the crack, the depth could be determined. This feature is self-calibrating because the phase of the crack signal is measured relative to the lift-off circle. (The lift-off signal roughly follows a circular path on the oscilloscope. This path is called the lift-off circle. The diameter of the lift-off circle depends on the system gain.)

Microwave eddy current systems have also been built using planar transmission lines rather than waveguides so that they are of the near-field type. This probe has a higher sensitivity than the others in Fig. 30, 31, and 32. The probes use a pair of adjacent coupled striplines, as shown in Fig. 33. The coupled striplines can support two orthogonal TEM modes, the even (Fig. 33a) and the odd (Fig. 33b). The direction of propagation is perpendicular to the plane of Fig. 33. For the even mode, the two strips are at the same potential relative to ground. For the odd mode, the potentials with respect to ground have potentials that are of the same magnitude with respect to ground but of opposite polarity. The strips carry opposite but equal currents.

Fig. 33 Two orthogonal modes for a pair of coupled striplines (support dielectric not shown). (a) Even mode. (b) Odd mode. Source: Ref 32

In the even mode, there will be no conversion to the odd mode as long as symmetry is maintained. However, when a surface crack in one ground plane perturbs the current under one strip but not the other, some power will be converted to the odd mode. Such a pair of coupled-strip transmission lines can be used as a crack detector if the surface to be inspected is one of the ground planes, if the strips are excited in the even mode, and only if the odd mode is detected. This type of probe depends on mode conversion to achieve a high sensitivity, as have the ones discussed previously.

A cross section of the probe used to inspect 175 mm shells is shown in Fig. 34. Two important features of the stripline probe are as follows:

- The striplines can be as long as desired
- The stripline probe can be made to conform to a curved surface if thin, flexible dielectric substrate is used

In Fig. 34, the shell body forms one ground plane of the strip transmission line as is necessary for detecting open cracks.

Fig. 34 Cross section of curved stripline crack detector. Dimensions given in inches. Source: Ref 33

The system used with the coupled stripline to detect cracks is shown in Fig. 35. By adjusting the variable attenuator and phase shifter connected to the output of the probe, it was found possible to achieve 50 to 75 dB of dynamic range (Ref 27). Quadrature detection and subsequent squaring and adding produced a phase-insensitive output. The frequency used was near 10 GHz. When the system illustrated in Fig. 35 was connected to the crack detector shown in Fig. 34, electric discharge machining slots as small as 2.54 mm (0.100 in.) long, 0.038 mm (0.0015 in.) wide, and 0.13 mm (0.005 in.) deep could be detected. It was, however, difficult to maintain high isolation between the even and odd modes (bridge balance) as the probe scanned the surface. This is usually because of slight lift-off of the detector from the shell. Perhaps lift-off effects could have been reduced if the in-phase and quadrature-phase signals were used rather than only the amplitude.

Microwave Inspection

William L. Rollwitz, Southwest Research Institute

Ferromagnetic Resonance Eddy Current Probes

An entirely different eddy current detection head (Ref 34, 35, 36, 37, 38, 39) is illustrated in Fig. 36. Instead of electromagnetic resonance, this probe makes use of ferromagnetic resonance (FMR) (Ref 40). Ferromagnetic materials exhibit a natural dispersion in their permeability. Such an effect has been studied in ferrites that typically have two resonances--one in the range of 3 to 500 MHz and a second at 1200 MHz without an external applied magnetic field (Ref 40). Evidence shows that the higher resonances are due to electron spin (Ref 40). These spin resonances occur naturally because there is an internal anisotropy magnetic field. This internal magnetic field tends to keep the electron magnetization vector aligned with a preferred crystal axis (Ref 40). Most of these resonances are very broad.

Fig. 36 Typical dimensions and feed arrangement for a ferromagnetic resonance eddy-current probe. M , internal magnetization. Source: Ref 34

Studies of the magnetic resonance of the garnets have given some narrow ferromagnetic resonance lines. Yttrium iron garnet (YIG) gives a very narrow ferromagnetic resonance line (Ref 40). The line with a polycrystalline YIG shows internal field values of 33, 14, and 4.0 kA · m⁻¹ (420, 180, and 50 Oe) (Ref 40). The properties are modified by substituting for part of the yttrium, chromium, and rare-earth elements such as gadolinium and dysprosium. An exceptionally narrow line is obtained when the substituted YIG is in the form of polished, single-crystal spheres. The best result was a width of 41 A · m⁻¹ (0.52 Oe) (Ref 40). The value of the internal field was 0.175 T (1750 G). The *Q*-factor for single crystals in the form of 0.8 mm (0.03 in.) diam spheres, with a line width of 185 A · m⁻¹ (2.3 Oe), is around 3000 in the frequency range of 9.5 to 67 GHz. External magnetic fields are required to cover this range of frequencies.

The resonator illustrated in Fig. 36 is a single crystal YIG sphere less than 1 mm (0.04 in.) in diameter. The resonant frequency of the sphere is determined by the strength and direction of an applied field, **H**_{DC}, shown in Fig. 36. The internal magnetic field in the YIG comes from the precessing magnetic field of the electrons in the YIG sphere because of their interaction with the applied magnetic field **H**_{DC}. The radian precession frequency, ω_0 is determined by:

$$\omega_0 = \gamma H_{DC} \tag{Eq 12}$$

where $\gamma = 2.8 \times 10^6$ rad/Oe · s. For a resonant frequency range of 500 to 2000 MHz, the value of **H**_{DC} is varied from 14.2 to 56.8 A · m⁻¹ (178 to 714 Oe). Magnetic field values in this range are readily supplied by small samarium-cobalt and other types of modern magnets.

Unlike lower-frequency eddy current probes, the coil shown in Fig. 36 is a single turn whose diameter is 1.5 times the diameter of the YIG sphere or from 0.25 to 0.75 mm (0.01 to 0.03 in.). The diameter of the wire used is 0.13 mm (0.005 in.).

The ferromagnetic resonance is a condition of the ferromagnetic material. When the YIG sphere is so small, boundary conditions must be taken into account. These lead to an infinite number of resonance modes, called magnetostatic modes, each with a characteristic distribution of the magnetization within the sphere and a characteristic frequency that depends on **H**_{DC}. When the microwave eddy current probe in Fig. 36 is fed as indicated in Fig. 37, the characteristics of a material placed within the radio-frequency (RF) field (**H**_{RF}) of the coil, as shown in Fig. 36, will cause a change in the losses and the mode coupling in the YIG. The material close to the probe causes changes in both the amplitude and frequency of the modes. This in turn will change the energy reflected from the single-turn loop inductor.

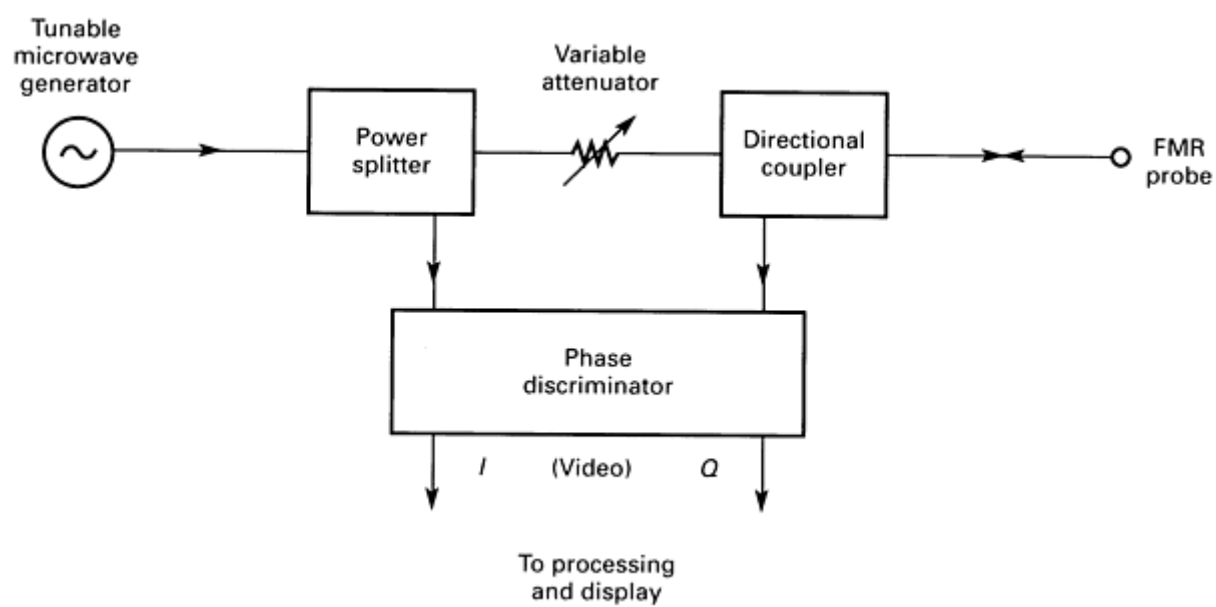

Fig. 37 Microwave system for measuring the reflection from an FMR probe. Source: Ref 38

The dominant mode is one in which the magnetization is uniformly distributed throughout the sphere and is precessing uniformly. The precession frequency is given by Eq 12 and can be represented by an electron dipole moment of strength

($\mathbf{m}_{\text{RF}} V_s$), where V_s is the volume of the sphere. The dipole moment, because of the cross product between \mathbf{H}_{DC} and \mathbf{m}_{RF} , is precessing about \mathbf{H}_{DC} at a frequency ω , according to the right-hand rule, in a plane perpendicular to \mathbf{H}_{DC} , as shown in Fig. 36. The precession is at the frequency of the drive current, I , applied to the coupling coil. The dipole moment \mathbf{m}_{RF} obtains its maximum amplitude when the precession frequency ω_0 (Eq 14) equals the precession frequency ω . The time-varying magnetic fields are created outside of the sphere by this rotating dipole moment. These outside time-varying magnetic fields interact with a flaw in the material and produce a flaw-detecting signal in the same way that the time-alternating magnetic fields do from low-frequency (conventional) eddy current probes.

In practice, the YIG sphere is mounted in a depression on a piece of microwave circuit board with a loop etched on the board. Wire leads connect the end of the loop to a semirigid coaxial transmission line. A small samarium-cobalt magnet in a brass holder supplies the bias field. The placement of the magnet can be adjusted to change the field orientation and the resonant frequency. This eddy current probe, because of its small size, gives excellent spatial resolution, discrimination against edge effects, and accessibility to restricted corners.

The high sensitivity and spatial resolution of the FMR eddy current probe have been experimentally verified (Ref 34, 39). In one case, the FMR probe was found to be 40 times more sensitive to an open slot than a commercial 100-kHz probe. The correlation between the flaw signature, detected by the FMR probe, and the width of the opening of a stressed fatigue crack has also been demonstrated.

Another group of researchers has applied the FMR probe to aluminum, type 316 stainless steel, Armco iron, and XC-38 (Ref 41). They used the YIG and gallium-doped yttrium iron garnet (GaYIG). The main difference between this garnet and the previous garnet is that the saturation magnetization is fixed at 0.075 T (750 G) for YIG, while that of the GaYIG varies with the amount of gallium. The resonator principle that was used is given in Fig. 38. The characterization of the spectrum line is done by measuring the reflection coefficient of the YIG resonator in Fig. 38. A microwave signal is applied onto the garnet by means of the copper loop. In the absence of resonance, the wave is reflected. As the resonance is approached, the incident wave is absorbed by the garnet, and the reflected wave is highly attenuated. The reflection coefficient is characterized either by a scalar analysis or by a vector analysis.

Fig. 38 Schematic of YIG resonator principle. H_D , continuous magnetic field; H_{HF} , microwave magnetic field. Source: Ref 41

In air (uncoupled to a sample), the resonant frequency is proportional to the applied bias field H_D in Fig. 38. The proportionality constant is 2.8 MHz/Oe. The resonance lines for YIG are located above 3 GHz. For GaYIG, the resonance frequency can go down to less than 1 GHz.

The garnets used have diameters of 375 or 500 μm (0.015 or 0.020 in.). The only garnets used were the YIG, which required a bias magnetic field between 80 and 160 $\text{kA} \cdot \text{m}^{-1}$ (1000 and 2000 Oe). The microwave loop is made on a printed circuit. Experience with microwave oscillators has shown that this loop should have a diameter of about 1.5 times that of the garnet and that the copper width should be 0.1 mm (0.004 in.).

In Ref 41, three different probes (A, B1, B2) were used. These three detection heads are illustrated in Fig. 39. These three probes are configured for use as follows:

- Probe A is for use with a nonmagnetic metal where the magnetic field is parallel to the surface of the metal and the fringe field of probe A will be in the surface of the nonmagnetic metal
- Probe B1 is for use with magnetic material where the FMR probe is between the metal and the magnet, providing the bias field for the YIG, and the RF field is perpendicular to the magnetic metal surface
- Probe B2 is for use with magnetic material where the FMR probe is between the magnet and the metal and the RF field from the YIG-coil system is parallel to the metal surface

Head B2 imposes a minimum distance of the order of approximately 1 mm (0.04 in.) between the metal and the garnet because of the position of the loop. This drawback can be overcome by using a half-loop. In head B1, there are numerous spurious modes, which are almost as intense as the main mode. However, this head appears to be of particular value in the separation of the distance effect from the flaw effect.

Fig. 39 Three microwave eddy current detection head configurations that use a YIG coil. (a) A, for nonmagnetic metal. (b) B1, for magnetic metal, RF field perpendicular to magnetic metal surface. (c) B2, for magnetic metal, RF field parallel to magnetic metal surface. Source: Ref 41

The measurement principle is described as the characterization of the resonance line and of its alteration in the presence of a flaw. The block diagram of the electronics used with the FMR probes is shown in Fig. 40. Figure 40(a) is for the scalar analysis, and Fig. 40(b) is for the vector analysis. For the scalar analysis, a wobulator (German for signal generator, specifically a frequency-modulated RF source) sends a wave through the coupler and through the circulator to the probe. The signal from the probe goes through the circulator and through a detector to the vertical axis of the oscilloscope. The signal used to vary the frequency is sent to the horizontal axis of the oscilloscope so that the oscilloscope presents the resonance of the probe as a function of frequency. An automatic control device makes it possible to determine the frequency, f , of the peak. The scanning of the metal takes place in a single direction, and the curves $f(x)$ are plotted. The flaw is characterized as a frequency shift.

(a)

(b)

Fig. 40 Schematic diagram for (a) scalar analysis and (b) vector analysis. Source: Ref 41

For the vector analysis, the block diagram shown in Fig. 40(b) is used. The reflected wave is sent to a vector analyzer, which makes it possible to display the reflection coefficient in the phase plane. The influence of the flaw is characterized by the displacement of the resonance loop in the phase plane. The synchronizer allows phase locking on the wobbulator to provide greater frequency stability when required.

Three metals were studied: aluminum, type 316 stainless steel, and Armco iron. The samples are surface ground to an arithmetic average roughness, R_a , of $0.1 \mu\text{m}$ ($4 \mu\text{in.}$).

The flaws used are straight artificial grooves, cutting the samples across their entire length. The parameter investigated is the frequency of the resonance peak. The results for aluminum and stainless steel are comparable. The differences between scalar analysis of the aluminum and the Armco iron were significant.

The lift-off effect is basically different for the aluminum and the Armco iron but the same for the aluminum and the stainless steel. For a lift-off, Δh , of more than 300 μm (0.012 in.), the frequency remains stable for aluminum, while from 300 to 100 μm (0.012 to 0.004 in.), the frequency increases from 4014 to 4024 MHz. For Armco iron, the frequency increases almost exponentially from 3800 MHz at 600 μm (0.024 in.) lift-off to 4300 MHz at 100 μm (0.004 in.). The frequency variation in iron is due to the variation of the space between the magnetic and the metal. In the nonmagnetic metals, the frequency variation is due to the eddy currents in the metal.

In the configurations illustrated in Fig. 39 and 40, the sensitivity of the frequency measurement is 100 kHz, mostly limited by instabilities. The graph of frequency shift caused by a $100 \times 100 \mu\text{m}$ (0.004×0.004 in.) flaw in each of the three metals with a lift-off of 100 μm (0.004 in.) is smallest for aluminum, medium for the stainless steel, and largest for the Armco iron. The values of frequency shift are 4 MHz for aluminum, 12 MHz for stainless steel, and 27 MHz for Armco iron. Flaws of $10 \times 5 \mu\text{m}$ ($400 \times 200 \mu\text{in.}$) were lost in the background for all three materials.

The experiments confirmed that FMR probes have better sensitivity to flaws for ferromagnetic materials than for nonmagnetic metals. On nonmagnetic metals, the frequency shift is due to eddy currents, while in ferromagnetic metals, the frequency shift is caused by a modification of the bias field by the flaw. Because a frequency shift of 0.1 MHz can be measured, a field variation of 0.05% can be detected.

Eddy Currents for Holes and Areas of Small Radii

To make microwave eddy current measurements in holes and in areas of small radii of curvature, a slow-wave structure has been used at Southwest Research Institute. This slow-wave structure is similar to a helical antenna or a helix TWT except that the last turn of the helix is shorted. This shorting forms a shorted spiral transmission line without a shield. In the test unit, the length and diameter will be adjusted so that when this helix is placed within the hole, it forms a helical resonator when the last turn is not shorted or a spiral delay line when the helix is shorted. When the helical antenna is used with the system shown in Fig. 32, the amplitude and phase signals will measure the surface impedance, which can be related to its corrosion susceptibility. Multiple helical probes could be constructed so that a number of hole sizes could be measured.

For an area with a small radius of curvature, the slow-wave helix could be made flexible so as to conform to the definite configuration of the part, or it could be scanned over the surface. By calibration, then, the surface impedance could be related to the corrosion susceptibility of the surface under inspection.

In any case, the microwave signal is carried either by a wire of the helix so that it has sensitivity both inside and outside of the helix or by a hollow pipe of circular or rectangular cross section that can be made sensitive for surface impedance measurements through slots or holes in the pipe. Therefore, a multitude of configurations are possible to meet the needs for surface impedance measurements on the different shapes of aircraft components.

Microwave Holography Practice

A hologram is a recording of an interference pattern formed by superimposing a reference electromagnetic wave on the object-scattered electromagnetic wave (Ref 42). Because the interference depends on the relative amplitudes and phases of the incident and scattered waves, highly coherent waves (same frequency and same phase) must be used to keep the phase relationship constant during the generation of the microwave hologram.

The reference wave is called \mathbf{E}_1 , and it is assumed to be a plane wave (same frequency, same phase). The object-scattered wave is \mathbf{E}_2 , and any point on the interference pattern in the x - y plane will be described by an intensity ($I(x,y)$) variation:

$$\begin{aligned} I(x,y) &= (\mathbf{E}_1 + \mathbf{E}_2)(\mathbf{E}_1 + \mathbf{E}_2)^* \\ &= |\mathbf{E}_1|^2 + |\mathbf{E}_2|^2 + \mathbf{E}_1\mathbf{E}_2^* + \mathbf{E}_1^*\mathbf{E}_2 \end{aligned} \quad (\text{Eq 13})$$

where the asterisk indicates the complex conjugate. In the photographic record, the last two terms, $\mathbf{E}_1\mathbf{E}_2^*$ and $\mathbf{E}_1^*\mathbf{E}_2$, are the only contributors because they are the relative signal-bearing terms. The $|\mathbf{E}_1|^2$ and $|\mathbf{E}_2|^2$ terms are the zero-order diffracted terms upon reconstruction. When the interference pattern is illuminated with a third plane wave, \mathbf{E}_3 , a modulated wave, \mathbf{E}_4 , is generated, which is given by:

$$\mathbf{E}_4 = \mathbf{E}_3\mathbf{E}_1\mathbf{E}_2^* + \mathbf{E}_3\mathbf{E}_1^*\mathbf{E}_2 \quad (\text{Eq 14})$$

Because both \mathbf{E}_1 and \mathbf{E}_3 are plane waves, $\mathbf{E}_1 = \mathbf{E}_1^*$ and the product terms $\mathbf{E}_3\mathbf{E}_1$ and $\mathbf{E}_3\mathbf{E}_1^*$ are constants. Equation 14 states that the object-scattered wave \mathbf{E}_2 and its conjugate \mathbf{E}_2^* are reconstructed so that virtual and real object images are reconstructed.

Zone Plates. A hologram can be looked upon as a microwave interference pattern consisting of many coherently superimposed zone plates. Then, holography, whether at microwave or light frequencies, becomes a relatively simple diffraction process that is fully understandable without concern for phase, modulation, coding, or some of the other concepts often mentioned as means to assist the understanding of holograms. Rogers was the first to note the similarity of holograms and zone plates (Ref 43). Later, he used holograms to generate microwave radar zones plates. A zone plate is defined as a diffracting screen so constructed that it obstructs alternate Fresnel zones of a wave front.

Figure 41 illustrates a zone plate with an opaque disk at its center element. The open spaces permit the passage of energy that will add at the focal point, f . The opaque rings prevent the passage of energy that would interfere at the focal point. The opaque or blocking zones can be replaced with open spaces, and the zone plate will function the same as the one shown in Fig. 41. The zone plate also generates a set of diverging waves, which is very important to the hologram. It is the diverging waves that give the three-dimensional view to the object obtained from the hologram.

Fig. 41 A zone plate having an opaque disk as its center element. The open spaces permit the passage of energy that will add at the focal point, and the opaque rings prevent the passage of energy that would interfere at that point. Source: Ref 43

The design procedure for zone plates is indicated in Fig. 41. Circles are drawn with centers at the desired focal point and with radii differing by one-half the design wavelength. The radii of these circles intercept the plane of the zone plate. The first circle has a radius of f . The radius of the second circle is $(f + \lambda/2)$. Where the second circle intersects the zone plate, the first transparent ring starts. The end of the first transparent ring is where the third circle of radius $(f + 3\lambda/2)$ intersects the zone plate. The third circle is also the start of the first opaque or blocking zone. This process continues with the radius of each successive circle being increased by $\lambda/2$ over the radius of the previous circle. The intersection of the first circle of radius $(f + \lambda/2)$ with the zone plate marks the end of the first or central blocking zone.

Optical Holography. The way a hologram of a point source of light might be made is shown in Fig. 42. In the developed photographic zone plate shown in Fig. 42(a), the open spaces pass only the energy that will add constructively at a desired focal point. The opaque rings prevent the passage of energy that would interfere destructively at the desired focal length. Where laser light illuminates the hologram in the reconstruction process, shown in Fig. 42(b), diffraction causes converging waves to create a real image of the spot of light at the focal point F . Diffraction at the zone plate also generates diverging waves that create, for a viewer, the illusion that there is a point of light also located at the conjugate

focal point F_c in Fig. 42(b). The diverging light is indistinguishable from the light from the pin hole, and the viewer imagines he sees the second source of light located in the space behind the illuminated zone plate (hologram). Detailed information is available in the article "Optical Holography" in this Volume.

Fig. 42 Schematic of the Gabor holographic. Construction (a) and reconstruction (b) when recording a point source of light (pinhole in an opaque screen). The interference pattern generated corresponds to the pattern of a two-dimensional zone plate. Source: Ref 43

Microwave Holography. Microwaves in microwave holography are analogous to laser light in optical holography. A microwave hologram can be defined as the photographically recorded interference pattern between a set of coherent (at the same frequency and phase) microwaves of interest and a coherent reference wave generated by the same source. This method is still used today.

The equipment for making a microwave hologram is illustrated in Fig. 43. The interference patterns were made visible by photographic scanning. In making the pattern, two wave sets are required. The first is the incident wave from the feed

To simulate a plane wave, using a reference wave, \mathbf{R} , added to the object signal, \mathbf{S} , the phase of the locally produced signal must vary linearly with the displacement of the probe in Fig. 9 in its direction of travel (Fig. 9). This linear variation in phase is most readily achieved by linking the motion of the probe to the rotations of the phase shifter (Ref 46).

The simulation of a spherical wave is more complicated. Within the Fresnel approximation, the phase can be made to vary quadratically (in-phase and quadrature-phase) with position, and this will suffice (Ref 46). This method of using a local reference signal, \mathbf{R} , with a programmable phase leads to more possibilities (Ref 46). For example, it is possible to simulate a slow wave in which the dielectric constant is larger than that of free space so that the wave travels slower than in free space. Because the phase is rotated in synchronism with the probe motion, the phase shifter can be rotated at any desired rate to simulate an arbitrarily large wave vector. This makes it possible to shift the spectrum of the object, even when it occupies a wide band, enough to avoid overlap with the image spectrum. This separates real and virtual images in the reconstruction.

Another possibility is the simulation of a noiselike reference wave in which the phase is made to vary in some arbitrary manner, such as $\phi(x,y)$, as a function of position. In this case, for the purpose of reconstruction, the function $\phi(x,y)$ must be stored for use during reconstruction (Ref 47). Further, the phase can be varied so that a simulation of the use of a diffuse reference wave is obtained. The same diffuse reference wave must be used for reconstruction. The advantages of using a programmable reference wave are (Ref 47):

- Easier instrumentation even in the case of a plane wave reference
- More flexibility
- The possibility of readily simulating complex modulation schemes

A further possibility is shown in Fig. 44(a), in which a product detector is used instead of the intensity-measuring device or a square-law detector, which is composed of a multiplier and a low-pass filter. It is also called a correlator and is widely used in interferometry and radio astronomy.

Fig. 44 Recording of (a) microwave product hologram and (b) microwave complex hologram $H_1 + jH_2$. C , product detector. Source: Ref 47

If R (reference) and S (signal) are the two inputs to the product detector and if S is from the object and R is from the locally produced reference, the output of the product detector is $\text{Re } R^*S$ (the asterisk means a complex conjugate and Re

means the real part of the product of \mathbf{R}^* and \mathbf{S}). The output recorded as a function of the probe position ($f(x,y)$, Fig. 44a) is called a product hologram. It can be transcribed to a photographic plate and used exactly as the intensity hologram in the reconstruction. The only difference is that the product hologram does not contain the unwanted terms $|\mathbf{R}|^2$ and $|\mathbf{S}|^2$ because these have been filtered out. In some cases of intensity holography, the spectrum of $|\mathbf{S}|^2$ could overlap $\mathbf{R}^*\mathbf{S}$ and $\mathbf{R}\mathbf{S}^*$, resulting in distortions. Because the product hologram is not always positive, it must be transcribed with its sign.

At microwave frequencies, it is relatively easy to record both phase and amplitude of the field instead of just the intensity. This can be done with two product detectors. One product detector correlates \mathbf{R} and \mathbf{S} and the other $j\mathbf{R}$ and \mathbf{S} , where $j\mathbf{R}$ is \mathbf{R} shifted by 90° . The two outputs are the real and imaginary parts of $\mathbf{R}^*\mathbf{S}$. Recorded as two functions, $\mathbf{H}_1(x,y)$ and $\mathbf{H}_2(x,y)$, they form the complex hologram.

For the complex hologram, the shifting of the phase of the reference is dispensed with. The function of phase shift was only to make it possible to recover the phase after recording only one intensity pattern. This phase recovery can be understood by a comparison with the complex hologram. If the phase of the reference wave, \mathbf{R} , varies very rapidly compared to the signal, \mathbf{S} , that is, if the signal \mathbf{S} does not change appreciably as \mathbf{R} goes through a complete phase rotation, two intensity measurements taken at points where the phase of \mathbf{R} differs by 90° will be equivalent to a measurement of $\mathbf{R}^*\mathbf{S}$. The complex hologram consists of two maps, $\mathbf{H}_1(x,y) = \text{Re } \mathbf{R}^*\mathbf{S}$ and $\mathbf{H}_2(x,y) = \text{Im } \mathbf{R}^*\mathbf{S}$, as functions of position in the plane of the record. If it is desired to reproduce \mathbf{S} at some point, then multiplying signal \mathbf{R} by \mathbf{H}_1 and $j\mathbf{R}$ by \mathbf{H}_2 and adding the results will accomplish it. If $k|\mathbf{R}|^2$ is taken as unity, then the output is precisely \mathbf{S} .

It is interesting that in contrast to the intensity hologram, only one image, the virtual image, is produced. If the real image is desired, all that needs to be done is to change the $+90^\circ$ phase shift to -90° .

Microwave and millimeter wave holography has several advantages over optical holography (Ref 47):

- More favorable propagation through the atmosphere so that images of reflecting objects can be made through fog, haze, and other optically opaque dielectric barriers
- The availability of well-established and more flexible detection and electronic processing methods so that image separation and enhancement can be achieved
- The information content is considerably lower than optical holograms, which permits real-time operation

Microwave holography has been used to aid airport security through the detection and identification of concealed weapons and to provide close-range visualization of airport runways in inclement weather.

Example 1: Use of Microwave Holography to Detect Concealed Weapons Aboard Aircraft Baggage.

A holographic imaging experiment was conducted to produce a visible image of guns at 70 GHz. The simplified block diagram of the system used is shown in Fig. 45(a). The weapon was irradiated with 70 GHz ($\lambda = 4.3$ mm, or 0.17 in.) in a CW mode. The output of the klystron used was 750 mW, and it was fed to a parabolic antenna that produced uniform irradiance of 0.2 mW/cm^2 (1.3 mW/in.^2). The phase distribution of the wave field scattered by the weapon was mapped by a spiral scanning pyramidal horn that had a 10×7.7 mm (0.39×0.30 in.) receiving aperture. The output of the receiver phase detection system is a value proportional to the phase of the field of the detected object. The display on an oscilloscope was photographed to produce a phasigram from which the image was retrieved by the method shown in Fig. 45(b). The reconstructed image of a gun showed that its general outline was that of the gun used. The edges of the gun were emphasized, as expected. The linear resolution at a range of 1 m (3.3 ft) from the antennas is about 10 mm (0.4 in.).

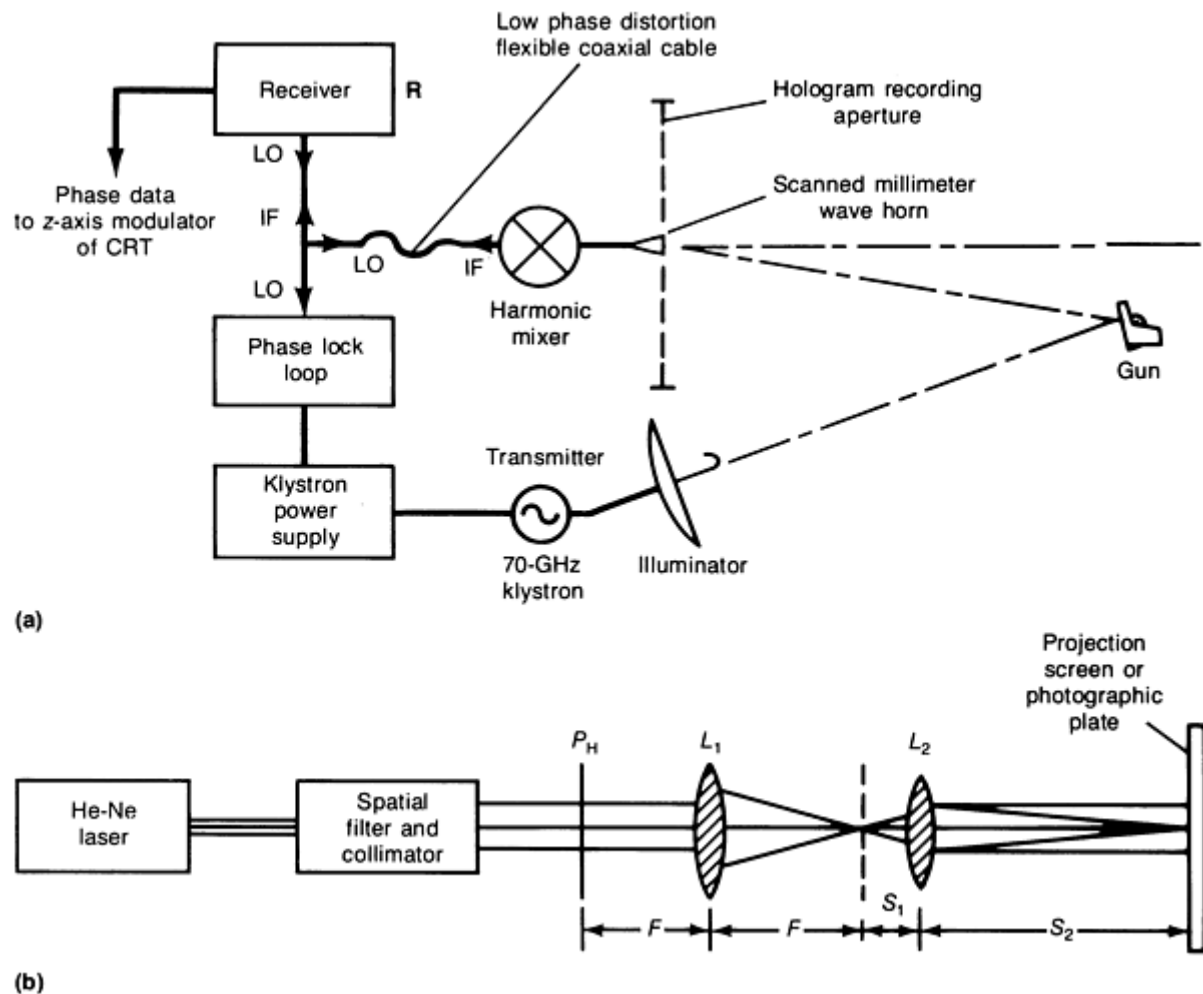

Fig. 45 Recording and reconstruction configurations for the detection of concealed weapons. (a) Simplified block diagram of recording system. (b) Image retrieval arrangement. IF, intermediate frequency; LO, local oscillator. Source: Ref 47

Example 2: Use of Microwave Holography to Provide Close-Range Visualization of Airport Runways.

The microwave holographic system was used for the close-range detection of a landing strip that was marked at regular intervals with retroreflectors (Ref 47). The microwave system was constructed to visualize holographically the distribution of the retroreflectors on the runway. The landing aircraft would illuminate the marked runway with two microwave beams. Because the one intended for imaging lies in the millimeter range, its wavelength is short enough so that it can easily resolve the target (the runway). The longer-wavelength radiation is used to realize a target-derived reference beam. This gives the advantages of reducing the required number of receiver elements in the airborne hologram recording array and relaxes the accuracy with which the position of the receiver elements in the array must be known. The imaging wavelength of 3 mm (0.12 in.) and a retroreflector separation of 6 in (20 ft) made the hologram recording array length, to resolve two adjacent retroreflectors, 1.5 m (4.9 ft) at a maximum operational range of 3 km (9800 ft) (Ref 47).

Incoherent-to-Coherent Image Converters. Three incoherent-to-coherent image converters are listed in Table 4. Although these devices were primarily developed for large-screen images, they are also potentially useful in real-time analog imaging reconstruction from incoherent light pattern displays of hologram intensity or phase information. The basic common property of these devices is their ability to transform an intensity pattern into a spatial amplitude or phase modulation of a visible wave front; this is accomplished by the reflection or transmission of an interrogating beam through them.

Table 4 Characteristics of incoherent-to-coherent image converters

Device	Threshold of sensitivity, mJ/cm^2	Contrast ratio	Resolution, lines/mm	Read in time, s	Erasure time, s	Operational mode
FERPIC (Ref 48)	$10 \text{ mW}/\text{cm}^2$	40:1	50	1 PVK 0.01 CdS	Same as read in	Storage
γ -Ruticon (Ref 49)	3×10^{-2}	...	80	TV frame rates	0.01 (80%)	Real time
Photoconductor liquid crystal sandwich (Ref 50, 51)	5×10^{-3}	30:1	10-20 (Ref 50, 51)	0.001 (Ref 52) 0.0001 (Ref 51)	$\approx 3 \times 10^{-3}$	Real time or storage

For example, the γ -Ruticon can be used to reconstruct millimeter or microwave holograms using the arrangement shown in Fig. 46. The γ -Ruticon consists of a layered structure made of a conductive transparent substrate (S), a thin photoconductive layer (C), an elastomer (E), and a thin flexible reflective gold electrode (G). A bias voltage, V_B , is applied between the conducting layers, as shown in the detail in Fig. 46. The device is capable of converting the hologram intensity or phase distribution data displayed on the CRT face plate into a demagnified relief pattern of the flexible gold surface. This surface behaves as a phase-modulated hologram from which the image can be retrieved with the aid of a helium-neon laser beam (Ref 47). The device has the advantage of being:

- Repeatedly usable
- Compatible with the CRT display
- Capable of a fast enough response time that allows TV frame rates and therefore real-time operation

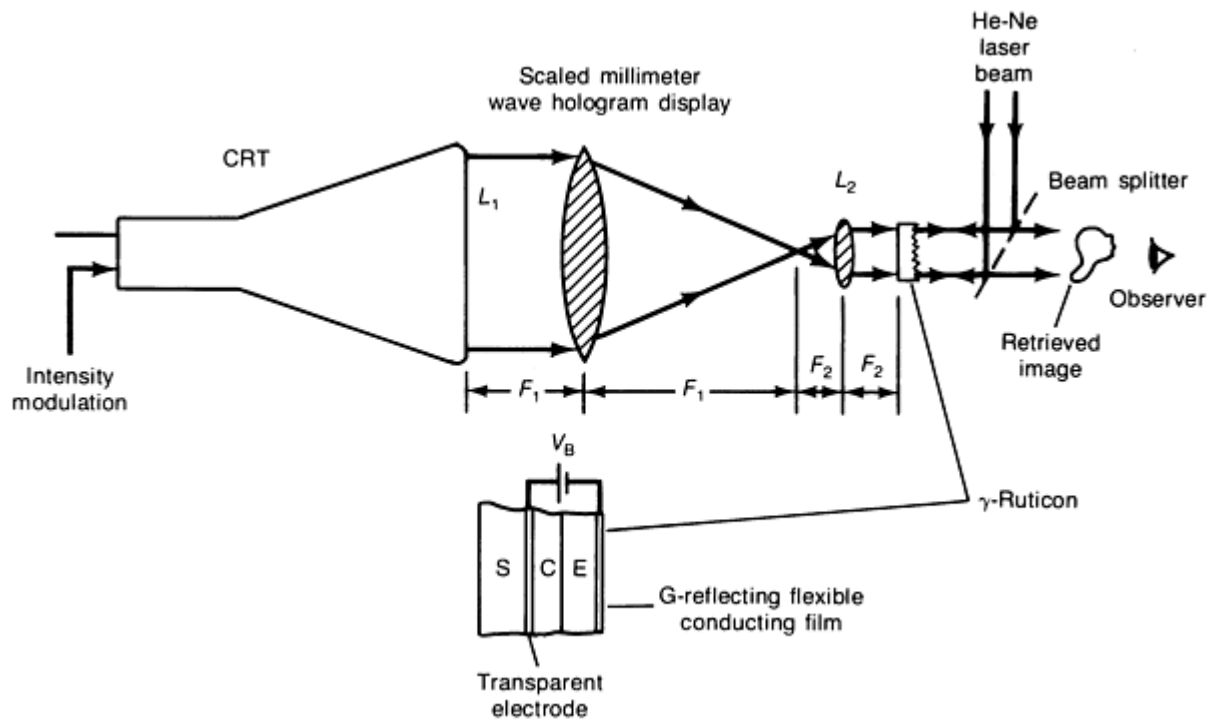

Fig. 46 Real-time millimeter wave hologram reconstruction utilizing a γ -Ruticon. See text for discussion.

Source: Ref 47

Both the photoconductor-liquid crystal sandwich and the ferroelectric photoconductor image camera (FERPIC), a storage and display device, can also be used in real-time image retrieval from microwave holograms by incorporating them in schemes such as that shown in Fig. 46.

Microwaves have been used for flaw detection in some articles, such as solid propellant grains, because of the difficulties involved in their inspection (Ref 54). The resolution of defects has not been particularly successful, especially for spherical voids. Holography and optical data processing are used for microwave inspection because they permit synthetic aperture techniques that integrate wide-angle signals from spherical reflectors and scatterers. This system avoids the use of a spheric correcting lens in CW holograms and in a swept-frequency, side-looking radar, which is useful at very short range.

Microwaves require a very large hologram to record much detail. The use of two very different wavelengths for recording and readout, as described previously, causes some severe problems. As a result, the expected advantages of microwave holography are not realized in terms of a realistic image of the object.

Side-looking radar is another approach. It is more attractive and feasible because there is a method of obtaining depth resolution at close range. The method uses a swept frequency rather than a pulse echo for depth resolution.

An optical coherent signal processor for A-scan data is illustrated in Fig. 47. It uses a collimator, which is a transform lens to produce the transform plane. The image lens produces the output, which is photographically recorded. The results are a series of in-line spots on the film. The first spot is for the front surface. Crack simulations were made and tested at 25, 50, 75, and 102 mm (1, 2, 3, and 4 in.). Each crack was clearly and cleanly defined.

Fig. 47 Coherent processor for optical processing of A-scan data. Source: Ref 47

An A-scan can be readily converted into a B-scan (Ref 54). The horizontal sweep for the oscilloscope, shown in Fig. 48, is replaced by a sweep synchronizer, and a cylinder lens replaces the spherical transform lens in the optical processor. This arrangement, along with three simulated delaminations, superficially resembles a side-looking radar system, but it does not have side-looking radar presentation, and it is further restricted to plane delaminations. Cylindrical flaws were placed in the simulator, but their round shape was not resolved.

Fig. 48 Optical recording of A-scan data. Source: Ref 47

To convert optically processed B-scans to swept-frequency, side-looking radar scans, all that is needed is to perform the optical processing in two dimensions (Ref 54). The scan of the antenna in this case synthesizes a hologram similar to that formed by an incident plane wave and the spherical waves reflected from the object. The incident wave is properly synthesized and serves as the reference beam of the hologram. The object beam travels twice the path from the antenna to the object. This is also true of airborne side-looking radars. The only difference is the way in which depth resolution is obtained. The hologram is composed of one-dimensional interference patterns produced along the scan direction. Their location in the other dimension is determined by the distance from the antenna to the object. The spacing of the interference fringes is also a function of distance, and this causes a tilt to the image plane. In airborne radars, a conical lens is used to make a correction so that all of the object points are imaged in the focal plane.

Fortunately, there is another approach to image formation from this type of hologram. The first step is to produce a Vander Lugt filter. The hologram of a point is made and used to make the Vander Lugt filter (Ref 54). On the hologram, an object point is represented by an interference point. If the pattern is recognizable, the object point that produced it can be identified. The Vander Lugt filter is made with the processor illustrated in Fig. 49. When the filter made in this manner is placed in Fig. 50, the correctly reconstructed image is formed. The filter is used with the processor shown in Fig. 49, which was used to make the filter but without the reference beam inserted by the beam splitter in Fig. 49. The forming of an image from a CW hologram using the Vander Lugt filter is accomplished with the equipment shown in Fig. 50. The processor shown in Fig. 50 will mark a spot on the output frame for each piece of the hologram contained in the input.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Introduction

ULTRASONIC INSPECTION is a nondestructive method in which beams of high-frequency sound waves are introduced into materials for the detection of surface and subsurface flaws in the material. The sound waves travel through the material with some attendant loss of energy (attenuation) and are reflected at interfaces. The reflected beam is displayed and then analyzed to define the presence and location of flaws or discontinuities.

The degree of reflection depends largely on the physical state of the materials forming the interface and to a lesser extent on the specific physical properties of the material. For example, sound waves are almost completely reflected at metal/gas interfaces. Partial reflection occurs at metal/liquid or metal/solid interfaces, with the specific percentage of reflected energy depending mainly on the ratios of certain properties of the material on opposing sides of the interface.

Cracks, laminations, shrinkage cavities, bursts, flakes, pores, disbonds, and other discontinuities that produce reflective interfaces can be easily detected. Inclusions and other inhomogeneities can also be detected by causing partial reflection or scattering of the ultrasonic waves or by producing some other detectable effect on the ultrasonic waves.

Most ultrasonic inspection instruments detect flaws by monitoring one or more of the following:

- Reflection of sound from interfaces consisting of material boundaries or discontinuities within the metal itself
- Time of transit of a sound wave through the testpiece from the entrance point at the transducer to the exit point at the transducer
- Attenuation of sound waves by absorption and scattering within the testpiece
- Features in the spectral response for either a transmitted or a reflected signal

Most ultrasonic inspection is done at frequencies between 0.1 and 25 MHz--well above the range of human hearing, which is about 20 Hz to 20 kHz. Ultrasonic waves are mechanical vibrations; the amplitudes of vibrations in metal parts being ultrasonically inspected impose stresses well below the elastic limit, thus preventing permanent effects on the parts. Many of the characteristics described in this article for ultrasonic waves, especially in the section "General Characteristics of Ultrasonic Waves," also apply to audible sound waves and to wave motion in general.

Ultrasonic inspection is one of the most widely used methods of nondestructive inspection. Its primary application in the inspection of metals is the detection and characterization of internal flaws; it is also used to detect surface flaws, to define bond characteristics, to measure the thickness and extent of corrosion, and (much less frequently) to determine physical properties, structure, grain size, and elastic constants.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Basic Equipment

Most ultrasonic inspection systems include the following basic equipment:

- An electronic signal generator that produces bursts of alternating voltage (a negative spike or a square wave) when electronically triggered
- A transducer (probe or search unit) that emits a beam of ultrasonic waves when bursts of alternating voltage are applied to it
- A couplant to transfer energy in the beam of ultrasonic waves to the testpiece

- A couplant to transfer the output of ultrasonic waves (acoustic energy) from the testpiece to the transducer
- A transducer (can be the same as the transducer initiating the sound or it can be a separate one) to accept and convert the output of ultrasonic waves from the testpiece to corresponding bursts of alternating voltage. In most systems, a single transducer alternately acts as sender and receiver
- An electronic device to amplify and, if necessary, demodulate or otherwise modify the signals from the transducer
- A display or indicating device to characterize or record the output from the testpiece. The display device may be a CRT, sometimes referred to as an oscilloscope; a chart or strip recorder; a marker, indicator, or alarm device; or a computer printout
- An electronic clock, or timer, to control the operation of the various components of the system, to serve as a primary reference point, and to provide coordination for the entire system

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Advantages and Disadvantages

The principal advantages of ultrasonic inspection as compared to other methods for nondestructive inspection of metal parts are:

- Superior penetrating power, which allows the detection of flaws deep in the part. Ultrasonic inspection is done routinely to thicknesses of a few meters on many types of parts and to thicknesses of about 6 m (20 ft) in the axial inspection of parts such as long steel shafts or rotor forgings
- High sensitivity, permitting the detection of extremely small flaws
- Greater accuracy than other nondestructive methods in determining the position of internal flaws, estimating their size, and characterizing their orientation, shape, and nature
- Only one surface needs to be accessible
- Operation is electronic, which provides almost instantaneous indications of flaws. This makes the method suitable for immediate interpretation, automation, rapid scanning, in-line production monitoring, and process control. With most systems, a permanent record of inspection results can be made for future reference
- Volumetric scanning ability, enabling the inspection of a volume of metal extending from front surface to back surface of a part
- Nonhazardous to operations or to nearby personnel and has no effect on equipment and materials in the vicinity
- Portability
- Provides an output that can be processed digitally by a computer to characterize defects and to determine material properties

The disadvantages of ultrasonic inspection include the following:

- Manual operation requires careful attention by experienced technicians
- Extensive technical knowledge is required for the development of inspection procedures
- Parts that are rough, irregular in shape, very small or thin, or not homogeneous are difficult to inspect
- Discontinuities that are present in a shallow layer immediately beneath the surface may not be detectable
- Couplants are needed to provide effective transfer of ultrasonic wave energy between transducers and

- parts being inspected
- Reference standards are needed, both for calibrating the equipment and for characterizing flaws

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Applicability

The ultrasonic inspection of metals is principally conducted for the detection of discontinuities. This method can be used to detect internal flaws in most engineering metals and alloys. Bonds produced by welding, brazing, soldering, and adhesive bonding can also be ultrasonically inspected. In-line techniques have been developed for monitoring and classifying material as acceptable, salvageable, or scrap and for process control. Both line-powered and battery-operated commercial equipment is available, permitting inspection in shop, laboratory, warehouse, or field.

Ultrasonic inspection is used for quality control and materials inspection in all major industries. This includes electrical and electronic component manufacturing; production of metallic and composite materials; and fabrication of structures such as airframes, piping and pressure vessels, ships, bridges, motor vehicles, machinery, and jet engines. In-service ultrasonic inspection for preventive maintenance is used for detecting the impending failure of railroad-rolling-stock axles, press columns, earthmoving equipment, mill rolls, mining equipment, nuclear systems, and other machines and components.

Some of the major types of equipment that are ultrasonically inspected for the presence of flaws are:

- *Mill components:* Rolls, shafts, drives, and press columns
- *Power equipment:* Turbine forgings, generator rotors, pressure piping, weldments, pressure vessels, nuclear fuel elements, and other reactor components
- *Jet engine parts:* Turbine and compressor forgings, and gear blanks
- *Aircraft components:* Forging stock, frame sections, and honeycomb sandwich assemblies
- *Machinery materials:* Die blocks, tool steels, and drill pipe
- *Railroad parts:* Axles, wheels, track, and welded rail
- *Automotive parts:* Forgings, ductile castings, and brazed and/or welded components

The flaws to be detected include voids, cracks, inclusions, pipe, laminations, debonding, bursts, and flakes. They may be inherent in the raw material, may result from fabrication and heat treatment, or may occur in service from fatigue, impact, abrasion, corrosion, or other causes.

Government agencies and standards-making organizations have issued inspection procedures, acceptance standards, and related documentation. These documents are mainly concerned with the detection of flaws in specific manufactured products, but they also can serve as the basis for characterizing flaws in many other applications.

Ultrasonic inspection can also be used to measure the thickness of metal sections. Thickness measurements are made on refinery and chemical-processing equipment, shop plate, steel castings, submarine hulls, aircraft sections, and pressure vessels. A variety of ultrasonic techniques are available for thickness measurements; several use instruments with digital readout. Structural material ranging in thickness from a few thousandths of an inch to several feet can be measured with accuracies of better than 1%. Ultrasonic inspection methods are particularly well suited to the assessment of loss of thickness from corrosion inside closed systems, such as chemical-processing equipment. Such measurements can often be made without shutting down the process. Special ultrasonic techniques and equipment have been used on such diverse problems as the rate of growth of fatigue cracks, detection of borehole eccentricity, measurement of elastic moduli, study of press fits, determination of nodularity in cast iron, and metallurgical research on phenomena such as structure, hardening, and inclusion count in various metals.

For the successful application of ultrasonic inspection, the inspection system must be suitable for the type of inspection being done, and the operator must be sufficiently trained and experienced. If either of these prerequisites is not met, there is a high potential for gross error in inspection results. For example, with inappropriate equipment or with a poorly trained operator, discontinuities having little or no bearing on product performance may be deemed serious, or damaging discontinuities may go undetected or be deemed unimportant.

The term flaw as used in this article means a detectable lack of continuity or an imperfection in a physical or dimensional attribute of a part. The fact that a part contains one or more flaws does not necessarily imply that the part is nonconforming to specification nor unfit for use. It is important that standards be established so that decisions to accept or reject parts are based on the probable effect that a given flaw will have on service life or product safety. Once such standards are established, ultrasonic inspection can be used to characterize flaws in terms of a real effect rather than some arbitrary basis that may impose useless or redundant quality requirements.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

General Characteristics of Ultrasonic Waves

Ultrasonic waves are mechanical waves (in contrast to, for example, light or x-rays, which are electromagnetic waves) that consist of oscillations or vibrations of the atomic or molecular particles of a substance about the equilibrium positions of these particles. Ultrasonic waves behave essentially the same as audible sound waves. They can propagate in an elastic medium, which can be solid, liquid, or gaseous, but not in a vacuum.

In many respects, a beam of ultrasound is similar to a beam of light; both are waves and obey a general wave equation. Each travels at a characteristic velocity in a given homogeneous medium--a velocity that depends on the properties of the medium, not on the properties of the wave. Like beams of light, ultrasonic beams are reflected from surfaces, refracted when they cross a boundary between two substances that have different characteristic sound velocities, and diffracted at edges or around obstacles. Scattering by rough surfaces or particles reduces the energy of an ultrasonic beam, comparable to the manner in which scattering reduces the intensity of a light beam.

Analogy with Waves in Water. The general characteristics of sonic or ultrasonic waves are conveniently illustrated by analogy with the behavior of waves produced in a body of water when a stone is dropped into it. Casual observation might lead to the erroneous conclusion that the resulting outward radial travel of alternate crests and troughs represents the movement of water away from the point of impact. The fact that water is not thus transported is readily deduced from the observation that a small object floating on the water does not move away from the point of impact, but instead merely bobs up and down. The waves travel outward only in the sense that the crests and troughs (which can be compared to the compressions and rarefactions of sonic waves in an elastic medium) and the energy associated with the waves propagate radially outward. The water particles remain in place and oscillate up and down from their normal positions of rest.

Continuing the analogy, the distance between two successive crests or troughs is the wavelength, λ . The fall from a crest to a trough and subsequent rise to the next crest (which is accomplished within this distance) is a cycle. The number of cycles in a specific unit of time is the frequency, f , of the waves. The height of a crest or the depth of a trough in relation to the surface at equilibrium is the amplitude of the waves.

The velocity of a wave and the rates at which the amplitude and energy of a wave decrease as it propagates are constants that are characteristic of the medium in which the wave is propagating. Stones of equal size and mass striking oil and water with equal force will generate waves that travel at different velocities. Stones impacting a given medium with greater energy will generate waves having greater amplitude and energy but the same wave velocity.

The above attributes apply similarly to sound waves, both audible and ultrasonic, propagating in an elastic medium. The particles of the elastic medium move, but they do not migrate from their initial spacial orbits; only the energy travels through the medium. The amplitude and energy of sound waves in the elastic medium depend on the amount of energy supplied. The velocity and attenuation (loss of amplitude and energy) of the sound waves depend on the properties of the medium in which they are propagating.

Wave Propagation. Ultrasonic waves (and other sound waves) propagate to some extent in any elastic material. When the atomic or molecular particles of an elastic material are displaced from their equilibrium positions by any applied force, internal stress acts to restore the particles to their original positions. Because of the interatomic forces between adjacent particles of material, a displacement at one point induces displacements at neighboring points and so on, thus propagating a stress-strain wave. The actual displacement of matter that occurs in ultrasonic waves is extremely small. The amplitude, vibration mode, and velocity of the waves differ in solids, liquids, and gases because of the large differences in the mean distance between particles in these forms of matter. These differences influence the forces of attraction between particles and the elastic behavior of the materials.

The concepts of wavelength, cycle, frequency, amplitude, velocity, and attenuation described in the preceding section "Analogy With Waves in Water" in this article apply in general to ultrasonic waves and other sound waves. The relation of velocity to frequency and wavelength is given by:

$$V = f\lambda \quad (\text{Eq 1})$$

where V is velocity (in meters per second), f is frequency (in hertz), and λ is wavelength (in meters per cycle). Other consistent units of measure can be used for the variables in Eq 1, where convenient.

On the basis of the mode of particle displacement, ultrasonic waves are classified as longitudinal waves, transverse waves, surface waves, and Lamb waves. These four types of waves are described in the following sections.

Longitudinal waves, sometimes called compression waves, are the type of ultrasonic waves most widely used in the inspection of materials. These waves travel through materials as a series of alternate compressions and rarefactions in which the particles transmitting the wave vibrate back and forth in the direction of travel of the waves.

Longitudinal ultrasonic waves and the corresponding particle oscillation and resultant rarefaction and compression are shown schematically in Fig. 1(a); a plot of amplitude of particle displacement versus distance of wave travel, together with the resultant rarefaction trough and compression crest, is shown in Fig. 1(b). The distance from one crest to the next (which equals the distance for one complete cycle of rarefaction and compression) is the wavelength, λ . The vertical axis in Fig. 1(b) could represent pressure instead of particle displacement. The horizontal axis could represent time instead of travel distance because the speed of sound is constant in a given material and because this relation is used in the measurements made in ultrasonic inspection.

Fig. 1 Schematic of longitudinal ultrasonic waves. (a) Particle oscillation and resultant rarefaction and compression. (b) Amplitude of particle displacement versus distance of wave travel. The wavelength, λ , is the distance corresponding to one complete cycle.

Longitudinal ultrasonic waves are readily propagated in liquids and gases as well as in elastic solids. The mean free paths of the molecules of liquids and gases at a pressure of 1 atm are so short that longitudinal waves can be propagated simply by the elastic collision of one molecule with the next. The velocity of longitudinal ultrasonic waves is about 6000 m/s (20,000 ft/s) in steel, 1500 m/s (5000 ft/s) in water, and 330 m/s (1080 ft/s) in air.

Transverse waves (shear waves) are also extensively used in the ultrasonic inspection of materials. Transverse waves are visualized readily in terms of vibrations of a rope that is shaken rhythmically, in which each particle, rather than vibrating parallel to the direction of wave motion as in the longitudinal wave, vibrates up and down in a plane perpendicular to the direction of propagation. A transverse wave is illustrated schematically in Fig. 2, which shows particle oscillation, wave front, direction of wave travel, and the wavelength, λ , corresponding to one cycle.

Fig. 2 Schematic of transverse (shear) waves. The wavelength, λ , is the distance corresponding to one complete cycle.

Unlike longitudinal waves, transverse waves cannot be supported by the elastic collision of adjacent molecular or atomic particles. For the propagation of transverse waves, it is necessary that each particle exhibit a strong force of attraction to its neighbors so that as a particle moves back and forth it pulls its neighbor with it, thus causing the sound to move through the material with the velocity associated with transverse waves, which is about 50% of the longitudinal wave velocity for the same material.

Air and water will not support transverse waves. In gases, the forces of attraction between molecules are so small that shear waves cannot be transmitted. The same is true of a liquid, unless it is particularly viscous or is present as a very thin layer.

Surface waves (Rayleigh waves) are another type of ultrasonic wave used in the inspection of materials. These waves travel along the flat or curved surface of relatively thick solid parts. For the propagation of waves of this type, the waves must be traveling along an interface bounded on one side by the strong elastic forces of a solid and on the other side by the practically negligible elastic forces between gas molecules. Surface waves leak energy into liquid couplants and do not exist for any significant distance along the surface of a solid immersed in a liquid, unless the liquid covers the solid surface only as a very thin film.

Surface waves are subject to attenuation in a given material, as are longitudinal or transverse waves. They have a velocity approximately 90% of the transverse wave velocity in the same material. The region within which these waves propagate with effective energy is not much thicker than about one wavelength beneath the surface of the metal. At this depth, wave energy is about 4% of the wave energy at the surface, and the amplitude of oscillation decreases sharply to a negligible value at greater depths.

Surface waves follow contoured surfaces. For example, surface waves traveling on the top surface of a metal block are reflected from a sharp edge, but if the edge is rounded off, the waves continue down the side face and are reflected at the lower edge, returning to the sending point. Surface waves will travel completely around a cube if all edges of the cube are rounded off. Surface waves can be used to inspect parts that have complex contours.

In surface waves, particle oscillation generally follows an elliptical orbit, as shown schematically in Fig. 3. The major axis of the ellipse is perpendicular to the surface along which the waves are traveling. The minor axis is parallel to the direction of propagation. Surface waves can exist in complex forms that are variations of the simplified waveform illustrated in Fig. 3.

Fig. 3 Diagram of surface (Rayleigh) waves propagating at the surface of a metal along a metal/air interface. The wavelength, λ , is the distance corresponding to one complete cycle.

Lamb waves, also known as plate waves, are another type of ultrasonic wave used in the nondestructive inspection of materials. Lamb waves are propagated in plates (made of composites or metals) only a few wavelengths thick. A Lamb wave consists of a complex vibration that occurs throughout the thickness of the material. The propagation characteristics of Lamb waves depend on the density, elastic properties, and structure of the material as well as the thickness of the testpiece and the frequency. Their behavior in general resembles that observed in the transmission of electromagnetic waves through waveguides.

There are two basic forms of Lamb waves:

- Symmetrical, or dilatational
- Asymmetrical, or bending

The form is determined by whether the particle motion is symmetrical or asymmetrical with respect to the neutral axis of the testpiece. Each form is further subdivided into several modes having different velocities, which can be controlled by the angle at which the waves enter the testpiece. Theoretically, there are an infinite number of specific velocities at which Lamb waves can travel in a given material. Within a given plate, the specific velocities for Lamb waves are complex functions of plate thickness and frequency. The specific velocities of Lamb waves are discussed in Ref 1 and 2.

In symmetrical (dilatational) Lamb waves, there is a compressional (longitudinal) particle displacement along the neutral axis of the plate and an elliptical particle displacement on each surface (Fig. 4a). In asymmetrical (bending) Lamb waves, there is a shear (transverse) particle displacement along the neutral axis of the plate and an elliptical particle displacement on each surface (Fig. 4b). The ratio of the major to minor axes of the ellipse is a function of the material in which the wave is being propagated.

Fig. 4 Diagram of the basic patterns of (a) symmetrical (dilatational) and (b) asymmetrical (bending) Lamb waves. The wavelength, λ , is the distance corresponding to one complete cycle.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Major Variables in Ultrasonic Inspection

The major variables that must be considered in ultrasonic inspection include both the characteristics of the ultrasonic waves used and the characteristics of the parts being inspected. Equipment type and capability interact with these variables; often, different types of equipment must be selected to accomplish different inspection objectives.

The frequency of the ultrasonic waves used affects inspection capability in several ways. Generally, a compromise must be made between favorable and adverse effects to achieve an optimum balance and to overcome the limitations imposed by equipment and test material.

Sensitivity, or the ability of an ultrasonic inspection system to detect a very small discontinuity, is generally increased by using relatively high frequencies (short wavelengths). Resolution, or the ability of the system to give simultaneous, separate indications from discontinuities that are close together both in depth below the front surface of the testpiece and in lateral position, is directly proportional to frequency band-width and inversely related to pulse length. Resolution generally improves with an increase of frequency.

Penetration, or the maximum depth (range) in a material from which useful indications can be detected, is reduced by the use of high frequencies. This effect is most pronounced in the inspection of metal that has coarse grain structure or minute inhomogeneities, because of the resultant scattering of the ultrasonic waves; it is of little consequence in the inspection of fine-grain, homogeneous metal.

Beam spread, or the divergence of an ultrasonic beam from the central axis of the beam, is also affected by frequency. As frequency decreases, the shape of an ultrasonic beam increasingly departs from the ideal of zero beam spread. This characteristic is so pronounced as to be observed at almost all frequencies used in inspection. Other factors, such as the transducer (search unit) diameter and the use of focusing equipment, also affect beam spread; these are discussed in greater detail in the sections "Beam Spreading" and "Acoustic Lenses" in this article. Sensitivity, resolution, penetration, and beam spread are largely determined by the selection of the transducer and are only slightly modified by changes in other test variables.

Acoustic Impedance. When ultrasonic waves traveling through one medium impinge on the boundary of a second medium, a portion of the incident acoustic energy is reflected back from the boundary while the remaining energy is transmitted into the second medium. The characteristic that determines the amount of reflection is the acoustic impedance of the two materials on either side of the boundary. If the impedances of the two materials are equal, there will be no reflection; if the impedances differ greatly (as between a metal and air, for example), there will be virtually complete reflection. This characteristic is used in the ultrasonic inspection of metals to calculate the amounts of energy reflected and transmitted at impedance discontinuities and to aid in the selection of suitable materials for the effective transfer of acoustic energy between components in ultrasonic inspection systems.

The acoustic impedance for a longitudinal wave, Z_l , given in grams per square centimeter-second, is defined as the product of material density, ρ , given in grams per cubic centimeter, and longitudinal wave velocity, V_l , given in centimeters per second:

$$Z_l = \rho V_l \tag{Eq 2}$$

The acoustic properties of several metals and nonmetals are listed in Table 1. The acoustic properties of metals and alloys are influenced by variations in structure and metallurgical condition. Therefore, for a given testpiece the properties may differ somewhat from the values listed in Table 1.

Table 1 Acoustic properties of several metals and nonmetals

The percentage of incident energy reflected from the interface between two materials depends on the ratio of acoustic impedances (Z_2/Z_1) and the angle of incidence. When the angle of incidence is 0° (normal incidence), the reflection coefficient, R , which is the ratio of reflected beam intensity, I_r , to incident beam intensity, I_i , is given by:

$$R = I_r/I_i = [(Z_2 - Z_1)/(Z_2 + Z_1)]^2 = [(r - 1)/(r + 1)]^2 \quad (\text{Eq 3})$$

where Z_1 is the acoustic impedance of medium 1, Z_2 is the acoustic impedance of medium 2, and r equals Z_2/Z_1 and is the impedance ratio, or mismatch factor. With T designating the transmission coefficient, $R + T = 100\%$, because all the energy is either reflected or transmitted, and T is simply obtained from this relation.

The transmission coefficient, T , can also be calculated as the ratio of the intensity of the transmitted beam, I_t , to that of the incident beam, I_i , from:

$$T = I_t/I_i = 4Z_2Z_1/(Z_2 + Z_1)^2 = 4r/(r + 1)^2 \quad (\text{Eq 4})$$

When a longitudinal ultrasonic wave in water (medium 1) is incident at right angles to the surface of an aluminum alloy 1100 testpiece (medium 2), the percentages of acoustic energy reflected and transmitted are calculated as shown below (the calculations are based on data from Table 1):

$$\begin{aligned} \text{Impedance ratio } (r) &= Z_2/Z_1 = 1.72/0.149 = 11.54 \\ \text{Reflection coefficient } (R) &= [(r - 1)/(r + 1)]^2 = (10.54/12.54)^2 = 0.71 = 71\% \\ \text{Transmission coefficient } (T) &= 1 - R = 0.29 = 29\% \end{aligned}$$

The same values are obtained for R and T when medium 1 is the aluminum alloy and medium 2 is water. For any pair of materials, reversing the order of the materials does not change the values of R and T .

Angle of Incidence. Only when an ultrasonic wave is incident at right angles on an interface between two materials (normal incidence; that is, angle of incidence = 0°) do transmission and reflection occur at the interface without any change in beam direction. At any other angle of incidence, the phenomena of mode conversion (a change in the nature of the wave motion) and refraction (a change in direction of wave propagation) must be considered. These phenomena may affect the entire beam or only a portion of the beam, and the sum total of the changes that occur at the interface depends on the angle of incidence and the velocity of the ultrasonic waves leaving the point of impingement on the interface. All possible ultrasonic waves leaving this point are shown for an incident longitudinal ultrasonic wave in Fig. 5. Not all the waves shown in Fig. 5 will be produced in any specific instance of oblique impingement of an ultrasonic wave on the interface between two materials. The waves that propagate in a given instance depend on the ability of a waveform to exist in a given material, the angle of incidence of the initial beam, and the velocities of the waveforms in both materials.

Fig. 5 Diagram showing relationship (by vectors) of all possible reflected and refracted waves to an incident longitudinal wave of velocity $V_{l(1)}$ impinging on an interface at angle α_i relative to normal to the interface. See text for explanation of vectors.

The general law that describes wave behavior at an interface is known as Snell's law. Although originally derived for light waves, Snell's law applies to acoustic waves (including ultrasound) and to many other types of waves. According to Snell's law, the ratio of the sine of the angle of incidence to the sine of the angle of reflection or refraction equals the ratio of the corresponding wave velocities. Snell's law applies even if mode conversion takes place. Mathematically, Snell's law can be expressed as:

$$\sin \alpha / \sin \beta = V_1 / V_2 \quad (\text{Eq 5})$$

where α is the angle of incidence, β is the angle of reflection or refraction, and V_1 , and V_2 are the respective velocities of the incident and reflected or refracted waves. Both α and β are measured from a line normal to the interface.

Equation 6 is the general relationship applying to reflection and refraction, taking into account all possible effects of mode conversion for an incident longitudinal ultrasonic wave, as shown in Fig. 5:

$$\begin{aligned} \sin \alpha_i / V_{l(1)} &= \sin \alpha'_i / V_{l(1)} = \sin \alpha'_t / V_{t(1)} \\ \sin \beta_l / V_{l(2)} &= \sin \beta_t / V_{t(2)} \end{aligned} \quad (\text{Eq 6})$$

where α_i is the angle of incidence for incident longitudinal wave in material 1, α'_i is the angle of reflection for reflected longitudinal wave in material 1 = α_i , α'_t is the angle of reflection for reflected transverse wave in material 1, β_l is the angle of refraction for refracted longitudinal wave in material 2, β_t is the angle of refraction for refracted transverse wave in material 2, $V_{l(1)}$ is the velocity of incident longitudinal wave in material 1 = velocity of reflected longitudinal wave in material 1, $V_{t(1)}$ is the velocity of reflected transverse wave in material 1, $V_{l(2)}$ is the velocity of refracted longitudinal wave in material 2, and $V_{t(2)}$ is the velocity of refracted transverse wave in material 2.

For quantities that are shown in Fig. 5 but do not appear in Eq 6, β_s is the angle of refraction for refracted surface (Rayleigh) wave in material 2 = 90° , and $V_{s(2)}$ is the velocity of refracted surface (Rayleigh) wave in material 2. Equation 6 can apply to similar relationships for an incident transverse (instead of longitudinal) wave by substituting the term $\sin \alpha'_t / V_{t(1)}$ for the first term, $\sin \alpha_i / V_{l(1)}$. Correspondingly, in Fig. 5, the incident longitudinal wave at angle α_i , (with velocity $V_{l(1)}$ in material 1) would be replaced by an incident transverse angle α_t equal to α'_t (with velocity $V_{t(1)}$).

Critical Angles. If the angle of incidence (α_i , Fig. 5) is small, sound waves propagating in a given medium may undergo mode conversion at a boundary, resulting in the simultaneous propagation of longitudinal and transverse (shear)

waves in a second medium. If the angle is increased, the direction of the refracted longitudinal wave will approach the plane of the boundary ($\beta_1 \rightarrow 90^\circ$). At some specific value of α_1 , β_1 will exactly equal 90° , above which the refracted longitudinal wave will no longer propagate in the material, leaving only a refracted (mode-converted) shear wave to propagate in the second medium. This value of α_1 is known as the first critical angle. If α_1 is increased beyond the first critical angle, the direction of the refracted shear wave will approach the plane of the boundary ($\beta_1 \rightarrow 90^\circ$). At a second specific value of α_1 , β_1 will exactly equal 90° , above which the refracted transverse wave will no longer propagate in the material. This second value of α_1 is called the second critical angle.

Critical angles are of special importance in ultrasonic inspection. Values of α_1 between the first and second critical angles are required for most angle-beam inspections. Surface wave inspection is accomplished by adjusting the incident angle of a contact-type search unit so that it is a few tenths of a degree greater than the second critical angle. At this value, the refracted shear wave in the bulk material is replaced by a Rayleigh wave traveling along the surface of the testpiece. As mentioned earlier in this article, Rayleigh waves can be effectively sustained only when the medium on one side of the interface (in this case, the surface of the testpiece) is a gas. Consequently, surface wave inspection is primarily used with contact methods.

In ordinary angle-beam inspection, it is usually desirable to have only a shear wave propagating in the test material. Because longitudinal waves and shear waves propagate at different speeds, echo signals will be received at different times, depending on which type of wave produced the echo. When both types are present in the test material, confusing echo patterns may be shown on the display device, which can lead to erroneous interpretations of testpiece quality. Frequently, it is desirable to produce shear waves in a material at an angle of 45° to the surface. In most materials, incident angles for mode conversion to a 45° shear wave lie between the first and second critical angles. Typical values of α_1 for all three of these--first critical angle, second critical angle, and incident angle for mode conversion to 45° shear waves--are listed in Table 2 for various metals.

Table 2 Critical angles for immersion and contact testing, and incident angle for 45° shear wave transmission, in various metals

Beam Intensity. The intensity of an ultrasonic beam is related to the amplitude of particle vibrations. Acoustic pressure (sound pressure) is the term most often used to denote the amplitude of alternating stresses exerted on a material by a propagating ultrasonic wave. Acoustic pressure is directly proportional to the product of acoustic impedance and amplitude of particle motion. The acoustic pressure exerted by a given particle varies in the same direction and with the same frequency as the position of that particle changes with time. Acoustic pressure is the most important property of an ultrasonic wave, and its square determines the amount of energy (acoustic power) in the wave. It should be noted that acoustic pressure is not the intensity of the ultrasonic beam. Intensity, which is the energy transmitted through a unit cross-sectional area of the beam, is proportional to the square of acoustic pressure.

Although transducer elements sense acoustic pressure, ultrasonic systems do not measure acoustic pressure directly. However, receiver-amplifier circuits of most ultrasonic instruments are designed to produce an output voltage proportional to the square of the input voltage from the transducer. Therefore, the signal amplitude of sound that is displayed on an oscilloscope or other readout device is a value proportional to the true intensity of the reflected sound.

The law of reflection and refraction described in Eq 5 or 6 gives information regarding only the direction of propagation of reflected and refracted waves and says nothing about the acoustic pressure in reflected or refracted waves. When ultrasonic waves are reflected or refracted, the energy in the incident wave is partitioned among the various reflected and refracted waves. The relationship among acoustic energies in the resultant waves is complex and depends both on the angle of incidence and on the acoustic properties of the matter on opposite sides of the interface.

Figure 6 shows the variation of acoustic pressure (not energy) with angle of reflection or refraction (α_1 , β_1 , or β_t , Fig. 5) that results when an incident longitudinal wave in water having an acoustic pressure of 1.0 arbitrary unit impinges on the surface of an aluminum testpiece. At normal incidence ($\alpha_1 = \alpha_1' = \beta_1 = 0^\circ$), acoustic energy is partitioned between a reflected longitudinal wave in water and a refracted (transmitted) longitudinal wave in aluminum. Because of different acoustic impedances, this partition induces acoustic pressures of about 0.8 arbitrary unit in the reflected wave in water and about 1.9 units in the transmitted wave in aluminum. Although it may seem anomalous that the transmitted wave has a higher acoustic pressure than the incident wave, it must be recognized that it is acoustic energy, not acoustic pressure, that is partitioned and conserved. Figure 7 illustrates the partition of acoustic energy at a water/steel interface.

Fig. 6 Variation of acoustic pressure with angle of reflection or refraction during immersion ultrasonic inspection of aluminum. The acoustic pressure of the incident wave equals 1.0 arbitrary unit. Points A and A' correspond to the first critical angle, and point B to the second critical angle, for this system.

Fig. 7 Partition of acoustic energy at a water/steel interface. The reflection coefficient, R , is equal to $1 - (L + S)$, where L is the transmission coefficient of the longitudinal wave and S is the transmission coefficient of the transverse (or shear) wave.

In Fig. 6, as the incident angle, α_1 , is increased, there is a slight drop in the acoustic pressure of the reflected wave, a corresponding slight rise in the acoustic pressure of the refracted longitudinal wave, and a sharper rise in the acoustic pressure of the refracted transverse wave. At the first critical angle for the water/aluminum interface ($\alpha_1 = 13.6^\circ$, $\beta_1 = 90^\circ$, and $\beta_2 = 29.2^\circ$), the acoustic pressure of the longitudinal waves reaches a peak, and the refracted waves go rapidly to zero (point A', Fig. 6). Between the first and second critical angles, the acoustic pressure in the reflected longitudinal wave in water varies as shown between points A and B in Fig. 6. The refracted longitudinal wave in aluminum meanwhile has disappeared. Beyond the second critical angle ($\alpha_1 = 28.8^\circ$), the transverse wave in aluminum disappears, and there is total reflection at the interface with no partition of energy and no variation in acoustic pressure, as shown to right of point B in Fig. 6.

Curves similar to those in Fig. 6 can be constructed for the reverse instance of incident longitudinal waves in aluminum impinging on an aluminum/water interface, for incident transverse waves in aluminum, and for other combinations of wave types and materials. Details of this procedure are available in Ref 1. These curves are important because they indicate the angles of incidence at which energy transfer across the boundary is most effective. For example, at an aluminum/water interface, peak transmission of acoustic pressure for a returning transverse wave echo occurs in the sector from about 16 to 22° in the water relative to a line normal to the interface. Consequently, 35 to 51° angle beams in

aluminum are the most efficient in transmitting detectable echoes across the front surface during immersion inspection and can therefore resolve smaller discontinuities than beams directed at other angles in the aluminum.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Attenuation of Ultrasonic Beams

The intensity of an ultrasonic beam that is sensed by a receiving transducer is considerably less than the intensity of the initial transmission. The factors that are primarily responsible for the loss in beam intensity can be classified as transmission losses, interference effects, and beam spreading.

Transmission losses include absorption, scattering, and acoustic impedance effects at interfaces. Interference effects include diffraction and other effects that create wave fringes, phase shift, or frequency shift. Beam spreading involves mainly a transition from plane waves to either spherical or cylindrical waves, depending on the shape of the transducer-element face. The wave physics that completely describe these three effects are discussed in Ref 1 and 2.

Acoustic impedance effects (see the section "Acoustic Impedance" in this article) can be used to calculate the amount of sound that reflects during the ultrasonic inspection of a testpiece immersed in water. For example, when an ultrasonic wave impinges at normal incidence ($\alpha_1 = 0^\circ$) to the surface of the flaw-free section of aluminum alloy 1100 plate during straight-beam inspection, the amount of sound that returns to the search unit (known as the back reflection) has only 6% of its original intensity. This reduction in intensity occurs because of energy partition when waves are only partly reflected at the aluminum/water interfaces. (Additional losses would occur because of absorption and scattering of the ultrasonic waves, as discussed in the sections "Absorption" and "Scattering" in this article.)

Similarly, an energy loss can be calculated for a discontinuity that constitutes an ideal reflecting surface, such as a lamination that is normal to the beam path and that interposes a metal/air interface larger than the sound beam. For example, in the straight-beam inspection of an aluminum alloy 1100 plate containing a lamination, the final returning beam, after partial reflection at the front surface of the plate and total reflection from the lamination, would have a maximum intensity 8% of that of the incident beam. By comparison, only 6% was found for the returning beam from the plate that did not contain a lamination. Similar calculations of the energy losses caused by impedance effects at metal/water interfaces for the ultrasonic immersion inspection of several of the metals listed in Table 1 yield the following back reflection intensities, which are expressed as a percentage of the intensity of the incident beam:

Material	Back reflection intensity, % of incident beam intensity
Magnesium alloy M1A	11.0
Titanium	3.0

Type 302 stainless steel	1.4
Carbon steel	1.3
Inconel	0.7
Tungsten	0.3

The loss in intensity of returning ultrasonic beams is one basis for characterizing flaws in metal testpieces. As indicated above, acoustic impedance losses can severely diminish the intensity of an ultrasonic beam. Because a small fraction of the area of a sound beam is reflected from small discontinuities, it is obvious that ultrasonic instruments must be extremely sensitive to small variations in intensity if small discontinuities are to be detected. The sound intensity of contact techniques is usually greater than that of immersion techniques; that is, smaller discontinuities will result in higher amplitude signals. Two factors are mainly responsible for this difference, as follows.

First, the back surface of the testpiece is a metal/air interface, which can be considered a total reflector. Compared to a metal/water interface, this results in an approximately 30% increase in back reflection intensity at the receiving search unit for an aluminum testpiece coupled to the search unit through a layer of water.

Second, if a couplant whose acoustic impedance more nearly matches that of the testpiece is substituted for the water, more energy is transmitted across the interface for both the incident and returning beams. For most applications, any couplant with an acoustic impedance higher than that of water is preferred. Several of these are listed in the nonmetals group in Table 1. In addition to the liquid couplants listed in Table 1, several semisolid or solid couplants (including wallpaper paste, certain greases, and some adhesives) have higher acoustic impedances than water.

The absorption of ultrasonic energy occurs mainly by the conversion of mechanical energy into heat. Elastic motion within a substance as a sound wave propagates through it alternately heats the substance during compression and cools it during rarefaction. Because heat flows so much more slowly than an ultrasonic wave, thermal losses are incurred, and this progressively reduces energy in the propagating wave. A related thermal loss occurs in polycrystalline materials; a thermoelastic loss arises from heat flow away from grains that have received more compression or expansion in the course of wave motion than did adjacent grains. For most polycrystalline materials, this effect is most pronounced at the low end of the ultrasonic frequency spectrum.

Vibrational stress in ferromagnetic and ferroelectric materials generated by the passage of an acoustic wave can cause motion of domain walls or rotation of domain directions. These effects may cause domains to be strengthened in directions parallel, antiparallel, or perpendicular to the direction of stress. Energy losses in ferromagnetic and ferroelectric materials may also be caused by a microhysteresis effect, in which domain wall motion or domain rotation lags behind the vibrational stress to produce a hysteresis loop.

In addition to the types of losses discussed above, other types exist that have not been accounted for quantitatively. For example, it has been suggested that some losses are caused by elastic-hysteresis effects due to cyclic displacements of dislocations in grains or grain boundaries of metals.

Absorption can be thought of as a braking action on the motion of oscillating particles. This braking action is more pronounced when oscillations are more rapid, that is, at high frequencies. For most materials, absorption losses increase directly with frequency.

Scattering of an ultrasonic wave occurs because most materials are not truly homogeneous. Crystal discontinuities, such as grain boundaries, twin boundaries, and minute nonmetallic inclusions, tend to deflect small amounts of ultrasonic energy out of the main ultrasonic beam. In addition, especially in mixed microstructures or anisotropic materials, mode conversion at crystallite boundaries tends to occur because of slight differences in acoustic velocity and acoustic impedance across the boundaries.

Scattering is highly dependent on the relation of crystallite size (mainly grain size) to ultrasonic wavelength. When grain size is less than 0.01 times the wavelength, scatter is negligible. Scattering effects vary approximately with the third power of grain size, and when the grain size is 0.1 times the wavelength or larger, excessive scattering may make it impossible to conduct valid ultrasonic inspections.

In some cases, determination of the degree of scattering can be used as a basis for acceptance or rejection of parts. Some cast irons can be inspected for the size and distribution of graphite flakes, as described in the section "Determination of Microstructural Differences" in this article. Similarly, the size and distribution of microscopic voids in some powder metallurgy parts, or of strengtheners in some fiber-reinforced or dispersion-strengthened materials, can be evaluated by measuring attenuation (scattering) of an ultrasonic beam.

Diffraction. A sound beam propagating in a homogeneous medium is coherent; that is, all particles that lie along any given plane parallel to the wave front vibrate in identical patterns. When a wave front passes the edge of a reflecting surface, the front bends around the edge in a manner similar to that in which light bends around the edge of an opaque object. When the reflector is very small compared to the sound beam, as is usual for a pore or an inclusion, wave bending (forward scattering) around the edges of the reflector produces an interference pattern in a zone immediately behind the reflector because of phase differences among different portions of the forward-scattered beam. The interference pattern consists of alternate regions of maximum and minimum intensity that correspond to regions where interfering scattered waves are respectively in phase and out of phase.

Diffraction phenomena must be taken into account during the development of ultrasonic inspection procedures. Unfortunately, only qualitative guidelines can be provided. Entry-surface roughness, type of machined surface, and machining direction influence inspection procedures. In addition, the roughness of a flaw surface affects its echo pattern and must be considered.

A sound beam striking a smooth interface is reflected and refracted; but the sound field maintains phase coherence, and beam behavior can be analytically predicted. A rough interface, however, modifies boundary conditions, and some of the beam energy is diffracted. Beyond the interface, a coherent wave must re-form through phase reinforcement and cancellation; the wave then continues to propagate as a modified wave.

The influence on the beam depends on the roughness, size, and contour of the modifying interface. For example, a plane wave striking a diaphragm containing a single hole one wavelength in diameter will propagate as a spherical wave from a point (Huygens) source. The wave from a larger hole will re-form in accordance with the number of wavelengths in the diameter. In ultrasonic inspection, a 2.5 μm (100 $\mu\text{in.}$) surface finish may have little influence at one inspection frequency and search-unit diameter, but may completely mask subsurface discontinuities at other inspection frequencies or search-unit diameters.

Near-Field and Far-Field Effects. The face of an ultrasonic-transducer crystal does not vibrate uniformly under the influence of an impressed electrical voltage. Rather, the crystal face vibrates in a complex manner that can be most easily described as a mosaic of tiny, individual crystals, each vibrating in the same direction but slightly out of phase with its neighbors. Each element in the mosaic acts like a point (Huygens) source and radiates a spherical wave outward from the plane of the crystal face. Near the face of the crystal, the composite sound beam propagates chiefly as a plane wave, although spherical waves emanating from the periphery of the crystal face produce short-range ultrasonic beams referred to as side lobes. Because of interference effects, as these spherical waves encounter one another in the region near the crystal face, a spatial pattern of acoustic pressure maximums and minimums is set up in the composite sound beam. The region in which these maximums and minimums occur is known as the near field (Fresnel field) of the sound beam.

Along the central axis of the composite sound beam, the series of acoustic pressure maximums and minimums becomes broader and more widely spaced as the distance from the crystal face, d , increases. Where d becomes equal to N (with N denoting the length of the near field), the acoustic pressure reaches a final maximum and decreases approximately exponentially with increasing distance, as shown in Fig. 8. The length of the near field is determined by the size of the radiating crystal and the wave-length, λ , of the ultrasonic wave. For a circular radiator of diameter D , the length of the near field can be calculated from:

$$N = \frac{(D^2 - \lambda^2)}{4\lambda} \quad (\text{Eq 7})$$

When the wavelength is small with respect to the crystal diameter, the near-field length can be approximated by:

$$N = \frac{D^2}{4\lambda} = \frac{A}{\pi\lambda}$$

(Eq 8)

where *A* is the area of the crystal face.

Fig. 8 Variation of acoustic pressure with distance ratio for a circular search unit. Distance ratio is the distance from the crystal face, *d*, divided by the length of the near field, *N*.

At distances greater than *N*, known as the far field of the ultrasonic beam, there are no interference effects. At distances from *N* to about 3*N* from the face of a circular radiator, there is a gradual transition to a spherical wave front. At distances of more than about 3*N*, the ultrasonic beam from a rectangular radiator more closely resembles a cylindrical wave, with the wave front being curved about an axis parallel to the long dimension of the rectangle.

Near-field and far-field effects also occur when ultrasonic waves are reflected from interfaces. The reasons are similar to those for near-field and far-field effects for transducer crystals; that is, reflecting interfaces do not vibrate uniformly in response to the acoustic pressure of an impinging sound wave. Near-field lengths for circular reflecting interfaces can be calculated from Eq 7 and 8. Table 3 lists near-field lengths corresponding to several combinations of radiator diameter and ultrasonic frequency. The values in Table 3 were calculated from Eq 7 for circular radiators in a material having a sonic velocity of 6 km/s (4 miles/s) and closely approximate actual lengths of near fields for longitudinal waves in steel, aluminum alloys, and certain other materials. Values for radiators with diameters of 25, 13, and 10 mm (1, $\frac{1}{2}$, and $\frac{3}{8}$ in.) correspond to typical search-unit sizes, and values for radiators with diameters of 3 and 1.5 mm ($\frac{1}{8}$ and 0.060 in.) correspond to typical hole sizes in standard reference blocks.

Table 3 Near-field lengths for circular radiators in a material having a sonic velocity of 6 km/s (4 miles/s)

Frequency, MHz	Wavelength		Near-field length for radiator with diameter of:									
			25 mm (1 in.)		13 mm ($\frac{1}{2}$ in.)		9.5 mm ($\frac{3}{8}$ in.)		3.2 mm ($\frac{1}{8}$ in.)		1.5 mm (0.060 in.)	
	mm	in.	cm	in.	cm	in.	cm	in.	cm	in.	cm	in.

1.0	6.0	0.24	2.5	1.0	0.52	0.20	0.23	0.09
2.0	3.0	0.12	5.3	2.1	1.3	0.50	0.68	0.27	0.009	0.0035
5.0	1.2	0.04	13.4	5.3	3.3	1.3	1.9	0.75	0.18	0.07	0.02	0.008
10.0	0.6	0.02	27	11	6.7	2.6	3.8	1.5	0.40	0.16	0.08	0.03
15.0	0.4	0.015	40	16	10	4.0	5.7	2.2	0.62	0.24	0.14	0.055
25.0	0.24	0.009	67	26	17	6.7	9.4	3.7	1.04	0.41	0.24	0.095

Beam Spreading. In the far field of an ultrasonic beam, the wave front expands with distance from a radiator. The angle of divergence from the central axis of the beam from a circular radiator is determined from ultrasonic wavelength and radiator size as follows:

$$\gamma = 2 \sin^{-1} \left(0.5 \frac{\lambda}{D} \right) \quad (\text{Eq 9})$$

where γ is the angle of divergence in degrees, λ is the ultrasonic wavelength, and D is the diameter of a circular radiator. Equation 9 is valid only for small values of λ/D , that is, only when the beam angle is small.

When the radiator is not circular, the angle of divergence cannot be assessed accurately by applying Eq 9. For noncircular search units, beam spreading is most accurately found experimentally.

Beam diameter also depends on the diameter of the radiator and the ultrasonic wavelength. The theoretical equation for -6 dB pulse-echo beam diameter is:

$$\text{-6 dB beam diameter} = 1.032 \frac{D}{4} \cdot S \quad (\text{Eq 10})$$

where S is the focusing factor and is ≤ 1 . Focusing the transducer ($S < 1$) produces a smaller beam. For a flat (that is, nonfocused) transducer ($S = 1$), the beam has a diameter of $0.25 D$ at the near-field distance N , where N depends on the ultrasonic wavelength as defined in Eq 7.

The overall attenuation of an ultrasonic wave in the far field can be expressed as:

$$P = P_0 \exp (-\alpha L) \quad (\text{Eq 11})$$

where P_0 and P are the acoustic pressures at the beginning and end, respectively, of a section of material having a length L and an attenuation coefficient α . Attenuation coefficients are most often expressed in nepers per centimeter or decibels per millimeter. Both nepers and decibels are units based on logarithms--nepers on natural logarithms (base e) and decibels on common logarithms (base 10). Numerically, the value of α in decibels per millimeter (dB/mm) is equal to 0.868 the value in nepers per centimeter.

A table of exact attenuation coefficients for various materials, if such data could be determined, would be of doubtful value. Ultrasonic inspection is a process subject to wide variation in responses, and these variations are highly dependent on structure and properties in each individual testpiece. Attenuation determines mainly the depth to which ultrasonic

inspection can be performed as well as the signal amplitude from reflectors with a testpiece. Table 4 lists the types of materials and approximate maximum inspection depth corresponding to low, medium, and high attenuation coefficients. Inspection depth is also influenced by the decibel gain built into the receiver-amplifier of an ultrasonic instrument and by the ability of the instrument to discriminate between low-amplitude echoes and electronic noise at high gain settings.

Table 4 Approximate attenuation coefficients and useful depths of inspection for various metallic and nonmetallic materials

Using 2-MHz longitudinal waves at room temperature

Attenuation coefficient, dB/mm (dB/in.)	Useful depth of inspection, m (ft)	Type of material inspected
Low: 0.001-0.01 (0.025-0.25)	1-10 (3-30)	Cast metals: aluminum ^(a) , magnesium ^(a) . Wrought metals: steel, aluminum, magnesium, nickel, titanium, tungsten, uranium
Medium: 0.01-0.1 (0.25-2.5)	0.1-1 (0.3-3)	Cast metals^(b): steel ^(c) , high-strength cast iron, aluminum ^(d) , magnesium ^(d) . Wrought metals^(b): copper, lead, zinc. Nonmetals: sintered carbides ^(b) , some plastics ^(e) , some rubbers ^(e)
High: >0.1 (>2.5)	0-0.1 (0-0.3)^(f)	Cast metals^(b): steel ^(d) , low-strength cast iron, copper, zinc. Nonmetals^(e): porous ceramics, filled plastics, some rubbers

- (a) Pure or slightly alloyed.
- (b) Attenuation mostly by scattering.
- (c) Plain carbon or slightly alloyed.
- (d) Highly alloyed.
- (e) Attenuation mostly by absorption.
- (f) Excessive attenuation may preclude inspection.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Basic Inspection Methods

The two major methods of ultrasonic inspection are the transmission method and the pulse-echo method. The primary difference between these two methods is that the transmission method involves only the measurement of signal attenuation, while the pulse-echo method can be used to measure both transit time and signal attenuation.

The pulse-echo method, which is the most widely used ultrasonic method, involves the detection of echoes produced when an ultrasonic pulse is reflected from a discontinuity or an interface of a testpiece. This method is used in flaw location and thickness measurements. Flaw depth is determined from the time-of-flight between the initial pulse and the echo produced by a flaw. Flaw depth might also be determined by the relative transit time between the echo produced by a flaw and the echo from the back surface. Flaw sizes are estimated by comparing the signal amplitudes of reflected sound from an interface (either within the testpiece or at the back surface) with the amplitude of sound reflected from a reference reflector of known size or from the back surface of a testpiece having no flaws.

The transmission method, which may include either reflection or through transmission, involves only the measurement of signal attenuation. This method is also used in flaw detection. In the pulse-echo method, it is necessary that an internal flaw reflect at least part of the sound energy onto a receiving transducer. However, echoes from flaws are not essential to their detection. Merely the fact that the amplitude of the back reflection from a testpiece is lower than that from an identical workpiece known to be free of flaws implies that the testpiece contains one or more flaws. The technique of detecting the presence of flaws by sound attenuation is used in transmission methods as well as in the pulse-echo method. The main disadvantage of attenuation methods is that flaw depth cannot be measured.

The principles of each of these two inspection methods are discussed in the following sections, along with corresponding forms of data presentation, interpretation of data, and effects of operating variables. Subsequent sections describe various components and systems for ultrasonic inspection, reference standards, and inspection procedures and applications. In addition, the article "Boilers and Pressure Vessels" in this Volume contains information on advanced ultrasonic techniques.

The application of ultrasonic techniques also involves other methods, such as acoustical holography, acoustical microscopy, the frequency modulation technique, spectral analysis, and sound conduction. The first two of these methods are discussed in the articles "Acoustical Holography" and "Acoustic Microscopy" in this Volume. The other three methods are briefly summarized below.

The frequency modulation (FM) method, which was the precursor of the pulse-echo method, is another flaw detection technique. In the FM method, the ultrasonic pulses are transmitted in wave packets whose frequency varies linearly with time. The frequency variation is repeated in successive wave packets so that a plot of frequency versus time has a sawtooth pattern. There is a time delay between successive packets. Returning echoes are displayed on the readout device only if they have certain characteristics as determined by the electronic circuitry in the instrument. Although not as widely used as the pulse-echo method, the FM method has a lower signal-to-noise ratio and therefore somewhat greater resolving power.

Spectral analysis, which can be used in the through transmission or pulse-echo methods, involves determination of the frequency spectrum of an ultrasonic wave after it has propagated through a testpiece. The frequency spectrum can be determined either by transmitting a pulse and using a fast Fourier transform to obtain the frequency spectrum of the received signal or by sweeping the transmission frequency in real time and acquiring the response at each frequency. The increasing use of the pulse method is attributed to improvements in the speed of digital fast Fourier transform devices.

Spectral analysis is used in transducer evaluations and may be useful in defect characterization. However, because the spectral signatures of defects are influenced by several other factors (such as the spectrum of the input pulse, coupling details, and signal attenuation), defect characterization primarily involves the qualitative interpretation of echoes in the time domain (see the section "Interpretation of Pulse-Echo Data" in this article).

Spectral analysis can also be used to measure the thickness of thin-wall specimens. A short pulse of ultrasound is a form of coherent radiation; in a thin-wall specimen that produces front and back wall echoes, the two reflected pulses show phase differences and can interfere coherently. If the pulse contains a wide band of frequencies, interference maxima and minima can occur at particular frequencies, and these can be related to the specimen thickness.

Sound conduction is utilized in flaw detection by monitoring the intensity of arbitrary waveforms at a given point on the testpiece. These waveforms transmit ultrasonic energy, which is fed into the testpiece at some other point without the existence of a well-defined beam path between the two points. This method is of relatively minor importance and is not discussed in this article.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Pulse-Echo Methods

In pulse-echo inspection, short bursts of ultrasonic energy (pulses) are introduced into a testpiece at regular intervals of time. If the pulses encounter a reflecting surface, some or all of the energy is reflected. The proportion of energy that is reflected is highly dependent on the size of the reflecting surface in relation to the size of the incident ultrasonic beam. The direction of the reflected beam (echo) depends on the orientation of the reflecting surface with respect to the incident beam. Reflected energy is monitored; both the amount of energy reflected in a specific direction and the time delay between transmission of the initial pulse and receipt of the echo are measured.

Principles of Pulse-Echo Methods

Most pulse-echo systems consist of:

- An electronic clock
- An electronic signal generator, or pulser
- A sending transducer
- A receiving transducer
- An echo-signal amplifier
- A display device

In the most widely used version of pulse-echo systems, a single transducer acts alternately as a sending and receiving transducer. The clock and signal generator are usually combined in a single electronic unit. Frequently, circuits that amplify and demodulate echo signals from the transducer are housed in the same unit. Specific characteristics of transducers and other equipment are discussed in subsequent sections of this article.

A pulse-echo system with a single transducer operates as follows. At regular intervals, the electronic clock triggers the signal generator, which imposes a short interval of high-frequency alternating voltage or a unipolar (negative) spike on the transducer. Simultaneously, the clock activates a time-measuring circuit connected to the display device. The operator can preselect a constant interval between pulses by means of a pulse-repetition rate control on the instrument; pulses are usually repeated 60 to 2000 times per second. In most commercially available flaw detectors, the pulse-repetition rate is controlled automatically except for some larger systems. Also, most systems are broadband when they transmit, but may be tuned or filtered for reception. The operator can also preselect the output frequency of the signal generator. For best results, the frequency (and sometimes the pulse-repetition rate) should be tuned to achieve the maximum response of the transducer (resonance in the vibrating element) and maximum signal-to-noise ratio (lowest amount of electronic noise) in the electronic equipment.

The transducer then converts the pulse of voltage into a pulse of mechanical vibration having essentially the same frequency as the imposed alternating voltage. The mechanical vibration (ultrasound) is introduced into a testpiece through a couplant and travels by wave motion through the testpiece at the velocity of sound, which depends on the material. When the pulse of ultrasound encounters a reflecting surface that is perpendicular to the direction of travel, ultrasonic energy is reflected and returns to the transducer. The returning pulse travels along the same path and at the same speed as the transmitted pulse, but in the opposite direction. Upon reaching the transducer through the couplant, the returning pulse causes the transducer element to vibrate, which induces an alternating electrical voltage across the transducer. The induced voltage is instantaneously amplified (and sometimes demodulated), then fed into the display device. This process

of alternately sending and receiving pulses of ultrasonic energy is repeated for each successive pulse, with the display device recording any echoes each time.

Theoretically, the maximum depth of inspection is controlled by the pulse-repetition rate. For example, if a 10 MHz pulse is transmitted at a pulse-repetition rate of 500 pulses per second, a longitudinal wave pulse can travel almost 12 m (40 ft) in steel or aluminum before the next pulse is triggered. This means one pulse can travel to a depth of 6 m (20 ft) and return before the next pulse is initiated.

Practically, however, inspection can be performed only to a depth that is considerably less than the theoretical maximum. Sound attenuation in a testpiece can limit the path length. The practical limit varies with the type and condition of the test material, test frequency, and system sensitivity. Furthermore, it is highly desirable for all ultrasonic vibrations (including successively re-reflected echoes of the first reflected pulse) to die out in the testpiece before the next initial pulse is introduced. As a rule, the pulse-repetition rate should be set so that one pulse can traverse the testpiece enough times to dissipate the sonic energy to a nondisplayable level before the next pulse is triggered. Both sound attenuation and pulse reverberation are of little consequence except when inspecting large parts (for example, in the axial inspection of long shafts).

Pulse-echo inspection can be accomplished with longitudinal, shear, surface, or Lamb waves. Straight-beam or angle-beam techniques can be used, depending on testpiece shape and inspection objectives. Data can be analyzed in terms of type, size, location, and orientation of flaws, or any combination of these factors. It should be noted, however, that some forms of data presentation are inherently unable to pin-point the location of flaws unless the flaws are favorably oriented with respect to the transmitted sonic beam. Similarly, type, location, and orientation of flaws often influence the procedures and techniques used to estimate flaw size.

Sometimes it is advantageous to use separate sending and receiving transducers for pulse-echo inspection. (Separate transducers are always used for through transmission inspection.) Depending mainly on geometric considerations, as discussed later in this article, these separate transducers can be housed in a single search unit or in two separate search units. The term pitch-catch is often used in connection with separate sending and receiving transducers, regardless of whether reflection methods or transmission methods are involved.

Presentation of Pulse-Echo Data

Information from pulse-echo inspection can be displayed in different forms. The basic data formats include:

- *A-scans*: This format provides a quantitative display of signal amplitudes and time-of-flight data obtained at a single point on the surface of the testpiece. The A-scan display, which is the most widely used format, can be used to analyze the type, size, and location (chiefly depth) of flaws
- *B-scans*: This format provides a quantitative display of time-of-flight data obtained along a line of the testpiece. The B-scan display shows the relative depth of reflectors and is used mainly to determine size (length in one direction), location (both position and depth), and to a certain degree the shape and orientation of large flaws
- *C-scans*: This format provides a semiquantitative or quantitative display of signal amplitudes obtained over an area of the testpiece surface. This information can be used to map out the position of flaws on a plan view of the testpiece. A C-scan format also records time-of-flight data, which can be converted and displayed by image-processing equipment to provide an indication of flaw depth

A-scan and B-scan data are usually presented on an oscilloscope screen; C-scan data are recorded by an x - y plotter or displayed on a computer monitor. With computerized data acquisition and image processing, the display formats can be combined or processed into more complex displays.

A-scan display is basically a plot of amplitude versus time, in which a horizontal baseline on an oscilloscope screen indicates elapsed time while the vertical deflections (called indications or signals) represent echoes (Fig. 9). Flaw size can be estimated by comparing the amplitude of a discontinuity signal with that of a signal from a discontinuity of known size and shape; the discontinuity signal also must be corrected for distance losses.

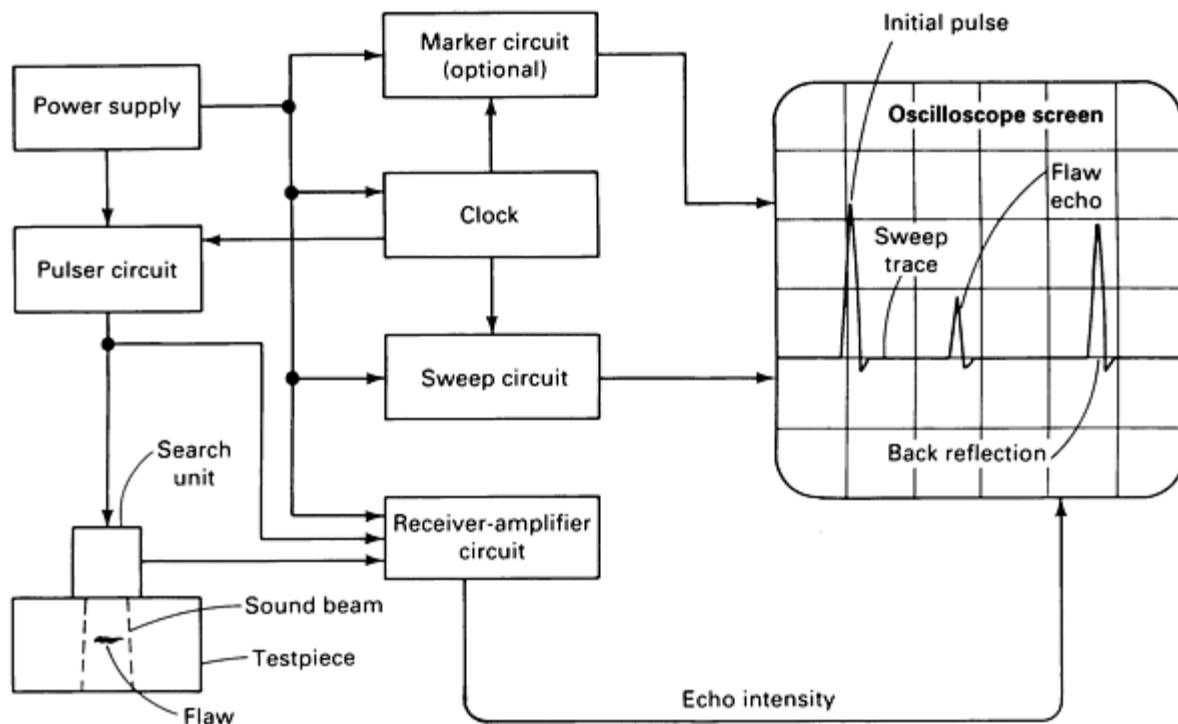

Fig. 9 Typical block diagram of an analog A-scan setup, including video-mode display, for basic pulse-echo ultrasonic inspection

Flaw location (depth) is determined from the position of the flaw echo on the oscilloscope screen. With a calibrated time base (the horizontal sweep of the oscilloscope), flaw location can be measured from the position of its echo on the horizontal scale calibrated to represent sound travel within the test object. The zero point on this scale represents the entry surface of the testpiece.

Display Modes. A-scan data can be displayed in either of two modes--radio frequency (RF) mode, in which the individual cycles comprising each pulse are visible in the trace; or video mode, in which only a rectified voltage corresponding to the envelope of the RF wave packet is displayed. The video mode is usually suitable for ordinary ultrasonic inspection, but certain applications demand use of the RF mode for optimum characterization of flaws.

System Setup. A typical A-scan setup that illustrates the essential elements in a basic system for pulse-echo inspection is shown in Fig. 9. These elements include:

- Power supply, which may run on alternating current or batteries
- Electronic clock, or timing circuit, to trigger pulser and display circuits
- Pulser circuit, or rate generator, to control frequency, amplitude, and pulse-repetition rate of the voltage pulses that excite the search unit
- Receiver-amplifier circuit to convert output signals from the search unit into a form suitable for oscilloscope display
- Sweep circuit to control (a) time delay between search-unit excitation and start of oscilloscope trace and (b) rate at which oscilloscope trace travels horizontally across the screen
- Oscilloscope screen, including separate controls for trace brightness, trace focus, and illuminated measuring grid

The search unit and the coaxial cable, although not strictly part of the electronic circuitry, must be matched to the electronics. Otherwise, the response of the transducer element to excitation voltages and the output voltage corresponding to echo vibrations can exhibit excessive ringing or an apparently low sensitivity.

Signal Display. The oscilloscope screen in Fig. 9 illustrates a typical video-mode A-scan display for a straight-beam test (as defined earlier in this section). The trace exhibits a large signal corresponding to the initial pulse, shown at left on the screen, and a somewhat smaller signal corresponding to the back reflection, at right on the screen. Between these two signals are indications of echoes from any interfaces within the testpiece; one small signal corresponding to the flaw shown in the testpiece, also illustrated in Fig. 9, appears between the initial pulse and the back reflection on the screen. The depth of the flaw can be quickly estimated by visual comparison of its position on the main trace relative to the positions of the initial pulse and back reflection. Its depth can be more accurately measured by counting the number of vertical reference lines from either the initial pulse or the back reflection of the flaw signal location on the screen in Fig. 9.

Applications. The A-scan display is not limited to the detection and characterization of flaws; it can also be used for measuring thickness, sound velocities in materials of known thickness, attenuation characteristics of specific materials, and beam spread of ultrasonic beams. Commercial instruments are usually adequate for these purposes, as well as for detecting the small cracks, porosity, and inclusions that are within the limits of resolution for the particular instrument and inspection technique. In addition to conventional single-transducer pulse-echo inspection, A-scan display can be used with transmission or reflection techniques that involve separate sending and receiving transducers.

B-scan display is a plot of time versus distance, in which one orthogonal axis on the display corresponds to elapsed time, while the other axis represents the position of the transducer along a line on the surface of the testpiece relative to the position of the transducer at the start of the inspection. Echo intensity is not measured directly as it is in A-scan inspection, but is often indicated semiquantitatively by the relative brightness of echo indications on an oscilloscope screen. A B-scan display can be likened to an imaginary cross section through the testpiece where both front and back surfaces are shown in profile. Indications from reflecting interfaces within the testpiece are also shown in profile, and the position, orientation, and depth of such interfaces along the imaginary cutting plane are revealed.

System Setup. A typical B-scan system is shown in Fig. 10. The system functions are identical to the A-scan system except for the following differences.

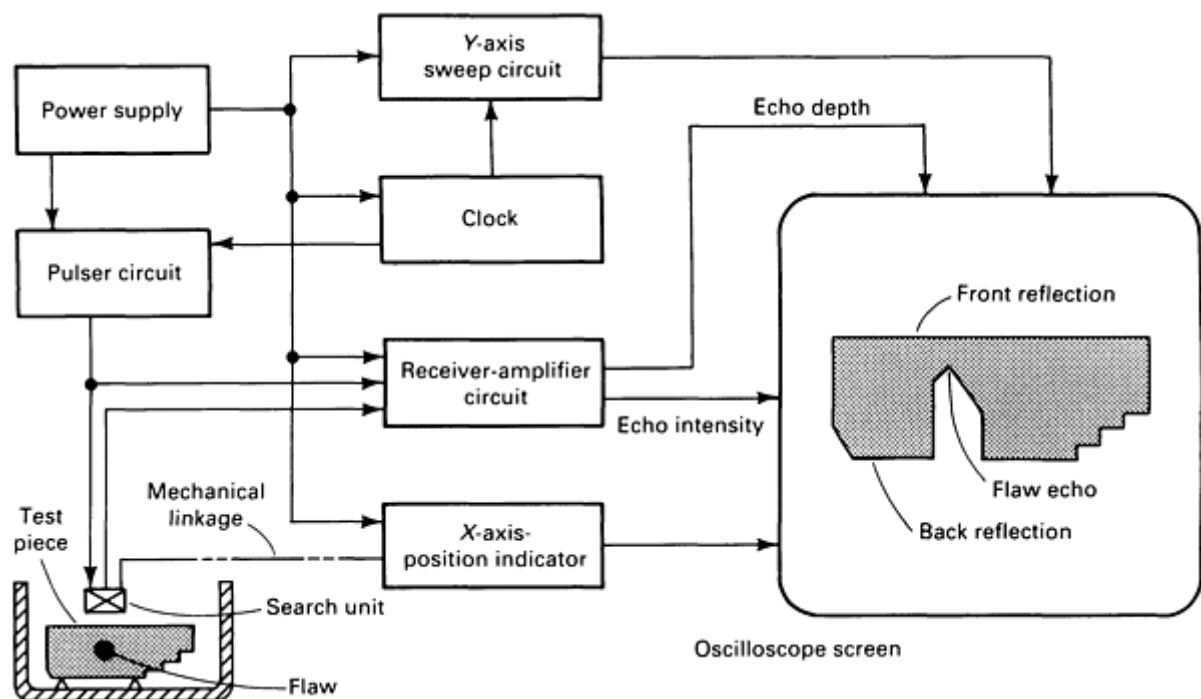

Fig. 10 Typical B-scan setup, including video-mode display, for basic pulse-echo ultrasonic inspection

First, the display is generated on an oscilloscope screen that is composed of a long-persistence phosphor, that is, a phosphor that continues to fluoresce long after the means of excitation ceases to fall on the fluorescing area of the screen. This characteristic of the oscilloscope in a B-scan system allows the imaginary cross section to be viewed as a whole without having to resort to permanent imaging methods, such as photographs. (Photographic equipment, facsimile

recorders, or x - y plotters can be used to record B-scan data, especially when a permanent record is desired for later reference.)

Second, the oscilloscope input for one axis of the display is provided by an electromechanical device that generates an electrical voltage or digital signals proportional to the position of the transducer relative to a reference point on the surface of the testpiece. Most B-scans are generated by scanning the search unit in a straight line across the surface of the testpiece at a uniform rate. One axis of the display, usually the horizontal axis, represents the distance traveled along this line.

Third, echoes are indicated by bright spots on the screen rather than by deflections of the time trace. The position of a bright spot along the axis orthogonal to the search-unit position axis, usually measured top to bottom on the screen, indicates the depth of the echo within the testpiece.

Finally, to ensure that echoes are recorded as bright spots, the echo-intensity signal from the receiver-amplifier is connected to the trace-brightness control on the oscilloscope. In some systems, the brightnesses corresponding to different values of echo intensity may exhibit enough contrast to enable semiquantitative appraisal of echo intensity, which is related to flaw size and shape.

Signal Display. The oscilloscope screen in Fig. 10 illustrates the type of video-mode display that is generated by B-scan equipment. On this screen, the internal flaw in the testpiece shown at left in Fig. 10 is shown only as a profile view of its top reflecting surface. Portions of the testpiece that are behind this large reflecting surface are in shadow. The flaw length in the direction of search-unit travel is recorded, but the width (in a direction mutually perpendicular to the sound beam and the direction of search-unit travel) is not recorded except as it affects echo intensity and therefore echo-image brightness. Because the sound beam is slightly conical rather than truly cylindrical, flaws near the back surface of the testpiece appear longer than those near the front surface.

Applications. The chief value of B-scan presentations is their ability to reveal the distribution of flaws in a part on a cross section of that part. Although B-scan techniques have been more widely used in medical applications than in industrial applications, B-scans can be used for the rapid screening of parts and for the selection of certain parts, or portions of certain parts, for more thorough inspection with A-scan techniques. Optimum results from B-scan techniques are generally obtained with small transducers and high frequencies.

C-scan display records echoes from the internal portions of testpieces as a function of the position of each reflecting interface within an area. Flaws are shown on a readout, superimposed on a plan view of the testpiece, and both flaw size (flaw area) and position within the plan view are recorded. Flaw depth normally is not recorded, although it can be measured semiquantitatively by restricting the range of depths within the testpiece that is covered in a given scan. With an increasing number of C-scan systems designed with on-board computers, other options in image processing and enhancement have become widely used in the presentation of flaw depth and the characterization of flaws. An example of a computer-processed C-scan image is shown in Fig. 11, in which a graphite-epoxy sample with impact damage was examined using time-of-flight data. The depth of damage is displayed with a color scale in the original photograph.

Fig. 11 Time-of-flight C-scan image of impact damage in graphite-epoxy laminate supported by two beams (arrows)

System Setup. In a basic C-scan system, shown schematically in Fig. 12, the search unit is moved over the surface of the testpiece in a search pattern. The search pattern may take many forms; for example, a series of closely spaced parallel lines, a fine raster pattern, or a spiral pattern (polar scan). Mechanical linkage connects the search unit to x -axis and y -axis position indicators, which in turn feed position data to the x - y plotter or facsimile device. Echorecording systems vary; some produce a shaded-line scan with echo intensity recorded as a variation in line shading, while others indicate flaws by an absence of shading so that each flaw shows up as a blank space on the display (Fig. 12).

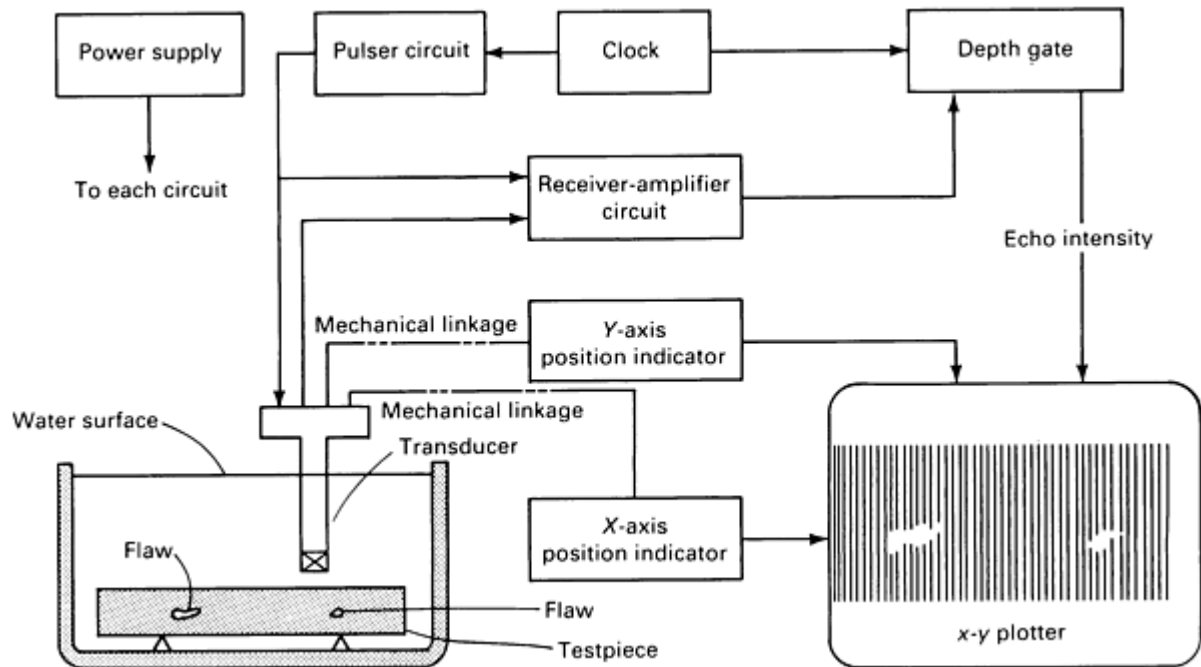

Fig. 12 Typical C-scan setup, including display, for basic pulse-echo ultrasonic immersion inspection

Gating. An electronic depth gate is another essential element in C-scan systems. A depth gate is an electronic circuit that allows only those echo signals that are received within a limited range of delay times following the initial pulse or interface echo to be admitted to the receiver-amplifier circuit. Usually, the depth gate is set so that front reflections and back reflections are just barely excluded from the display. Thus, only echoes from within the testpiece are recorded, except for echoes from thin layers adjacent to both surfaces of the testpiece. Depth gates are adjustable. By setting a depth gate for a narrow range of delay times, echo signals from a thin slice of the testpiece parallel to the scanned surface can be recorded, with signals from other portions being excluded from the display.

Some C-scan systems, particularly automatic units, incorporate additional electronic gating circuits for marking, alarming, or charting. These gates can record or indicate information such as flaw depth or loss of back reflection, while the main display records an overall picture of flaw distribution.

Interpretation of Pulse-Echo Data

The interpretation of pulse-echo data is relatively straightforward for B-scan and C-scan presentations. The B-scan always records the front reflection, while internal echoes or loss of back reflection, or both, are interpreted as flaw indications. Flaw depth is measured as the distance from the front reflection to a flaw echo, with the latter representing the front surface of the flaw. The length of a flaw can be measured as a proportion of the scan length or can be estimated visually in relation to total scan length or to the size of a known feature of the testpiece. The position of a flaw can be determined by measuring its position along the scan with respect to either a predetermined reference point or a known feature of the

testpiece. C-scan presentations are interpreted mainly by comparing the x and y coordinates of any flaw indication with the x and y coordinates of either a predetermined reference point or a known feature of the testpiece. The size of a flaw is estimated as a percentage of the scanned area. If a known feature is the size or position reference for the interpretation of either B-scan or C-scan data, it is presumed that this feature produces an appropriate echo image on the display.

In contrast to normal B-scan and C-scan displays, A-scan displays are sometimes quite complex. They may contain electronic noise, spurious echoes, or extra echoes resulting from scattering or mode conversion of the transmitted or interrogating pulse, all of which must be disregarded in order to focus attention on any flaw echoes that may be present. Furthermore, flaw echoes may exhibit widely varying shapes and amplitudes. Accurate interpretation of an A-scan display depends on the ability of the operator to:

- Recognize the type of flaw based on echo shape or echo-intensity effects
- Determine flaw location by accurately measuring echo position on the time trace
- Estimate flaw size, mainly from echo amplitudes with or without simultaneously manipulating the search unit
- Assess the quality of the testpiece by evaluating the A-scan data in terms of appropriate specifications or reference standards

Basic A-scan displays are of the type shown in Fig. 13 for the immersion inspection of a plate containing a flaw. The test material was 25 mm (1 in.) thick aluminum alloy 1100 plate containing a purely reflecting planar flaw. The flaw depth was 45% of plate thickness (11.25 mm, or 0.44 in.), exactly parallel to the plate surfaces, and had an area equal to one-third the cross section of the sound beam. Straight-beam immersion testing was done in a water-filled tank. There were negligible attenuation losses within the test plate, only transmission losses across front and back surfaces.

Fig. 13 Schematic of straight-beam immersion inspection of a 25 mm (1 in.) thick aluminum alloy 1100 plate containing a planar discontinuity showing (a) inspection setup, (b) complete video-mode A-scan display, and (c) normal oscilloscope display

Figures 13(a), 13(b), and 13(c), respectively, illustrate the inspection setup, the complete video-mode A-scan display, and the normal video-mode display as seen on the oscilloscope screen. The normal display (Fig. 13c) represents only a portion

of the complete display (Fig. 13b). The normal display is obtained by adjusting two of the oscilloscope controls (horizontal position and horizontal sweep) to display only the portion of the trace corresponding to the transit time (time of flight) required for a single pulse of ultrasound to traverse the testpiece from front surface to back surface and return. Also, the gain in the receiver-amplifier is adjusted so that the height of the first back reflection equals some arbitrary vertical distance on the screen, usually a convenient number of grid lines.

As illustrated in Fig. 13(b), there is a tendency for echoes to reverberate, that is, to bounce back and forth between reflecting surfaces. Each time an echo is reflected from the front surface, a portion of the sound wave energy escapes through the boundary to impinge on the transducer and produce an indication on the display. In Fig. 13(b), the indications labeled 1 through 6 are reverberations of the back reflection, those labeled A through K are reverberations of the primary flaw echo, and those labeled X through Z are reverberations of a subordinate flaw echo induced by re-reflection of the first back reflection.

Only a few types of flaws will produce the types of indications described above. Most flaws are not exactly parallel to the surface of the testpiece, not truly planar but have rough or curved interfaces, not ideal reflectors, and of unknown size. These factors, together with the specific sound-attenuating characteristics of the bulk material, affect the shape and size of the echo signals. The following sections describe how specific material conditions produce and modify A-scan indications.

Echo shape is primarily affected by the shape, orientation, and sound-reflecting characteristics of an interface. Metal/air interfaces produce sharp indications if the interfaces are relatively smooth and essentially parallel to the front surface. If an interface is curved (such as the surface of a large pore) or rough (such as a crack, seam, or lamination) or if it is not ideally reflecting (such as the surface of a metallic inclusion or a slag inclusion), the interface will produce a broadened echo indication, as shown in Fig. 14. If the interface is smaller in area than the cross section of the ultrasonic beam or if ultrasonic waves are transmitted through the interface, a back-surface echo (back reflection) will appear to the right of the flaw echo on the oscilloscope screen, as shown in Fig. 14(a). However, if the flaw is larger than the ultrasonic beam or if the back surface is not normal to the direction of wave travel, no back reflection will appear on the screen, as shown in Fig. 14(b). Often, the amplitude of a broad indication will decrease with increasing depth, as in Fig. 14(b), especially when the echo is from a crack, seam, or lamination rather than an inclusion. Sometimes, especially if the echo is from a spherical flaw or from an interface that is not at right angles to the sound beam, the echo amplitude will increase with depth.

Fig. 14 A-scan displays of broadened-echo indications from curved rough or scattering interfaces showing (a) indications with back reflection and (b) indications without back reflection. See text for discussion.

Echo amplitude, which is a measure of the intensity of a reflected sound beam, is a direct function of the area of the reflecting interface for flat parallel reflectors. If the interface is round or curved or is not perpendicular to the sound beam, echo amplitude will be reduced. The effects of roughness, shape, and orientation of the interface on echo amplitude must be understood because these factors introduce errors in estimates of flaw size.

Flaw size is most often estimated by comparing the amplitude of an echo from an interface of unknown size with the amplitude of echoes from flat-bottom holes of different diameter in two or more reference blocks. To compensate for any sound attenuation within the testpiece, these guidelines should be followed:

- Reference holes should be about the same depth from the front (entry) surface of the reference block as the flaw is from the front surface of the testpiece
- Reference blocks should be made of material with acoustic properties similar to those of the testpiece
- The sound beam should be larger than the flaw. (This can best be determined by moving the search unit back and forth on the surface of the part being inspected relative to a position centered over the flaw and observing the effect on both flaw echo and back reflection. If the search unit can be moved slightly without affecting the height of either the flaw echo or back reflection, it can be assumed that the sound beam is sufficiently larger than the flaw)
- Control settings on the instrument and physical arrangement of search unit, couplant, and specimen are the same regardless of whether the specimen is a testpiece or a reference block

In practice, a calibration curve is constructed using reference blocks, as described in the section "Determination of Area-Amplitude and Distance-Amplitude Curves" in this article. Flaw size is then determined by reading the hole size corresponding to the amplitude of the flaw echo directly from the calibration curve. Flaw size determined in this manner is only an estimate of minimum size and should not be assumed equal to the actual flaw size. The amount of sound energy reflected back to the search unit will be less than that from a flat-bottom hole of equal size if an interface has a surface rougher than the bottom surfaces of the reference holes, is oriented at an angle other than 90° to the sound beam, is curved, or transmits some of the sound energy rather than acting as an ideal reflector. Therefore, to produce equal echo heights, actual flaws having any of these characteristics must be larger than the minimum size determined from the calibration curve. This is why flaw sizes are frequently reported as being no smaller than x , where x is the flaw size that has been estimated from the calibration curve.

It may seem logical to estimate flaw size by comparing the amplitude of a flaw echo to the amplitude of the back reflection. Although an assumption that the ratio of flaw-echo height to back reflection amplitude is equal to the ratio of flaw area to sound beam cross section has been used in the past, this assumption should be considered to be completely unreliable, even when distance-amplitude corrections are applied.

Loss of Back Reflection. If a flaw is larger than a few percent of the cross section of a sound beam, the amplitude of the back reflection is less than that of a similar region of the testpiece (or of another testpiece) that is free of flaws. Because sound travels essentially in straight lines, the reflecting interfaces within the testpiece (flaws) cast sound shadows on the back surface, in a manner similar to that in which opaque objects introduced into a beam of light cast shadows on a screen. Sound shadows reduce the amount of energy reflected from the back surface by reducing the effective area of the sound beam. The back reflection is not reduced in direct proportion to the percentage of the original sound beam intercepted by the flaw; the exact proportion varies widely. This effect is termed loss of back reflection, regardless of whether the back-surface signal echo is lost completely or merely reduced in amplitude.

A flaw indication is produced when an internal interface reflects sound onto the receiving transducer. A loss of back reflection can occur even if no flaw indication appears on the A-scan display. If the sound is reflected to the side, where the reflection cannot be picked up by the transducer, there is still a loss of back reflection because of the shadow effect. This provides an additional means of detecting the presence of flaws. Although no direct indication shows on the oscilloscope screen, the size of a flaw can be estimated from the percentage lost from the height of the back reflection indication. This estimate is generally less accurate than an estimate made from an actual flaw indication. There is no assurance that only one flaw produces a given loss of back reflection; other factors, such as excessive roughness of the back surface or internal microporosity, can also reduce the amplitude of the back reflection.

One means of distinguishing whether a certain loss of back reflection is due to the presence of identifiable flaws is to move the search unit back and forth about a mean position over the suspected flaw. If the back reflection rises and falls as the search unit is moved, the presence of specific identifiable flaws can be presumed. Angle-beam techniques or other nondestructive inspection methods can then be used for positive identification of the flaw. However, if the back reflection remains relatively steady as the search unit is moved but the amplitude of the indication is measurably lower than the expected or standard value, the material presumably contains many small flaws distributed over a relatively broad region.

This material condition may or may not be amenable to further study using other ultrasonic techniques or other nondestructive methods.

Spurious indications from reflections or indications of sources other than discontinuities are always a possibility. Reflections from edges and corners, extra reflections due to mode conversion, and multiple reflections from a single interface often look like flaw indications. Sometimes, these false, or nonrelevant, indications can be detected by correlation of the apparent flaw location with some physical feature of the testpiece. On other occasions, only the experience of the operator and thorough preliminary analysis of probable flaw types and locations can separate nonrelevant indications due to echoes from actual flaws. As a rule, any indication that remains consistent in amplitude and appearance as the search unit is moved back and forth on the surface of the testpiece should be suspected of being a nonrelevant indication if it can be correlated with a known reflective or geometric boundary. Nonrelevant indications are more likely to occur in certain types of inspection--for example, in longitudinal wave inspection from one end of a long shaft, inspection of complex-shape testpieces, inspection of parts where mixed longitudinal and shear waves may be present, and various applications of shear wave or surface wave techniques.

There are certain other types of indications that may interfere with the interpretation of A-scan data. All electronic circuits generate a certain amount of noise consisting of high-frequency harmonics of the main-signal frequency. Electronic noise is generally of low amplitude and is troublesome only when the main signal is also of low amplitude. In ultrasonic inspection, electronic noise can appear on an A-scan display as a general background, or waviness (called grass), in the main trace at all depths (Fig. 15a). This waviness, or grass, is more pronounced at the higher gain settings. Many instruments are equipped with reject circuits that filter out grass, although usually with some attendant loss of echo-signal amplitude, as shown in Fig. 15(b). When reject circuits are used, they should be adjusted so that grass is reduced only enough not to be a hindrance. If too much rejection is used, small-amplitude echoes will be suppressed along with the grass, and there will be a loss in sensitivity of the inspection technique and the linearity of the instrument will be affected.

Fig. 15 A-scan displays showing (a) appearance of electronic noise as waviness (grass) and (b) grass filtered out by use of a reject circuit with some attendant loss of echo-signal amplitude

A second type of interference occurs when coarse-grain materials are inspected. Reflections from the grain boundaries of coarse-grain materials can produce spurious indications throughout the test depth (Fig. 16). This type of interference, called hash, is most often encountered in coarse-grain steels; it is less troublesome with fine-grain steels or nonferrous metals. Sometimes, hash can be suppressed by adjusting the frequency and pulse length of the ultrasonic waves so that the sound beam is less sensitive to grain-boundary interfaces.

Fig. 16 A-scan display showing coarse-grain indications (hash) that interfere with detection of discontinuities

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection

Angle-Beam Techniques

In angle-beam techniques, the incident sound pulse enters the testpiece at an oblique angle instead of at a right angle. In contrast with straight-beam tests, this approach eliminates echoes from the front and back surfaces and only displays reflections from discontinuities that are normal to the incident beam. Only rarely will a back surface be oriented properly to give a back reflection indication.

Figure 17 shows the arrangement of an angle-beam technique with a contact transducer on a pipe and a plate. The sound beam enters the test material at an angle and propagates by successive zigzag reflections from the specimen boundaries until it is interrupted by a discontinuity or boundary where the beam reverses direction and is reflected back to the transducer. According to the angle selected, the wave modes produced in the test material may be mixed longitudinal and shear, shear only, or surface modes. Usually, angle-beam testing is accomplished with shear waves, although refracted longitudinal waves or surface waves can be used in some applications.

Fig. 17 Angle-beam testing with a contact transducer on a plate (a) and pipe (b)

Angle-beam techniques are used for testing welds, pipe or tubing, sheet and plate material, and specimens of irregular shape (such as welds) where straight beams are unable to contact all of the surface. Angle-beam techniques are also useful in flaw location when there is a loss of back reflection. In flaw location, the time base (horizontal scale) on the oscilloscope must be carefully calibrated because in angle-beam testing there is no back reflection echo to provide a reference for depth estimates of the flaw. Usually, an extended time base is used so that flaws are located with one or two skip distances from the search unit (see Fig. 17 for the definition of skip distance).

Figure 17(a) shows how a shear wave from an angle-beam transducer progresses through a flat testpiece--by reflecting from the surfaces at points called "nodes". The linear distance between two successive nodes on the same surface is called the "skip distance" and is important in defining the path over which the transducer should be moved for reliable and efficient scanning. The skip distance can easily be measured by using a separate receiving transducer to detect the nodes or by using an angle-beam test block, or it can be calculated. Once the skip distance is known, the region over which the transducer should be moved to scan can be determined.

Moving the search unit back and forth between one-half skip distance and one skip distance from an area of interest can be used not only for the purpose of defining the location, depth, and size of a flaw but also for the general purpose of initially detecting flaws. Figure 18 illustrates this back-and-forth movement as a way of scanning a weld for flaws.

Fig. 18 Three positions of the contact type of transducer along the zigzag scanning path used during the manual angle-beam ultrasonic inspection of welded joints. The movement of the sound beam path across the weld is shown on a section taken along the centerline of the transducer as it is moved from the far left position in the scanning path (a), through an intermediate position (b), to the far right position (c).

Sometimes, moving the search unit in an arc about the position of a suspected flaw or swiveling the search unit about a fixed position can be equally useful (Fig. 19a). As shown in Fig. 19(b), traversing the search unit in an arc about the location of a gas hole produces little or no change in the echo; the indication on the oscilloscope screen remains constant in both amplitude and position on the trace as the search unit is moved. On the other hand, if the search unit were to be swiveled on the same spot, the indication would abruptly disappear after the search unit had been swiveled only a few degrees.

Fig. 19 Angle-beam inspection of a weldment showing effect of search-unit movements on oscilloscope screen display patterns from three different types of flaws in welds. (a) Positions of search units on the testpiece. (b) Display pattern obtained from a gas hole as the result of traversing the search unit in an arc about the location of the flaw. (c) Display pattern obtained from a slag inclusion as the result of swiveling the search unit on a fixed point. (d) Display pattern obtained from a crack, using the same swiveling search-unit movement as in (c).

If the flaw is a slag inclusion (Fig. 19a), swiveling the search unit on the same spot causes the echo indication to vary randomly; some peaks rise and others fall, and the position of the signal shifts in either direction on the time trace, as indicated by arrows on the oscilloscope screen display in Fig. 19(c). Traversing the search unit in an arc would cause the signal to vary randomly in amplitude and to broaden slightly rather than shift in position.

If the flaw is a crack (Fig. 19a), swiveling the search unit in either direction away from the direction of maximum echo amplitude causes the peak to fall rapidly, accompanied by a slight shift to the right on the time trace, as indicated by arrows on the display in Fig. 19(d). Traversing the search unit in an arc would cause the echo signal to broaden slightly and fall rapidly with no change in position.

Surface Wave Technique. A special adaptation of the angle-beam technique results in the propagation of a surface wave, as discussed in the section "Angle-Beam Units" in this article. Surface waves are mainly used for the detection of shallow surface cracks and other similar flaws occurring at or just below the surface of the testpiece. This technique is most effective when flaws are most likely to extend to the surface or to be located in the dead zone for other techniques. Display appearance is similar to that for ordinary angle-beam testing; only flaw indications are displayed on an extended-time sweep trace.

Polar backscattering is basically an angle-beam technique, in which a single transducer has an oblique incidence with the front and back surface of a testpiece. Like other angle-beam techniques, this approach eliminates the detection of reflections from the front and back of the testpiece and only accounts for scattering from discontinuities that are normal to the ultrasonic pulse. In polar backscattering, however, the primary objective is to measure the amplitude of scattering as a function of transducer orientation. Polar backscattering is a useful nondestructive evaluation method for composite materials because their defects mostly have angle-dependent characteristics, which can be revealed by this method (Ref 3).

The test setup for polar backscattering is shown schematically in Fig. 20. Generally, fibers or discontinuities backscatter when the polar angle is normal to their surfaces. Figure 21 shows the response from a cross-ply SiC/Ti laminate tested at an incidence angle of 16.5° . The maxima in backscattering are observed each time the ultrasonic beam is normal to a fiber axis. The finite width of the peaks on the angular spectrum is determined by the transducer and the fiber directivity. The test can be performed in the frequency range of 1 to 25 MHz, using broadband pulses.

Fig. 20 Schematic of polar backscattering setup. α , angle of incidence; θ , polar angle (the angle between the y -axis and the projection of the beam path on the x - y plane)

Fig. 21 Polar backscattering response from a SiC/Ti cross-ply laminate. The angle of incidence was 16.5° .

Polar backscattering can be used to detect matrix cracking because matrix cracks generate much higher backscattering than the backscattering of the fibers (about 30 dB for graphite-epoxy). By setting a gate with a cutoff level above the

backscattering amplitude of the fibers, matrix cracking can be easily detected, as indicated in Fig. 22. This concept can also be applied to the detection of transverse cracking in ARALL laminates, which consist of aramid-aluminum layers (Ref 4).

Fig. 22 C-scan image of polar backscattering from transverse cracks in a graphite-epoxy laminate. (a) Fatigued sample. (b) Statically loaded sample

Porosity is another type of defect that can be detected by polar backscattering. Generally, porosity accumulates between the layers of a composite laminate. Because the layers are randomly spread and have no preferred orientation, they generate backscattering at all polar angles. This behavior of porosity is shown in Fig. 23, in which the backscattering responses are shown for two laminates. As can be seen, porosity introduces an increase in scattering for angles that are not normal to the fiber axis as compared to the response from a defect-free laminate. This behavior of the fibers generates a spatial window in the backscattering through which defects of different scattering directivity can be characterized.

Fig. 23 Effect of porosity on the polar backscattering from a graphite-epoxy laminate

Backscattering can also be used to detect corrosion in various metals. This is feasible because corrosion disrupts the surface of the tested metal (Ref 4). Pitting corrosion, as well as scale, can be very easy to detect when testing aluminum plates at a 16° angle of incidence.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection

Transmission Methods**

Regardless of whether transmission ultrasonic testing is done with direct beams or reflected beams, flaws are detected by comparing the intensity of ultrasound transmitted through the testpiece with the intensity transmitted through a reference standard made of the same material. Transmission testing requires two search units--one to transmit the ultrasonic waves and one to receive them. Immersion techniques or water-column (bubbler or squirter) techniques (see the section "Water-Column Designs" in this article) are most effective because they provide efficient and relatively uniform coupling between the search units and the testpiece.

Good coupling is critical to transmission methods because variations in sound transmission through the couplants have corresponding effects on measured intensity. These variations in measured intensity introduce errors into the test results and frequently lead to invalid tests. For example, if go/no-go testing is being done and the criterion for rejection is a 10% loss in transmitted intensity, variations of 10% or more in coupling efficiency can cause the rejection of flaw-free testpieces. In addition to good coupling, accurate positioning of the search units with respect to each other is critical. Once proper alignment of the search units is established, they should be rigidly held in position so that no variations in measured sound intensity can result from relative movement between them. Scanning is then accomplished by moving testpieces past the search units.

Displays of transmission test data can be either oscilloscope traces, strip chart recordings, or meter readings. Oscilloscopes are used to record data mainly when pulsed sound beams are used for testing; strip charts and meters are more appropriate for continuous beams. With all three types of display, alarms or automatic sorting devices can be used to give audible warning or to shunt defective workpieces out of the normal flow of production.

Pitch-catch testing can be done either with direct beams (through transmission testing) or with reflected beams using two transducers. The transducers may be housed in separate search units--one sending and the other receiving--or they may be combined in a single search unit. In both instances, pulses of ultrasonic energy pass through the material, and the intensities of the pulses are measured at the point of emergence. An oscilloscope display is triggered simultaneously with the initial pulse, and the transmitted-pulse indication appears on the screen to the right of the initial-pulse indication in a manner quite similar to the back reflection indication in pulse-echo testing. A major advantage of pitch-catch testing is that disturbances and spurious indications can be separated from the transmitted pulse by their corresponding transit times. Only the intensity of the transmitted pulse is monitored; all other sound waves reaching the receiver are ignored. An electronic gate can be set to operate an alarm or a sorting device when the monitored intensity drops below a preset value.

When reflected pulses are used, the technique is almost identical to the loss of back reflection technique that is often used in ordinary pulse-echo testing. In reflected-beam transmission testing, however, no attempt is made to evaluate any signal other than the main reflected pulse; echo signals that would be carefully interpreted in pulse-echo testing are not considered in transmission testing.

Continuous-beam testing does not require a pulser circuit or an oscilloscope. The initial intensity is not monitored, just the transmitted intensity. In this type of testing, considerable interference from standing waves occurs when the ultrasound of a single frequency is introduced into a part. Usually, only a small amount of the direct beam is absorbed by the receiver; the remainder is reflected back and forth repeatedly within the testpiece, soon filling the entire volume of material with a spatial field of standing waves. These standing waves create interference patterns of nodes and antinodes that alter the intensity of the direct beam. Small differences in dimensions or sound-transmission properties between two testpieces of the same design can result in large differences in the measured sound beam intensity because of a shift in the spatial distribution of standing waves.

Standing waves are avoided when pulsed ultrasonic beams are used. They cannot be eliminated when continuous beams are used; however, the effect can be made relatively constant by "wobbling" the test frequency, that is, by rapidly modulating the test frequency about the fundamental test frequency. Either periodic or aperiodic modulation can be used with equivalent results as long as the range of modulation is wide enough. The required range can be estimated from:

$$\frac{f_1}{f_2} = \frac{4n}{(4n + 1)} \quad (\text{Eq 12})$$

where f_1 and f_2 are the results of the frequency range and n is the number of wavelength modes in the shortest direct-beam path from transmitter to receiver. The value of n is determined from:

$$n = \frac{fx}{V} \quad (\text{Eq 13})$$

where f is the fundamental frequency, x is the path length of the direct beam, and V is the velocity of the particular wave form involved.

The frequency modulation range ($f_2 - f_1$) varies with the length of the direct-beam path, as shown in Fig. 24 for a sound wave velocity of 6 km/s (4 miles/s). When applied to the straight-beam, longitudinal wave inspection of steel plate, which has a sound wave velocity of about 6 km/s (4 miles/s), the horizontal scale in Fig. 24 can be read directly as plate thickness. The frequency modulation range ($f_2 - f_1$) is independent of fundamental frequency, f , but when it is considered as a percentage of the fundamental frequency, higher test frequencies require a lower percentage of modulation to average out standing-wave effects. This is important, because some search units lose sensitivity when the operating frequency differs from the design frequency by more than a few percent. Consequently, higher frequencies are required for the transmission testing of thin testpieces than for thick testpieces. In some cases, equipment limitations may make it impossible to use transmission methods on thin testpieces.

Fig. 24 Effect of direct-beam path length on frequency modulation range needed to avoid standing waves in the continuous-beam transmission testing of a material in which sound velocity is 6 km/s (4 miles/s).

Applications. The main application of transmission methods is the inspection of plate for cracks and laminations that have relatively large dimensions compared to the size of the search units. The following two examples illustrate the variation of ultrasonic transmission in the nondestructive evaluation of metal-matrix composite panels.

Example 1: Ultrasonic Inspection of Titanium-Matrix Composite Panels.

Three titanium-matrix composite panels were made available for nondestructive characterization by ultrasonic inspection, velocity measurements, and film radiography. Only one panel showed significant anomalies, as revealed by the ultrasonic C-scan (Fig. 25). No significant variation was seen in the velocity or x-ray inspection data.

Fig. 25 C-scan of ultrasonic signal amplitudes after transmission through a titanium-matrix composite panel (six plies with 0° fiber orientation). Zone A indicates a region of poor sound transmission; Zone B is a region of good sound transmission. Courtesy of Textron Specialty Materials

The panel was then sectioned parallel to the fiber lay-up, and tensile bar specimens were removed from good (zone B, Fig. 25) and poor (zone A) sound-transmission regions. The results of tensile testing from good and bad C-scan zones showed no correlation. This should be expected because the fiber strength dominates and because the matrix contribution is minimal even with porosity or laminar-matrix defects.

The broken tensile specimens were then polished and photomicrographs taken from the good and bad C-scan zones. Figure 26(a) shows the region of poor ultrasonic transmission (zone A, Fig. 25). Inadequate consolidation, porosity sites, bunched fibers, and large grain sizes are visible throughout this zone. Specimens sectioned through the region of good ultrasonic transmission (zone B) exhibited no porosity (Fig. 26b).

Fig. 26 Photomicrographs of specimens taken from the good and bad C-scan zones shown in Fig. 25. (a) Specimen from zone A. 115×. (b) Specimen from zone B. 230×

Example 2: Ultrasonic Inspection of Surface Cracks and Delamination in a Metal-Matrix Composite Panel.

Figure 27(a) shows an ultrasonic C-scan of a titanium-matrix composite with surface cracks. This scan was performed with a 50-MHz focused transducer at 10× magnification. Penetration of the sound was minimal because of the high

frequency being used, although there is some indication of poor consolidation (delamination) to the right of the centered crack.

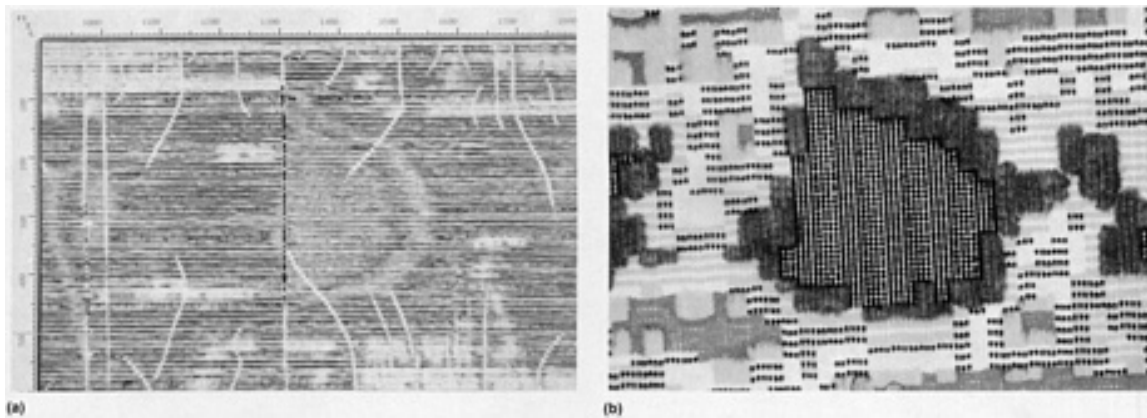

Fig. 27 Ultrasonic C-scans of a titanium-matrix composite panel with surface cracks and delamination. (a) C-scan using a 50-MHz focused transducer at a magnification of 10 \times . (b) C-scan of same defect using a 10-MHz focused transducer

Figure 27(b) shows an ultrasonic C-scan of the same defect area produced with a 10-MHz focused transducer. The C-scan at this frequency provided better resolution of the delaminated area, although it was found to be inadequate for determining fiber integrity and surface cracking conditions.

Lamb Wave Testing. For the high-speed testing of a plate, strip, or wire, where the thickness is of the order of a few wavelengths, there is considerable benefit in using Lamb waves (Ref 5). Lamb waves (or plate waves) are elastic waves that propagate in plates of finite thickness as guided waves and are associated with particle motion in a plane normal to the surface. As mentioned in the section "Lamb Waves" in this article, Lamb waves can be symmetrical or asymmetrical, and they can be of different modes or mixed modes, with the velocity depending on the mode.

The present understanding of Lamb waves is based on theoretical considerations and empirical observations; the precise particle motion involved has not been established unequivocally. However, knowledge about the phenomena associated with Lamb waves has been developed, so that there is a sound basis for their use in nondestructive inspection.

Lamb waves are generated by the oblique incidence of an ultrasonic wave with a properly selected transmission frequency. In addition to the common piezoelectric transducer, Lamb waves can be generated and detected with an electromagnetic-acoustic (EMA) probe with the appropriate coil configuration (see the section "EMA Transducers" in this article).

The most widely applied technique is to monitor the transmission along a plate between two probes with a fixed spacing. For example, the quality of a spot or seam weld between two sheets can be monitored by the transmission along one sheet and through the spot weld (Fig. 28). This can be done as on-line monitoring of the welding operation, but temperature effects at the weld nugget and mode conversions at the liquid/metal interface complicate the interpretation of the results. In wire specimens, the waves are usually known as rod waves, and there is an advantage in generating them by magnetostriction, with a coil over the end, so that no surface contact is needed. Spirally rotating surface waves can also be generated in a wire with a pair of probes angled to the wire axis.

Fig. 28 Use of Lamb waves to inspect a spot-welded joint. Source: Ref 5

Leaky Lamb Wave Testing. In recent years, substantial progress has been made in the understanding of the Lamb wave. This has resulted from the development of sophisticated theoretical and experimental techniques and the use of powerful computing tools. It is now possible to predict and measure the response of Lamb waves even in anisotropic layered materials, such as fiber-reinforced composites. One approach in this effort involves the use of the leaky Lamb wave (LLW) phenomenon. Recent research indicates that this phenomenon can be used to detect and characterize defects that would remain undetected in conventional ultrasonic techniques (Ref 6).

In LLW testing, Lamb waves are induced in a plate through a mode conversion by obliquely insonifying the plate at a properly selected transmission frequency. If a laminate is immersed in a fluid, the Lamb waves leak energy into the fluid at an angle that is established by Snell's law and the Lamb wave phase velocity. When an LLW is induced, the reflected field is distorted. The specular component of the wave and the leaky wave interfere, with a phase cancellation occurring and a null being generated between them. A schematic of LLW field behavior is shown in Fig. 29. For nondestructive evaluation, one can monitor changes in the frequency of given LLW modes or changes in amplitude at the null zone.

Fig. 29 Schematic of LLW phenomenon. Zone A represents the specular component, while zone B represents the LLW component. The presence of LLWs shifts the observation of reflected energy into zone A.

A theory has been developed and corroborated regarding the behavior of LLWs in composites (Ref 7). A matrix method solved the problem of wave propagation in multilayered anisotropic media subjected to time-harmonic (single-frequency) or transient (pulse) disturbances. The method was applied to obtain a formal solution of the response of layered composite plates. The solution led to stable numerical schemes for the evaluation of the displacement and stress fields within the laminate. This analysis of LLW behavior was applied to both multiorientation laminates and bonded structures with different interface conditions.

Leaky Lamb wave tests are performed with a pitch-catch setup and flat broadband transducers; the receiver is placed at the null zone of the LLW field. The LLW field can be tested at various angles of incidence in the frequency range of 0.1 to 15.0 MHz using either tone bursts or pulses. For tone burst, signals with a duration sufficiently long to establish a steady-state condition are used. The signals are either displayed as a function of time for a single frequency or as a function of frequency in a sweep mode. For tests with short-duration pulses, the transducers are first adjusted to place the receiver at the null zone, using the tone-burst setup. Then the transducer is substituted with a pulser-receiver, and the signals are tested from the A-scan display. The two aspects of LLW phenomena that are commonly measured are described below.

Reflection Field. At specific angles of incidence, the spectral response, namely, the reflected amplitude as a function of frequency, is examined. An example of such spectra for a unidirectional graphite-epoxy laminate tested along the fibers is shown in Fig. 30. The reflected field can also be analyzed in the time domain using pulses and commercial pulser-receivers, with the receiving transducer placed at the null zone (Ref 6). In this case, two parameters can be used to examine the composite laminate: the amplitude and the time-of-flight.

Fig. 30 Experimental and theoretical LLW spectral response of a unidirectional graphite-epoxy laminate obtained with a 15° angle of incidence. The x-axis is usually expressed in frequency times thickness to eliminate the effect of total thickness of the plate from the data.

Using amplitude measurements while C-scanning a laminate can reveal material property variations and many types of defects. These include delaminations, ply-gap, porosity, and resin/fiber ratio changes. Further details are obtained when using time-of-flight measurements because the depths of the discontinuities are also presented. An example of a time-of-flight LLW C-scan is shown in Fig. 31, in which different colors were assigned to the various time-of-flight ranges to indicate the depth of the defects in the sample. The dark lines along the C-scan image are parallel to the fiber orientation and are a result of the migration of porosity (microballoons of 0.04 mm, or 0.0016 in., diameter) from the center of the sample outward during the laminate cure.

Fig. 31 Pulsed LLW C-scan showing time-of-flight variations in a graphite-epoxy laminate tested at 45° with the fibers

Dispersion curves provide a plot of the phase velocity of Lamb waves as a function of frequency. The x -axis is usually expressed in frequency times thickness; therefore, the effect of the total thickness of the plate is eliminated from the data. The modes are determined from the reflected spectra by finding the frequencies at which the minima occur. By an inversion process, one can employ the theory to determine the elastic properties of composite laminates from experimental dispersion curves.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Electronic Equipment

Although the electronic equipment used for ultrasonic inspection can vary greatly in detail among equipment manufacturers, all general-purpose units consist of a power supply, a pulser circuit, a search unit, a receiver-amplifier circuit, an oscilloscope, and an electronic clock. Many systems also include electronic equipment for signal conditioning, gating, automatic interpretation, and integration with a mechanical or electronic scanning system. Moreover, advances in microprocessor technology have extended the data acquisition and signal-processing capabilities of ultrasonic inspection systems.

Power Supply. Circuits that supply current for all functions of the instrument constitute the power supply, which is usually energized by conventional 115-V or 230-V alternating current. There are, however, many types and sizes of portable instruments for which the power is supplied by batteries contained in the unit.

Pulser Circuit. When electronically triggered, the pulser circuit generates a burst of alternating voltage. The principal frequency of this burst, its duration, the profile of the envelope of the burst, and the burst repetition rate may be either fixed or adjustable, depending on the flexibility of the unit.

Search Units. The transducer is the basic part of any search unit. A sending transducer is one to which the voltage burst is applied, and it mechanically vibrates in response to the applied voltage. When appropriately coupled to an elastic medium, the transducer thus serves to launch ultrasonic waves into the material being inspected.

A receiving transducer converts the ultrasonic waves that impinge on it into a corresponding alternating voltage. In the pitch-catch mode, the transmitting and receiving transducers are separate units; in the pulse-echo mode, a single transducer alternately serves both functions. The various types of search units are discussed later in this article.

Receiver-amplifier circuits electronically amplify return signals from the receiving transducer and often demodulate or otherwise modify the signals into a form suitable for display. The output from the receiver-amplifier circuit is a signal directly related to the intensity of the ultrasonic wave impinging on the receiving transducer. This output is fed into an oscilloscope or other display device.

Oscilloscope. Data received are usually displayed on an oscilloscope in either video mode or radio frequency mode. In videomode display, only peak intensities are visible on the trace; in the RF mode, it is possible to observe the waveform of signal voltages. Some instruments have a selector switch so that the operator can choose the display mode, but others are designed for single-mode operation only.

Clock. The electronic clock, or timer, serves as a source of logic pulses, reference voltage, and reference waveform. The clock coordinates operation of the entire electronic system.

Signal-conditioning and gating circuits are included in many commercial ultrasonic instruments. One common example of a signal-conditioning feature is a circuit that electronically compensates for the signal-amplitude loss caused by attenuation of the ultrasonic pulse in the testpiece. Electronic gates, which monitor returning signals for pulses of selected amplitudes that occur within selected time-delay ranges, provide automatic interpretation. The set point of a gate corresponds to a flaw of a certain size that is located within a prescribed depth range. Gates are often used to trigger alarms or to operate automatic systems that sort testpieces or identify rejectable pieces.

Image- and Data-Processing Equipment. As a result of the development of microprocessors and modern electronics, many ultrasonic inspection systems possess substantially improved capabilities in terms of signal processing and data acquisition. This development allows better flaw detection and evaluation (especially in composites) by improving the acquisition of transient ultrasonic waveforms and by enhancing the display and analysis of ultrasonic data. The development of microprocessor technology has also been useful in portable C-scan systems with hand-held transducers (see the section "Scanning Equipment" in this article).

In an imaging system, the computer acquires the position of the transducer and the ultrasonic data from the point. Combining the two, an image is produced on the computer monitor, either in color or in gray-scale shades; each point is represented by a block of a predetermined size. To expedite the inspection, it is common to use large blocks. Areas that require special attention are then inspected with a higher resolution by using smaller blocks. Built-in software in the system allows users to analyze available information under precise, controlled conditions and enables simulation of a top view regardless of transducer angle.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Control Systems

Even though the nomenclature used by different instrument manufacturers may vary, certain controls are required for the basic functions of any ultrasonic instrument. These functions include power supply, clock, pulser, receiver-amplifier, and display. In most cases, the entire electronic assembly, including the controls, is contained in one instrument. A typical pulse-echo instrument is shown in Fig. 32.

Fig. 32 Typical pulse-echo ultrasonic instrument

The power supply is usually controlled by switches and fuses. Time delays can be incorporated into the system to protect circuit elements during warm-up. The pulses of ultrasonic energy transmitted into the testpiece are adjusted by controls for pulse-repetition rate, pulse length, and pulse tuning. A selector for a range of operating frequencies is usually labeled "frequency," with the available frequencies given in megahertz.

For single-transducer inspection, transmitting and receiving circuits are connected to one jack, which is connected to a single transducer. For double-transducer inspection, such as through transmission or pitch-catch inspection, a T (transmit) jack is provided to permit connecting one transducer for use as a transmitter, and an R (receive) jack is provided for the use of another transducer for receiving only. A selector switch (test switch) for through (pitch-catch) or normal (pulse-echo) transmission is provided for control of the T and R jacks.

Gain controls for the receiver-amplifier circuit usually consist of fine- and coarse-sensitivity selectors or one control marked "sensitivity." For a clean video display, with low-level electronic noise eliminated, a reject control can be provided.

The display (oscilloscope) controls are usually screwdriver-adjusted, with the exception of the scale illumination and power on/off. After initial setup and calibration, the screwdriver-adjusted controls seldom require additional adjustment. The controls and their functions for the display unit usually consist of the following:

- Controls for vertical position of the display on the oscilloscope screen
- Controls for horizontal position of display on the oscilloscope screen
- Controls for brightness of display
- Control for adjusting focus of trace on the oscilloscope screen
- Controls to correct for distortion or astigmatism that may be introduced as the electron beam sweeps across the oscilloscope screen
- A control that varies the level of illumination for a measuring grid usually incorporated in the transparent faceplate covering the oscilloscope screen
- Timing controls, which usually consist of sweep-delay and sweep-rate controls, to provide coarse and fine adjustments to suit the material and thickness of the testpiece. The sweep-delay control is also used to position the sound entry point on the left side of the display screen, with a back reflection or multiples of back reflections visible on the right side of the screen
- On/off switch

In addition to those listed above, there are other controls that may or may not be provided, depending on the specific type of instrument. These controls include the following:

- A marker circuit, which provides regularly spaced secondary indications (often in the form of a square wave) on or below the sweep line to serve the same purpose as scribe marks on a ruler. This circuit is activated or left out of the display by a marker switch for on/off selection. Usually there will also be a marker-calibration or marker-adjustment control to permit selection of marker-circuit frequency. The higher the frequency, the closer the spacing of square waves, and the more accurate the measurements. Marker circuits are controlled by timing signals triggered by the electronic clock. Most modern ultrasonic instruments do not have marker circuits
- A circuit to electronically compensate for a drop in the amplitude of signals reflected from flaws located deep in the testpiece. This circuit may be known as distance-amplitude correction, sensitivity-time control, time-corrected gain, or time-varied gain
- Damping controls that can be used to shorten the pulse duration and thus adjust the length of the wave packet emanating from the transducer. Resolution is improved by higher values of damping
- High-voltage or low-voltage driving current, which is selected for the transducer with a transducer-voltage switch
- Gated alarm units, which enable the use of automatic alarms when flaws are detected. This is accomplished by setting up controllable time spans on the display that correspond to specific zones within the testpiece. Signals appearing within the gates may automatically operate visual or audible alarms. These signals may also be passed on to display devices or strip-chart recorders or to external control devices. Gated alarm units usually have three controls: the gate-start or delay control, which adjusts the location of the leading edge of the gate on the oscilloscope trace; the gate-length control, which adjusts the length of the gate or the location of the gate trailing edge; and the alarm-level or sensitivity control, which establishes the minimum echo height necessary to activate an alarm circuit. A positive/negative logic switch determines whether the alarm is triggered above or below the threshold level

Ultrasonic Inspection

Transducer Elements

The generation and detection of ultrasonic waves for inspection are accomplished by means of a transducer element acting through a couplant. The transducer element is contained within a device most often referred to as a search unit (or sometimes as a probe). Piezoelectric elements are the most commonly used transducer in ultrasonic inspection, although EMA transducers and magnetostriction transducers are also used.

Piezoelectric Transducers

Piezoelectricity is pressure-induced electricity; this property is characteristic of certain naturally occurring crystalline compounds and some man-made materials. As the name piezoelectric implies, an electrical charge is developed by the crystal when pressure is applied to it. Conversely, when an electrical field is applied, the crystal mechanically deforms (changes shape). Piezoelectric crystals exhibit various deformation modes; thickness expansion is the principal mode used in transducers for ultrasonic inspection.

The most common types of piezoelectric materials used for ultrasonic search units are quartz, lithium sulfate, and polarized ceramics such as barium titanate, lead zirconate titanate, and lead metaniobate. Characteristics and applications of these materials are summarized in Table 5.

Table 5 Characteristics and applications of transducer (piezoelectric) elements

Piezoelectric element	Characteristics of piezoelectric elements ^(a)							Suitability of element in ^(a)		
	Efficiency				Tolerance to elevated temperature	Damping ability	Undesired modes (inherent noise)			
	Transmit	Receive	Coupling					Contact inspection		Immerse inspection
			To water	To metal				Straight-beam	Angle-beam	
Quartz	P	G	G	F	G	F	G	G	F	G
Lithium sulfate	F	E	E	P	P	E	E	P	F	E
Barium titanate	G	P	G	G	P	P	P	G	G	F
Lead zirconate titanate	E	F	F	E	E	F	P	E	E	F
Lead metaniobate	G	F	G	E	E	E	G	E	E	G

(a) E, excellent; G, good; F, fair; P, poor

Quartz crystals were initially the only piezoelectric elements used in commercial ultrasonic transducers. Properties of the transducers depended largely on the direction along which the crystals were cut to make the active transducer elements. Principal advantages of quartz-crystal transducer elements are electrical and thermal stability, insolubility in most liquids, high mechanical strength, wear resistance, excellent uniformity, and resistance to aging. A limitation of quartz is its comparatively low electromechanical conversion efficiency, which results in low loop gain for the system.

Lithium Sulfate. The principal advantages of lithium sulfate transducer elements are ease of obtaining optimum acoustic damping for best resolution, optimum receiving characteristics, intermediate conversion efficiency, and negligible mode interaction. The main disadvantages of lithium sulfate elements are fragility and a maximum service temperature of about 75 °C (165 °F).

Polarized ceramics generally have high electromechanical conversion efficiency, which results in high loop gain and good search-unit sensitivity. Lead zirconate titanate is mechanically rugged, has a good tolerance to moderately elevated temperature, and does not lose polarization with age. It does have a high piezoelectric response in the radial mode, which sometimes limits its usefulness.

Barium titanate is also mechanically rugged and has a high radial-mode response. However, its efficiency changes with temperature, and it tends to depolarize with age, which makes barium titanate less suitable for some applications than lead zirconate titanate.

Lead metaniobate exhibits low mechanical damping and good tolerance to temperature. Its principal limitation is a high dielectric constant, which results in a transducer element with a high electrical capacitance.

Selection of a piezoelectric transducer for a given application is done on the basis of size (active area) of the piezoelectric element, characteristic frequency, frequency bandwidth, and type (construction) of search unit. Descriptions of various types of search units with piezoelectric elements are given in the section "Search Units" in this article. Different piezoelectric materials exhibit different electrical-impedance characteristics. In many cases, tuning coils or impedance-matching transformers are installed in the search-unit housing to render a better impedance match to certain types of electronic instrumentation. It is important to match impedances when selecting a search unit for a particular instrument.

Both the amount of sound energy transmitted into the material being inspected (radiated power) and beam divergence are directly related to the size (active area) of the transducer element. Thus, it is sometimes advisable to use a larger search unit to obtain greater depth of penetration or greater sound beam area.

Each transducer has a characteristic resonant frequency at which ultrasonic waves are most effectively generated and received. This resonant frequency is determined mainly by the material and thickness of the active element. Any transducer responds efficiently at frequencies in a band centered on the resonant frequency. The extent of this band, known as bandwidth, is determined chiefly by the damping characteristics of the backing material that is in contact with the rear face of the piezoelectric element.

Narrow-bandwidth transducers exhibit good penetrating capability and sensitivity, but relatively poor resolution. (Sensitivity is the ability to detect small flaws; resolution is the ability to separate echoes from two or more reflectors that are close together in depth.) Broad-bandwidth transducers exhibit greater resolution, but lower sensitivity and penetrating capability, than narrow-bandwidth transducers.

Operating frequency, bandwidth, and active-element size must all be selected on the basis of inspection objectives. For example, high penetrating power may be most important in the axial examination of long shafts. It may be best to select a large-diameter, narrow-bandwidth, low-frequency transducer for this application, even though such a transducer will have both low sensitivity (because of low frequency and large size) and low resolution (because of narrow bandwidth).

When resolution is important, such as in the inspection for near-surface discontinuities, use of a broad-bandwidth transducer is essential. Penetrating capability probably would not be very important, so the relatively low penetrating power accompanying the broad bandwidth would not be a disadvantage. If necessary, high sensitivity could be achieved by using a small, high-frequency, broad-bandwidth transducer; an increase in both sensitivity and penetrating power would require the use of a large, high-frequency transducer, which would emit a more directive ultrasonic beam. Resolution can also be improved by using a very short pulse length, an immersion technique, or delay-tip or dual-element contact-type search units.

Array Transducers. In recent years, there has been a growing need to increase the speed of ultrasonic inspections. The fastest means of scanning is the use of an array of transducers that are scanned electronically by triggering each of the transducers sequentially. Such transducers consist of several crystals placed in a certain pattern and triggered one at a time, either manually or by a multiplexer. Array transducers can either transmit normal to their axis or can have an angle beam. To perform beam steering, sound is generated from the various crystals with a predetermined phase difference. The degree of difference determines the beam angle.

EMA Transducers

Electromagnetic-acoustic (EMA) phenomena can be used to generate ultrasonic waves directly into the surface of an electrically conductive specimen without the need for an external vibrating transducer and coupling. Similar probes can also be used for detection, so that a complete non-contact transducer can be constructed. The method is therefore particularly suitable for use on high-temperature specimens, rough surfaces, and moving specimens. The received ultrasonic signal strength in EMA systems is 40 to 50 dB lower than a conventional barium titanate probe, but input powers can be increased.

The principle of EMA transducers is illustrated in Fig. 33. A permanent magnet or an electromagnet produces a steady magnetic field, while a coil of wire carries an RF current. The radio frequency induces eddy currents in the surface of the specimen, which interact with the magnetic field to produce Lorentz forces that cause the specimen surface to vibrate in sympathy with the applied radio frequency. When receiving ultrasonic energy, the vibrating specimen can be regarded as a moving conductor or a magnetic field, which generates currents in the coil. The clearance between the transducer and the metal surface affects the magnetic field strength and the strength of the eddy currents generated, and the ultrasonic

intensity falls off rapidly with increasing gap. Working at 2 MHz, a gap of 1.0 to 1.5 mm (0.04 to 0.06 in.) has been found to be practicable provided it is kept reasonably constant (Ref 5).

Fig. 33 Schematic of EMA transducer. (a) Arrangement for the production of shear waves. (b) Arrangement for the production of compressional waves

Magnetostriction Transducers

Although magnetostriction transducers are seldom used in the ultrasonic inspection of metals, magnetostriction has advantages in the Lamb wave testing of wire specimens (see the section "Lamb Wave Testing" in this article). Magnetostrictive materials change their form under the influence of a magnetic field, and the most useful magnetostrictive material in practice is nickel. A nickel rod placed in a coil carrying a current experiences a change in length as a function of the current through the coil. A stack of plates of magnetostrictive material with a coil through them can produce an ultrasonic beam at right angles to the plate stack, and the frequency depends on the thickness. Transducers of this type are useful for very low ultrasonic frequencies (<200 kHz).

Couplants

Air is a poor transmitter of sound waves at megahertz frequencies, and the impedance mismatch between air and most solids is great enough that even a very thin layer of air will severely retard the transmission of sound waves from the transducer to the testpiece. To perform satisfactory contact inspection with piezoelectric transducers, it is necessary to eliminate air between the transducer and the testpiece by the use of a couplant.

Couplants normally used for contact inspection include water, oils, glycerin, petroleum greases, silicone grease, wallpaper paste, and various commercial pastelike substances. Certain soft rubbers that transmit sound waves may be used where adequate coupling can be achieved by applying hand pressure to the search unit.

The following should be considered in selecting a couplant:

- Surface finish of testpiece
- Temperature of test surface
- Possibility of chemical reactions between test surface and couplant
- Cleaning requirements (some couplants are difficult to remove)

Water is a suitable couplant for use on a relatively smooth surface; however, a wetting agent should be added. It is sometimes appropriate to add glycerine to increase viscosity; however, glycerine tends to induce corrosion in aluminum and therefore is not recommended in aerospace applications.

Heavy oil or grease should be used on hot or vertical surfaces or on rough surfaces where irregularities need to be filled.

Wallpaper paste is especially useful on rough surfaces when good coupling is needed to minimize background noise and yield an adequate signal-to-noise ratio.

Water is not a good couplant to use with carbon steel testpieces, because it can promote surface corrosion. Oils, greases, and proprietary pastes of a noncorrosive nature can be used.

Heavy oil, grease, or wallpaper paste may not be good choices when water will suffice, because these substances are more difficult to remove. Wallpaper paste, like some proprietary couplants, will harden and may flake off if allowed to stand exposed to air. When dry and hard, wallpaper paste can be easily removed by blasting or wire brushing. Oil or grease often must be removed with solvents.

Couplants used in contact inspection should be applied as a uniform, thin coating to obtain uniform and consistent inspection results. The necessity for a couplant is one of the drawbacks of ultrasonic inspection and may be a limitation, such as with high-temperature surfaces. When the size and shape of the part being inspected permit, immersion inspection is often done. This practice satisfies the requirement for uniform coupling.

Search Units

Search units with piezoelectric transducers are available in many types and shapes. Variations in search-unit construction include transducer-element material; transducer-element thickness, surface area, and shape; and type of backing material and degree of loading. A reference that is frequently used in determining search-unit characteristics is American Society for Testing and Materials (ASTM) specification E 1065.

The four basic types of search units are the straight-beam contact type, the angle-beam contact type, the dual-element contact type, and the immersion type; Table 6 lists their primary areas of application. Sectional views of these search

units, together with a special type (delay-tip contact-type search unit), are shown in Fig. 34. These units, as well as several other special types of search units, are discussed in this section.

Table 6 Primary applications of four basic types of ultrasonic search units with piezoelectric transducers
Straight-beam contact-type units

Manufacturing-induced flaws
Billets: inclusions, stringers, pipe
Forgings: inclusions, cracks, segregations, seams, flakes, pipe
Rolled products: laminations, inclusions, tears, seams, cracks
Castings: slag, porosity, cold shuts, tears, shrinkage cracks, inclusions
Service-induced flaws
Fatigue cracks, corrosion, erosion, stress-corrosion cracks

Angle-beam contact-type units

Manufacturing-induced flaws
Forgings: cracks, seams, laps
Rolled products: tears, seams, cracks, cupping
Welds: slag inclusions, porosity, incomplete fusion, incomplete penetration, drophthrough, suckback, cracks in filler metal and base metal
Tubing and pipe: circumferential and longitudinal cracks
Service-induced flaws
Fatigue cracks, stress-corrosion cracks

Dual-element contact-type units

Manufacturing-induced flaws
Plate and sheet: thickness measurements, lamination detection
Tubing and pipe: measurement of wall thickness
Service-induced flaws
Wall thinning, corrosion, erosion, stress-corrosion cracks

Immersion-type units

Manufacturing-induced flaws

Billets: inclusions, stringers, pipe
 Forgings: inclusions, cracks, segregations, seams, flakes, pipe
 Rolled products: laminations, inclusions, tears, seams, cracks
 Welds: inclusions, porosity, incomplete fusion, incomplete penetration, drop through, cracks, base-metal laminations
 Adhesive-bonded, soldered or brazed products: lack of bond
 Composites: voids, resin rich, resin poor, lack of filaments
 Tubing and pipe: circumferential and longitudinal cracks

Service-induced flaws

Corrosion, fatigue cracks

Fig. 34 Sectional views of five typical piezoelectric search units in ultrasonic inspection

Contact-Type Units

Although contact-type search units can sometimes be adapted to automatic scanning, they are usually hand held and manually scanned in direct contact with the surface of a testpiece. A thin layer of an appropriate couplant is almost always required for obtaining transmission of sound energy across the interface between the search unit and the entry surface.

Straight-Beam Units. Figure 34(a) illustrates a straight-beam (longitudinal wave) contact-type search unit. In service, this unit is hand held and manually scanned in direct contact with the surface of the testpiece. The contact face is subject to abrasion and in most cases is required to couple efficiently to metals having high acoustic impedances. This type of search unit projects a beam of ultrasonic vibrations perpendicular to the entry surface. It can be used for either the reflection (echo) method or the through transmission method.

Echo inspection can be performed with either one or two search units. With the technique using a single search unit, the search unit acts alternately as transmitter and receiver. It projects a beam of longitudinal waves into the material being inspected and receives echoes reflected back to it from the opposite surface and from flaws in the path of the beam, as shown in Fig. 35(a).

Fig. 35 Applications of the straight-beam (longitudinal wave) contact-type search unit illustrated in Fig. 34(a) showing reflection techniques with (a) single search unit and (b) two search units, and (c) through transmission technique with two search units

The technique with two search units is used when the testpiece is of irregular shape and reflecting interfaces or back surfaces are not parallel with the entry surface. One search unit is the transmitter, and the second search unit is the receiver. The transmitting search unit projects a beam of vibrations into the material; the vibrations travel through the material and are reflected back to the receiving search unit from flaws or from the opposite surface, as shown in Fig. 35(b).

In the through transmission technique, two search units are used--one as a transmitter and the second as a receiver. The transmitting search unit projects a beam of vibrations into the testpiece; these vibrations travel through the material to the opposite surface, where they are picked up by the receiving search unit (Fig. 35c). Flaws in the path of the beam cause a reduction in the amount of energy (sound beam intensity) passing through to the receiving search unit. For optimum results when using two search units, it may be desirable to use different transmitter and receiver materials, depending on the electrical characteristics of the ultrasonic instrument used. For example, a polarized-ceramic search unit can be used as the transmitter, and a lithium sulfate search unit as the receiver.

Angle-Beam Units. Figure 34(b) illustrates the construction of an angle-beam contact-type search unit. A plastic wedge between the piezoelectric element and the contact surface establishes a fixed angle of incidence for the search unit. The plastic wedge must be designed to reduce or eliminate internal reflections within the wedge that could result in undesired false echoes.

Angle-beam search units are used for the inspection of sheet or plate, pipe welds or tubing, and testpieces having shapes that prevent access for straight beam. Angle-beam search units can be used to produce shear waves or combined shear and longitudinal waves, depending on the wedge angle and testpiece material. There is a single value of wedge angle that will produce the desired beam direction and wave type in any given testpiece. A search unit having the appropriate wedge angle is selected for each specific application.

The surface wave search unit is an angle-beam unit insofar as it uses a wedge to position the crystal at an angle to the surface of the testpiece. It generates surface waves by mode conversion as described in the section "Critical Angles" in

this article. The wedge angle is chosen so that the shear wave refraction angle is 90° and the wave resulting from mode conversion travels along the surface.

Dual-Element Units. Figure 34(c) shows a dual-element contact-type search unit. Dual-element units provide a method of increasing the directivity and resolution capabilities (especially near-surface resolution) in contact inspection. By splitting the transmitting and receiving functions, two-transducer, send and receive inspection can be done with a single search unit. The dual-element design allows the receiving function to be electrically and acoustically isolated from effects of the excitation pulse by the use of an acoustical barrier separating the transmitter element from the receiver. The receiving transducer is always in a quiescent state and can respond to the signal reflected from a flaw close to the testpiece surface.

Delay-Tip Units. Figure 34(d) illustrates the construction of a delay-tip (standoff) contact-type search unit. Its primary application is in thickness measurement and for thin materials that require a high degree of resolution.

The delay shoe allows the indication from the front surface of the testpiece to be delayed by the transmission time through the delay shoe. This separates the front-surface signal from the large excitation pulse, thus eliminating much of the dead zone encountered in contact inspection with a search unit that does not have a delay shoe. Reducing the extent of the dead zone allows the piezoelectric crystal to respond to front and back reflections that occur close together in time. This provides improved accuracy in the thickness measurement of thin plate and sheet.

Paintbrush Transducers. The inspection of large areas with small single-element transducers is a long and tedious process. To overcome this and to increase the rate of inspection, the paintbrush transducer was developed. It is so named because it has a wide beam pattern that, when scanned, covers a relatively wide swath in the manner of a paintbrush. Paintbrush transducers are usually constructed of a mosaic or series of matched crystal elements. The primary requirement of a paintbrush transducer is that the intensity of the beam pattern not vary greatly over the entire length of the transducer. At best, paintbrush transducers are designed to be survey devices; their primary function is to reduce inspection time while still giving full coverage. Standard search units are usually employed to pinpoint the location and size of a flaw that has been detected by a paintbrush transducer.

Immersion-Type Units

The advantages of immersion inspection include speed of inspection, ability to control and direct sound beams, and adaptability for automated scanning. Angulation is used in immersion inspection to identify more accurately the orientation of flaws below the surface of the testpiece. If the direction of the sound beam, its point of entry, and its angle of incidence are known, the direction and angle of refraction within the testpiece can be calculated from Eq 5. Only a single search unit is required for conventional immersion inspection, regardless of incident angle. The construction of a conventional immersion-type search unit is shown in Fig. 34(e); several inspection techniques are shown in Fig. 36.

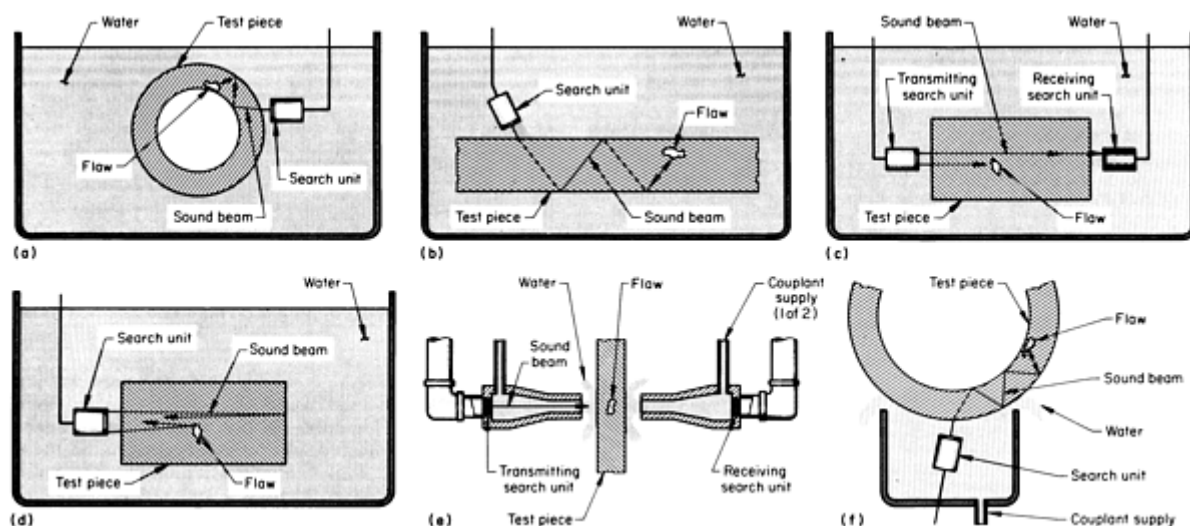

Fig. 36 Schematic views of several immersion techniques using search units of the basic construction shown in Fig. 34(e). (a) Angle-beam pulse-echo inspection of pipe or tube. (b) Angle-beam pulse-echo inspection of

sheet or plate. (c) Through transmission inspection. (d) Straight-beam pulse-echo inspection. (e) Through transmission inspection using squirter-type search units. (f) Angle-beam pulse-echo inspection of pipe or tubing using a bubbler-type unit

There are three broadly classified scanning methods that utilize immersion-type search units:

- Conventional immersion methods in which both the search unit and the testpiece are immersed in liquid (Fig. 36a to d)
- Squirter and bubbler methods in which the sound is transmitted in a column of flowing water (Fig. 36e and f)
- Scanning with a wheel-type search unit (Fig. 37), which is generally classified as an immersion method because the transducer itself is immersed

Fig. 37 Several techniques and applications for wheel-type search units. (a) Typical setup for a wheel-type search unit. (b) Straight-beam inspection with beam entering the testpiece perpendicular to the surface. (c) Angle-beam inspection with beam entering the testpiece at 45° to the surface. Beam can also be directed forward or to the side at 90° to the direction of wheel rotation. (d) Use of two transducers to cross and angle the beams to the sides and forward cross-eyed Lamb unit

Basic Immersion Inspection. In conventional immersion inspection, both the search unit and the testpiece are immersed in water. The sound beam is directed into the testpiece using either a straight-beam (longitudinal wave) technique or one of the various angle-beam techniques, such as shear, combined longitudinal and shear, or Lamb wave. Immersion-type search units are basically straight-beam units and can be used for either straight-beam or angle-beam inspection through control and direction of the sound beam (Fig. 36a to d).

In straight-beam immersion inspection, the water path (distance from the face of the search unit to the front surface of the testpiece) is generally adjusted to require a longer transit time than the depth of scan (front surface to back surface) so that the first multiple of the front reflection will appear farther along the oscilloscope trace than the first back reflection (Fig. 13b). This is done to clear the displayed trace of signals that may be misinterpreted. Water path adjustment is particularly important when gates are used for automatic signaling and recording. Longitudinal wave velocity in water is

approximately one-fourth the velocity in aluminum or steel; therefore, on the time base of the oscilloscope, 25 mm (1 in.) of water path is approximately equal to 100 mm (4 in.) of steel or aluminum. Therefore, a rule of thumb is to make the water path equal to one-fourth the testpiece thickness plus 6 mm ($\frac{1}{4}$ in.).

Water-Column Designs. In many cases, the shape or size of a testpiece does not lend itself to conventional immersion inspection in a tank. The squirter scanning method, which operates on the immersion principle, is routinely applied to the high-speed scanning of plate, sheet, strip, cylindrical forms, and other regularly shaped testpieces (Fig. 36e). In the squirter method, the sound beam is projected into the material through a column of water that flows through a nozzle on the search unit. The sound beam can be directed either perpendicular or at an angle to the surface of the testpiece. Squirter methods can also be adapted for through transmission inspection. For this type of inspection, two squirter-type search units are used, as shown in Fig. 36(e). The bubble method (Fig. 36f) is a minor modification of the squirter method that gives a less directional flow of couplant.

Wheel-type search units (Fig. 37) operate on the immersion principle in that a sound beam is projected through a liquid path into the testpiece. An immersion-type search unit, mounted on a fixed axle inside a liquid-filled rubber tire, is held in one position relative to the surface of the testpiece while the tire rotates freely. The wheel-type search unit can be mounted on a stationary fixture and the testpiece moved past it, or it can be mounted on a mobile fixture that moves over a stationary testpiece, as shown in Fig. 37(a). The position and angle of the transducer element are determined by the inspection method and technique to be used and are adjusted by varying the position of either the immersion unit inside the tire or the mounting yoke of the entire unit.

For straight-beam inspection, the ultrasonic beam is projected straight into the testpiece perpendicular to the surface of the testpiece (Fig. 37b). Applications of the straight-beam technique include the inspection of plate for laminations and of billet stock for primary and secondary pipe.

In angle-beam inspection, ultrasound is projected into the material at an angle to the surface of the testpiece (Fig. 37c). The most commonly used angle of sound beam propagation is 45°; however, other angles can be used where required. The beam can be projected forward, in the direction of wheel rotation, or can be projected to the side, 90° to the direction of wheel rotation. The flexibility of the tire permits angles other than those set by the manufacturer to be obtained by varying the mounting-yoke axis with respect to the surface of the testpiece.

Special wheel-type search units can be made with beam direction or other features tailored to the specific application. One such unit is the cross-eyed Lamb, which utilizes two transducer elements that are mounted at angles to the axle so that the two sound beams cross each other in a forward direction, as shown in Fig. 37(d). This unit is used in the Lamb wave inspection of narrow, thin strip for edge nicks and laminations. By selecting incident angles and beam directions that are appropriate for the thickness, width, and material of the strip being inspected, Lamb waves are set up by the combined effect of the two ultrasonic beams.

Focused Units

Sound can be focused by acoustic lenses in a manner similar to that in which light is focused by optic lenses. Most acoustic lenses are designed to concentrate sound energy, which increases beam intensity in the zone between the lens and the focal point. When an acoustic lens is placed in front of the search unit, the effect resembles that of a magnifying glass; that is, a smaller area is viewed but details in that area appear larger. The combination of a search unit and an acoustic lens is known as a focused search unit or focused transducer; for optimum sound transmission, the lens of a focused search unit is usually bonded to the transducer face. Focused search units can be immersion or contact types.

Acoustic lenses are designed similarly to optic lenses. Acoustic lenses can be made of various materials; several of the more common lens materials are methyl methacrylate, polystyrene, epoxy resin, aluminum, and magnesium. The important properties of materials for acoustic lenses are:

- Large index of refraction in water
- Acoustic impedance close to that of water or the piezoelectric element
- Low internal sound attenuation
- Ease of fabrication

Acoustic lenses for contour correction are usually designed on the premise that the entire sound beam must enter the testpiece normal to the surface of the testpiece. For example, in the straight-beam inspection of tubing, a narrow diverging beam is preferred for internal inspection and a narrow converging beam for external inspection. In either case, with a flat-face search unit there is a wide front-surface echo caused by the inherent change in the length of the water path across the width of the sound beam, which results in a distorted pattern of multiple back reflections (Fig. 38a). A cylindrically focused search unit completely eliminates this effect (Fig. 38b).

Fig. 38 Comparison of oscilloscope traces resulting from straight-beam immersion inspection by (a) an uncorrected (flat-face) search unit and (b) a contour-corrected (contour-face or cylindrically focused) search unit

The shapes of acoustic lenses vary over a broad range; two types are shown in Fig. 39--a cylindrical (line-focus) search unit in Fig. 39(a) and a spherical (spot-focus) search unit in Fig. 39(b). The sound beam from a cylindrical search unit illuminates a rectangular area that can be described in terms of beam length and width. Cylindrically focused search units are mainly used for the inspection of thin-wall tubing and round bars. Such search units are especially sensitive to fine surface or subsurface cracks within the walls of tubing. The sound beam from a spherical search unit illuminates a small circular spot. Spherical transducers exhibit the greatest sensitivity and resolution of all the transducer types; but the area covered is small, and the useful depth range is correspondingly small.

Fig. 39 Two types of focused search units, and the sound beam shapes produced

Focusing can also be achieved by shaping the transducer element. The front surface of a quartz crystal can be ground to a cylindrical or spherical radius. Barium titanate can be formed into a curved shape before it is polarized. A small piezoelectric element can be mounted on a curved backing member to achieve the same result.

Focal Length. Focused transducers are described by their focal length, that is, short, medium, long, or extralong. Short focal lengths are best for the inspection of regions of the testpiece that are close to the front surface. The medium, long, and extralong focal lengths are for increasingly deeper regions. Frequently, focused transducers are specially designed for a specific application. The longer the focal length of the transducer, the deeper into the testpiece the point of high sensitivity will be.

The focal length of a lens in water has little relation to its focal depth in metal, and changing the length of the water path in immersion inspection produces little change in focal depth in a testpiece. The large differences in sonic velocity between water and metals cause sound to bend at a sharp angle when entering a metal surface at any oblique angle. Therefore, the metal surface acts as a second lens that is much more powerful than the acoustic lens at the transducer, as shown in Fig. 40. This effect moves the focal spot very close to the front surface, as compared to the focal point of the same sound beam in water. This effect also causes the transducer to act as a notably directional and distance-sensitive

receiver, sharpens the beam, and increases sensitivity to small reflectors in the focal zone. Thus, flaws that produce very low amplitude echoes can be examined in greater detail than is possible with standard search units.

Fig. 40 Effect of a metal surface on the convergence of a focused sound beam. See text for discussion.

Useful Range. The most useful portion of a sound beam starts at the point of maximum sound intensity (end of the near field) and extends for a considerable distance beyond this point. Focusing the sound beam moves the maximum-intensity point toward the transducer and shortens the usable range beyond.

The useful range of focused transducers extends from about 0.25 to approximately 250 mm (0.010 to 10 in.) below the front surface. In materials 0.25 (0.010 in.) or less in thickness, resonance or antiresonance techniques can be used. These techniques are based on changes in the duration of ringing of the echo, or the number of multiples of the back-surface echo.

The advantages of focused search units are listed below; these advantages apply mainly to the useful thickness range of 0.25 to 250 mm (0.010 to 10 in.) below the front surface:

- High sensitivity to small flaws
- High resolving power
- Low effects of surface roughness
- Low effects of front-surface contour
- Low metal noise (background)

The echo-masking effects of surface roughness and metal noise can be reduced by concentrating the energy into a smaller beam. The side lobe energy produced by a flat transducer is reflected away by a smooth surface. When the surface is rough, some of the side lobe energy returns to the transducer and widens the front reflection, causing loss of resolving power and increasing the length of the dead zone. The use of a focusing lens on a transducer will reduce the side lobe energy, thus reducing the effects of rough surfaces. The limitation of focused search units is the small region in the test part in the area of sound focusing that can be effectively interrogated.

Noise. Material noise (background) consists of low-amplitude, random signals from numerous small reflectors irregularly distributed throughout the testpiece. Some of the causes of metal noise are grain boundaries, microporosity, and segregations. The larger the sound beam area, the greater the number of small reflectors encountered by the beam. If echoes from several of these small reflectors have the same transit time, they may produce an indication amplitude that exceeds the acceptance level. Focused beams reduce background by reducing the volume of metal inspected, which reduces the probability that the sound beam will encounter several small reflectors at the same depth. Echoes from discontinuities of unacceptable size are not affected and will rise well above the remaining background.

Focused search units allow the highest possible resolving power to be achieved with standard ultrasonic equipment. When a focused search unit is used, the front surface of the testpiece is not in the focal zone, and concentration of sound beam energy makes the echo amplitude from any flaw very large. The resolving power of any system can be greatly improved by using a focused transducer designed specifically for the application and a defined region within the testpiece. Special configurations consist of spherical, conical, and toroidal apertures (Fig. 41) with improvements in beam width and depth of field.

Scanning Equipment

Scanning of testpieces is accomplished by the use of a search unit connected to the ultrasonic instrument by a suitable coaxial cable. During scanning, the search unit is continuously moved over the surface of the testpiece, often in a predetermined search pattern.

Scanning can be done without immersion (contact inspection), provided there is a suitable couplant covering the entire area to be scanned. For example, computerized C-scan systems can be built as a portable system with a hand-held

transducer. Although portable C-scan systems are still in their infancy, their impact on in-service inspection is increasing. Some applications of portable ultrasonic imaging systems are discussed in Ref 8. For testpieces of appropriate size and shape, immersion scanning is widely used. Tanks of various designs and shapes have been built for the immersion of specific testpieces. In addition, standard units (often referred to as universal units or installations) and computerized motion control are available. Computerized systems are capable of following contours at high speed and thus overcoming one of the major limitations of ultrasonics, namely, the need to maintain normal incidence of the ultrasonic beam to ensure the highest defect detection sensitivity.

Most universal units consist of a bridge and manipulator that support and position a pulse-echo inspection system over a large water tank, as shown in Fig. 42. Drive mechanisms move the bridge along the side rails of the tank while traversing mechanisms move the manipulator from side to side along the bridge. Most of these units are automated, although some early units were manually operated.

Fig. 42 Principal components of a universal unit for the immersion scanning of testpieces of various shapes and sizes. See text for discussion.

Adjustable brackets and lazy-susan turntables can be provided on the tank bottom for support of testpieces. Clean, deaerated water containing a wetting agent usually covers a testpiece by a foot or more, providing excellent coupling between search unit and testpiece. For operator comfort, water temperature is usually kept at about 21 °C (70 °F), often by automatic control.

The immersion-scanning unit shown in Fig. 42 represents a high degree of versatility in its capability to accommodate testpieces of various sizes and shapes and to scan using various search patterns. The entire instrument cabinet and search unit can be moved longitudinally on side rails along the length of the tank. Also, the search unit is suspended from a manipulator mounted on a bridge, thus enabling it to be moved from side to side. These movements of the search unit are most appropriate for scanning rectangular flat testpieces.

The universal unit illustrated in Fig. 42 can also be used for scanning testpieces of various circular shapes. For example, a round disklike workpiece can be placed on the turntable (shown at right end of tank) and rotated while the search unit is moved radially outward, thus producing a spiral scanning pattern. The spiral pattern is displayed on a disk-type recorder. A cylindrical testpiece can be scanned in a helical pattern, with a drum-type recorder being used to display the data. Accessory equipment is also available for scanning long cylinders in a horizontal position.

Inspection Standards

The standardization of ultrasonic inspection allows the same test procedure to be conducted at various times and locations, and by both customer and supplier, with reasonable assurance that consistent results will be obtained. Standardization also provides a basis for estimating the sizes of any flaws that are found.

An ultrasonic inspection system includes several controls that can be adjusted to display as much information as is needed on the oscilloscope screen or other display device. If the pulse length and sensitivity controls (or their equivalents) are adjusted to a high setting, numerous indications may appear on an A-scan display between the front-surface and back-surface indications. On the other hand, at a low setting, the trace between front-surface and back-surface indications may show no indications even if flaws of prohibited size are present. Inspection or reference standards are used as a guide for adjusting instrument controls to reveal the presence of flaws that may be considered harmful to the end use of the product and for determining which indications come from flaws that are insignificant, so that needless reworking or scrapping of satisfactory parts is avoided.

The inspection or reference standards for pulse-echo testing include test blocks containing natural flaws, test blocks containing artificial flaws, and the technique of evaluating the percentage of back reflection. Inspection standards for thickness testing can be plates of various known thicknesses or can be stepped or tapered wedges.

Test blocks containing natural flaws are metal sections similar to those parts being inspected. Sections known to contain natural flaws can be selected for test blocks.

Test blocks containing natural flaws have only limited use as standards, for two principal reasons:

- It is difficult to obtain several test blocks that give identical responses. Natural flaws vary in shape, surface characteristics, and orientation, and echoes from natural flaws vary accordingly
- It is often impossible to determine the exact nature of a natural flaw existing in the test block without destructive sectioning

Test blocks containing artificial flaws consist of metal sections containing notches, slots, or drilled holes. These test blocks are more widely accepted as standards than are test blocks that contain natural flaws.

Test blocks containing drilled holes are widely used for longitudinal wave, straight-beam inspection. The hole in the block can be positioned so that ultrasonic energy from the search unit is reflected either from the side of the hole or from the bottom of the hole. The flat-bottom hole is used most because the flat bottom of the hole offers an optimum reflecting surface that is reproducible. A conical-bottom hole, such as is obtained with conventional drills, is undesirable, because a large portion of the reflected energy may never reach the search unit. Differences of 50% or more can easily be encountered between the energy reflected back to the search unit from flat-bottom holes and from conical-bottom holes of the same diameter. The difference is a function of both transducer frequency and distance from search unit to hole bottom. Figure 43(a) shows a typical design for a test block that contains a flat-bottom hole. In using such a block, high-frequency sound is directed from the surface called "entry surface" toward the bottom of the hole, and the reflection from it is used either as a standard to compare with signal responses from flaws or as a reference value for setting the controls of the ultrasonic instrument.

(a)

(b)

Fig. 43 Typical designs of test blocks that are used as reference standards in the detection of flaws by ultrasonic inspection. (a) Test block for straight-beam inspection. (b) Test block for angle-beam inspection.

Dimensions given in millimeters

In the inspection of sheet, strip, welds, tubing, and pipe, angle-beam inspection can be used. This type of inspection generally requires a reference standard in the form of a block that has a notch (or more than one notch) machined into the block. The sides of the notch can be straight and at right angles to the surface of the test block, or they can be at an angle (for example, a 60° included angle). The width, length, and depth of the notch are usually defined by the applicable specification. The depth is usually expressed as a percentage of testpiece thickness. Figure 43(b) shows a typical design for a test block for the angle-beam inspection of plate.

In some cases, it may be necessary to make one of the parts under inspection into a test block by adding artificial discontinuities, such as flat-bottom holes or notches. These artificial discontinuities can sometimes be placed so that they will be removed by subsequent machining.

When used to determine the operating characteristics of the instruments and transducers or to establish reproducible test conditions, a test block is called a calibration block. When used to compare the height or location of the echo from a discontinuity in a part to that from an artificial discontinuity in the test block, the block is called a reference block. The same physical block, or blocks, can be used for both purposes. Blocks whose dimensions have been established and sanctioned by any of the various groups concerned with materials-testing standards are called standard reference blocks.

Reference blocks establish a standard of comparison so that echo intensities can be evaluated in terms of flaw size. Numerous factors that affect the ultrasonic test can make exact quantitative determination of flaw size extremely difficult, if not impossible. One factor is the nature of the reflecting surface. Although a flat-bottom hole in a reference block has been chosen because it offers an optimum reflecting surface and is reproducible, natural flaws can be of diverse shape and offer nonuniform reflecting surfaces. The origin of a flaw and the amount and type of working that the product has received will influence the shape of the flaw. For example, a pore in an ingot might be spherical and therefore scatter most of the sound away from the search unit, reflecting back only a small amount to produce a flaw echo. However, when worked by forging or rolling, a pore usually becomes elongated and flat and therefore reflects more sound back to the search unit.

On the screen, the height of the echo indication from a hole varies with the distance of the hole from the front (entry) surface in a predictable manner based on near-field and far-field effects, depending on the test frequency and search-unit size, as long as the grain size of the material is not large. Where grain size is large, this normal variation can be altered. Figure 44 shows the differences in ultrasonic transmissibility that can be encountered in reference blocks of a material with two different grain sizes. It can be seen in Fig. 44 that for the austenitic stainless steel inspected, increasing the grain size affected the curve of indication height versus distance from the entry surface so that the normal increase in height with distance in the near field did not occur. This was caused by rapid attenuation of ultrasound in the large-grain stainless steel. In some cases where the grain size is quite large, it may not even be possible to obtain a back reflection at normal test frequencies.

Fig. 44 Distance-amplitude curves for type 304 stainless steel showing effect of grain size on ultrasonic transmissibility. Tests were conducted at 5 MHz with a 30 mm ($1\frac{1}{8}$ in.) diam search unit on three reference

blocks having various metal distances to 20 mm ($\frac{3}{4}$ in.) deep, 3 mm ($\frac{1}{8}$ in.) diam, flat-bottom holes.

In the inspection of aluminum, a single set of reference blocks can be used for most parts regardless of alloy or wrought mill product. This is considered acceptable practice because ultrasonic transmissibility is about the same for all aluminum alloy compositions. For ferrous alloys, however, ultrasonic transmissibility can vary considerably with composition. Consequently, a single set of reference blocks cannot be used when inspecting various products made of carbon steels, stainless steels, tool steels, low-alloy steels, and high-temperature alloys. For example, if a reference block prepared from fine-grain steel were used to set the level of test sensitivity and the material being inspected were coarse grained, flaws could be quite large before they would yield an indication equal to that obtained from the bottom of the hole in the reference block. Conversely, if a reference block prepared from coarse-grain steel were used when inspecting fine-grain steel, the instrument could be so sensitive that minor discontinuities would appear to be major flaws. Thermal treatment can also have an appreciable effect on the ultrasonic transmissibility of steel. For this reason, the stage in the fabrication process at which the ultrasonic inspection is performed may be important. In some cases, it may determine whether or not a satisfactory ultrasonic inspection can be performed.

Reference blocks are generally used to adjust the controls of the ultrasonic instrument to a level that will detect flaws having amplitudes above a certain predetermined level. It is usual practice to set instrument controls to display a certain amplitude of indication from the bottom of the hole or from the notch in a reference block and to record and evaluate for accept/reject indications exceeding that amplitude, depending on the codes or applicable standards. The diameter of the reference hole and the number of flaw indications permitted are generally related to performance requirements for the part and are specified in the applicable codes or specifications.

The following should be considered when setting controls for inspection:

- The larger the section or testpiece, the greater the likelihood of encountering flaws of a particular size
- Flaws of a damaging size may be permitted if found to be in an area that will be subsequently removed by machining or that is not critical
- It is generally recognized that the size of the flaw whose echo exceeds the rejection level usually is not the same as the diameter of the reference hole. In a reference block, sound is reflected from a nearly perfect flat surface represented by the bottom of the hole. In contrast, natural flaws are usually neither flat nor perfectly reflecting
- The material being inspected may conduct sound differently from the material of the reference block. Normally, a reference block will be made from material of the same general type as that being inspected
- The depth of a flaw from the entry surface will influence the height of its echo that is displayed on the oscilloscope screen. Figure 45 shows the manner in which echo height normally varies with flaw depth. Test blocks of several lengths are used to establish a reference curve for the distance-amplitude correction of inspection data

Fig. 45 Effect of distance (depth) of flaws of equal size from the entry surface of a testpiece on the echo height of ultrasonic indications

Percentage of Back Reflection. As an alternative to reference blocks, an internal standard can be used. In this technique, the search unit is placed over an indication-free area of the part being inspected, the instrument controls are adjusted to obtain a predetermined height of the first back reflection, and the part is evaluated on the basis of the presence or absence of indications that equal or exceed a certain percentage of this predetermined amplitude. This technique, known as the percentage of back reflection technique, is most useful when lot-to-lot variations in ultrasonic transmissibility are large or unpredictable--a condition often encountered in the inspection of steels.

The size of a flaw that produces a rejectable indication will depend on grain size, depth of the flaw below the entry surface, and test frequency. When acceptance or rejection is based on indications that equal or exceed a specified percentage of the back reflection, rejectable indications may be caused by smaller flaws in coarse-grain steel than in fine-grain steel. This effect becomes less pronounced, or is reversed, as the transducer frequency and corresponding sensitivity necessary to obtain a predetermined height of back reflection are lowered. Flaw evaluation may be difficult when the testpiece grain size is large or mixed.

Generally, metallurgical structure such as grain size has an effect on ultrasonic transmissibility for all metals. The significantly large effect shown in Fig. 44 for type 304 stainless steel is also encountered in other materials. The magnitude of the effect is frequency dependent, that is, the higher the test frequency, the greater the attenuation of ultrasound. In any event, when the grain size approaches ASTM No. 1, the effect is significant regardless of alloy composition or test frequency.

Other techniques are used besides the reference block technique and the percentage of back reflection technique. For example, in the inspection of stainless steel plate, a procedure can be used in which the search unit is moved over the rolled surface, and the display on the screen is observed to determine whether or not an area of defined size is encountered where complete loss of back reflection occurs with or without the presence of a discrete flaw indication. If such an area is encountered, the plate is rejected unless the loss of back reflection can be attributed to surface condition or large grain size.

Another technique that does not rely on test blocks is to thoroughly inspect one or more randomly chosen sample parts for natural flaws by the method to be used on production material. The size and location of any flaws that are detected by ultrasonic testing are confirmed by sectioning the part. The combined results of ultrasonic and destructive studies are used to develop standards for instrument calibration and to define the acceptance level for production material.

Thickness Blocks. Stepped or tapered test blocks are used to calibrate ultrasonic equipment for thickness measurement. These blocks are carefully ground from material similar to that being inspected, and the exact thickness at various positions is marked on the block. Either type of block can be used as a reference standard for resonance inspection; the stepped block can also be used for transit-time inspection.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Standard Reference Blocks

Many of the standards and specifications for ultrasonic inspection require the use of standard reference blocks, which can be prepared from various alloys, may contain holes, slots, or notches of several sizes, and may be of different sizes or shapes. The characteristics of an ultrasonic beam in a testpiece are affected by the following variables, which should be considered when selecting standard reference blocks:

- Nature of the testpiece
- Alloy type

- Grain size
- Effects of thermal or mechanical processing
- Distance-amplitude effects (attenuation)
- Flaw size
- Direction of the ultrasonic beam

Information regarding standard reference blocks is available in ASTM E 127 (see also the "Selected References" at the end of this article). Three types of standard blocks are ordinarily used for calibration or reference: area-amplitude blocks, distance-amplitude blocks, and blocks of the type sanctioned by the International Institute of Welding (IIW). These blocks must be prepared from material having the same or similar alloy content, heat treatment, and amount of hot or cold working as the material to be inspected to ensure equal sonic velocity, attenuation, and acoustic impedance in both the reference standard and the testpiece. If blocks of identical material are not available, the difference between the material in the testpiece and the material used in the standard reference blocks must be determined experimentally.

Area-amplitude blocks provide artificial flaws of different sizes at the same depth. Eight blocks made from the same 50 mm (2 in.) diam round stock, each 95 mm ($3\frac{3}{4}$ in.) high, constitute a set of area-amplitude blocks. The block material must have the same acoustic properties as the testpiece material. Each block has a 20 mm ($\frac{3}{4}$ in.) deep flat-bottom hole drilled in the center of the bottom surface (Fig. 46); the hole diameters vary from 0.4 to 3.2 mm ($\frac{1}{64}$ to $\frac{8}{64}$ in.). The blocks are numbered to correspond with the diameter of the holes; that is, block No. 1 has a 0.4 mm ($\frac{1}{64}$ in.) diam hole, No. 2 has a 0.8 mm ($\frac{2}{64}$ in.) diam hole, and so on, up to No. 8, which has a 3.2 mm ($\frac{8}{64}$ in.) diam hole. Similar area-amplitude blocks made from 49 mm ($1\frac{15}{16}$ in.) square stock are sometimes known as Series-A blocks.

Fig. 46 Standard reference blocks for use in straight-beam ultrasonic inspection. (a) Area-amplitude block. (b) Distance-amplitude block. Dimensions given in inches

The amplitude of the echo from a flat-bottom hole in the far field of a straight-beam search unit is proportional to the area of the bottom of the hole. Therefore, these blocks can be used to check the linearity of a pulse-echo inspection system and to relate signal amplitude to the area (or, in other words, the size) of the flaw. Because a flat-bottom hole is an ideal reflector and most natural flaws are less than ideal in reflective properties, an area-amplitude block defines a lower limit for the size of a flaw that yields a given height of indication on the oscilloscope screen; that is, if the amplitude of the indication from a flaw in a testpiece is six scale units high and this is also the amplitude of the indication from a 2.0 mm ($\frac{5}{64}$ in.) diam flat-bottom hole at the same depth as the flaw, it is certain that the flaw is no smaller in area than the 2.0

mm ($\frac{5}{64}$ in.) diam hole. Unfortunately, with ultrasonic inspection methods, it is not possible to determine how much larger than the reference hole the flaw actually is.

Distance-amplitude blocks provide artificial flaws of a given size at various depths. From ultrasonic wave theory, it is known that the decrease in echo amplitude from a flat-bottom hole using a circular search unit is inversely proportional to the square of the distance to the hole bottom. Distance-amplitude blocks (also known as Series-B or Hitt blocks) can be used to check actual variations of amplitude with distance for straight-beam inspection in a given material. They also serve as a reference for setting or standardizing the sensitivity (gain) of the inspection system so that readable indications will be displayed on the oscilloscope screen for flaws of a given size and larger, but the screen will not be flooded with indications of smaller discontinuities that are of no interest. On instruments so equipped, these blocks are used to set the sensitivity-time control or distance-amplitude correction so that a flaw of a given size will produce an indication on the oscilloscope screen that is of a predetermined height regardless of distance from the entry surface.

There are 19 blocks in a Series-B set. All are 50 mm (2 in.) diam blocks of the same material as that being inspected, and all have a 20 mm ($\frac{3}{4}$ in.) deep flat-bottom hole drilled in the center of the bottom surface (Fig. 46). The hole diameter is the same in all the blocks of a set; sets can be made with hole diameters of 1.2, 2.0, and 3.2 mm ($\frac{3}{64}$, $\frac{5}{64}$, and $\frac{8}{64}$ in.). The blocks vary in length to provide metal distances of 1.6 to 145 mm ($\frac{1}{16}$ to $5\frac{3}{4}$ in.) from the top (entry) surface to the hole bottom. Metal distances are:

- 1.6 mm ($\frac{1}{16}$ in.)
- 3.2 mm through 25 mm ($\frac{1}{8}$ in. through 1 in.) in increments of 3.2 mm ($\frac{1}{8}$ in.)
- 32 mm through 150 mm ($1\frac{1}{4}$ in. through $5\frac{3}{4}$ in.) in increments of 13 mm ($\frac{1}{2}$ in.)

Each Series-B block is identified by a code number consisting of a digit, a dash, and four more digits. The first digit is the diameter of the hole in one sixty-fourths of an inch. The four other digits are the metal distance from the top (entry) surface to the hole bottom in one hundredths of an inch. For example, a block marked 3-0075 has a 1.2 mm ($\frac{3}{64}$ in.) diam hole and a 20 mm ($\frac{3}{4}$ in.) metal distance.

ASTM blocks can be combined into various sets of area-amplitude and distance-amplitude blocks. The ASTM basic set consists of ten 50 mm (2 in.) diam blocks, each with a 20 mm ($\frac{3}{4}$ in.) deep flat-bottom hole drilled in the center of the bottom surface. One block has a 1.2 mm ($\frac{3}{64}$ in.) diam hole at a 75 mm (3 in.) metal distance. Seven blocks have 20 mm ($\frac{5}{64}$ in.) diam holes at metal distances of 3.2, 6.4, 13, 20, 40, 75, and 150 mm ($\frac{1}{8}$, $\frac{1}{4}$, $\frac{1}{2}$, $\frac{3}{4}$, $1\frac{1}{2}$, 3 and 6 in.). The remaining blocks have 3.2 mm ($\frac{8}{64}$ in.) diam holes at 75 and 150 mm (3 and 6 in.) metal distances. The three blocks with a 75 mm (3 in.) metal distance and hole diameter of 1.2, 2.0, and 3.2 mm ($\frac{3}{64}$, $\frac{5}{64}$, and $\frac{8}{64}$ in.) form an area-amplitude set, and the set with the 2.0 mm ($\frac{5}{64}$ in.) diam holes provides a distance-amplitude set. In addition to the basic set, ASTM lists five more area-amplitude standard reference blocks and 80 more distance-amplitude blocks.

Each ASTM block is identified by a code number, using the same system as that used for the Series-B set. The dimensions of all ASTM blocks are given in ASTM E 127, which also presents the recommended practice for fabricating and checking aluminum alloy standard reference blocks. The recommended practice for fabricating and control of steel standard reference blocks is found in ASTM E 428.

IIW blocks are mainly used to calibrate instruments prior to contact inspection using an angle-beam search unit; these blocks are also useful for:

- Checking the performance of both angle-beam and straight-beam search units
- Determining the sound beam exit point of an angle-beam search unit

The use of the ASTM reference plate for inspecting steel is described in ASTM A 503.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Determination of Area-Amplitude and Distance-Amplitude Curves

Determination of the area-amplitude and distance-amplitude responses of a straight-beam pulse-echo ultrasonic inspection system for flaw detection requires a series of test blocks containing flat-bottom holes. Any of the standard reference blocks of this type can be used. Listed below are typical procedures using ASTM blocks.

Area-amplitude curves are determined by the procedure in the list that follows:

1. Select a No. 5 block
2. Position the search unit on the top (entry) surface of the block when using the contact technique, or over the block and at a distance to give a water path of 75 mm (3 in.) when using the immersion technique. If the immersion technique is used, adjust the water path to within ± 0.8 mm ($\pm \frac{1}{32}$ in.) using a gage, and position the ultrasonic beam perpendicular to the top surface of the block by tilting (angulating) the search unit slightly until the front-reflection indication on the oscilloscope screen is maximum
3. Move the search unit horizontally until the hole-bottom indication is maximum
4. Adjust the gain control on the ultrasonic instrument so that the height of the hole-bottom indication is

about one-third the maximum indication height obtainable on the screen

5. Replace the No. 5 block with the other area-amplitude blocks in the set, each in turn
6. With each replacement block, repeat steps 2 and 3. Keep the water path constant for all immersion tests
7. Read the heights of the hole-bottom indications, without changing the gain-control setting that was established with the No. 5 block
8. Plot the heights of each hole-bottom indication against the square of the block number for that indication, as shown in Fig. 49. The square of the block number is proportional to the area of the hole bottom
9. Draw a straight line through the indication height for the No. 5 block and the origin. Significant deviations from this line of ideal linearity are noted (shaded region, Fig. 49) and used as corrections to the indications from actual flaws

Fig. 49 Typical area-amplitude response curve from ultrasonic test blocks having flat-bottom holes

Distance-amplitude curves are determined by the following procedure:

1. Select a No. 5-0300 block
2. Position the search unit as in step 2 for area-amplitude calibration
3. Move the search unit as in step 3 for area-amplitude calibration
4. Adjust the gain control to give a hole-bottom indication height about one-fourth of the maximum obtainable
5. Replace block No. 5-0300 with the other distance-amplitude blocks in the set, each in turn
6. With each replacement block, repeat steps 2 and 3 as for area-amplitude calibration
7. Read the indication height as for area-amplitude calibration
8. Plot the heights of each hole-bottom indication against the metal distance for that indication. The resulting curve is similar to that in Fig. 45, with indication height increasing as metal distance in the near-field region is increased, and decreasing with metal distance in the farfield region

Ultrasonic Inspection

Calibration

In many cases, the determination of area-amplitude and distance-amplitude curves constitutes the calibration of a straight-beam pulse-echo system for the detection of flaws. Calibration of an angle-beam pulse-echo ultrasonic test system for flaw detection can be accomplished using an IIW standard calibration block such as the one shown in Fig. 47(a). The large (100 mm, or 4 in., radius) curved surface at one end of the block is used to determine the index point of angle-beam search units (the point where the beam leaves the unit). The mark labeled "beam exit point" in Fig. 47(a) is at the center of this 100 mm (4 in.) radius. Regardless of the angle of the search unit, a maximum echo is received from the curved surface when the index point of the search unit is at the "beam exit point." To determine the index point of an angle-beam search unit, the search unit is placed on surface A in the position shown in Fig. 50(a) and is moved along the surface of the block until the echo is at maximum amplitude. The point on the search unit that is directly over the beam exit point of the block can then be marked as the index point of the search unit.

Fig. 50 Positioning of angle-beam and straight-beam search units for calibration using the IIW standard reference block shown in Fig. 47(a). See text for explanation. Dimensions given in inches

Beam Angle. Once the index point of the search unit is marked, the 50 mm (2 in.) diam hole is used to determine the angle of the beam in the low-carbon steel from which the block is prepared. The search unit is placed on surface A or surface B and is aimed toward the 50 mm (2 in.) diam hole. Then, the search unit is moved along the surface until a maximum-amplitude echo is received. At this position, the index point on the search unit indicates the beam angle, which is read from one of the degree scales marked along the sides of the block at the edges of surfaces A and B (Fig. 50b).

Beam spread can be determined by moving the search unit in one direction (toward either higher or lower beam angles) from the point of maximum-amplitude echo until the echo disappears and noting the beam angle at the index point. The search unit is then moved in the opposite direction, past the point of maximum-amplitude echo to the point where the echo again disappears. The beam spread is the difference between the angles indicated by the index point at these two extreme positions.

Time Base. The 25 mm (1 in.) radius curved slot (Fig. 47a) is used in conjunction with the 100 mm (4 in.) radius surface for calibrating the time base of the ultrasonic instrument being used with the angle-beam search unit. A direct reflection from the 100 mm (4 in.) radius surface represents a metal distance of 200 mm (8 in.). Similarly, a beam traveling from the beam exit point to the 100 mm (4 in.) radius, then reflecting in turn to surface A, then to the 25 mm (1 in.) radius, back to surface A, once again to the 100 mm (4 in.) radius, and finally back to the search unit, as shown in Fig. 50(c), will give an echo indication at 460 mm (18 in.) metal distance. The time base and marker spacing can be adjusted until the echoes corresponding to 200, 250, 450, 500, 700 mm (8, 10, 18, 20, 28 in.) and so on are aligned with appropriate grid lines on the screen or with a convenient number of marker signals. Upon completion of these adjustments, the instrument time base is calibrated in terms of metal distance in steel. Metal distance can be converted to depth from the entry surface by dividing by 2 and multiplying by the cosine of the beam angle when using a full "vee" path.

The calibration for steel can be converted to a calibration for another material by multiplying metal distance by the ratio of sound velocity in the other material to the corresponding sound velocity in steel (Table 1); transverse wave velocities are ordinarily used because most angle-beam inspection is done with this type of ultrasonic wave. Depth in another material is determined from metal distance as described in the preceding paragraph, but values of metal distance and beam angle for the new material are used instead of the values for steel.

Linearity. Calibration in terms of metal distance or reflector depth assumes a linear oscilloscope sweep for the instrument, which can be checked using a straight-beam search unit. The search unit is placed on either surface C or D to obtain multiple echoes from the 25 mm (1 in.) thickness. These echo indications will be aligned with evenly spaced grid lines or scale marks if the time base is linear. Linearity within $\pm 1\%$ (or less) of the full-scale value of thickness is usually obtainable.

Resolution. A straight-beam search unit, as well as the instrument, can be checked for back-surface resolution by placing the search unit on surface A and reflecting the beam from the bottom of the 2 mm (0.080 in.) wide notch and from surfaces B and E on either side of it, as shown in Fig. 50(d). With proper resolution, the indications from these three surfaces should be clearly separated and not overlapped so as to appear as one broad, jagged indication. Because resolution is affected by test conditions and by characteristics of the search unit and instrument amplifier, this degree of resolution sometimes may not be obtainable.

The dead zone is the depth below the entry surface that cannot be inspected because the initial pulse interferes with echo signals. An indication of the length of the dead zone of a straight-beam search unit can be obtained by placing the search unit on surface A or F in line with the 50 mm (2 in.) diam hole (Fig. 47a). When the search unit is placed on surface A, a discernible echo from the 50 mm (2 in.) diam hole indicates a dead zone of less than 5 mm (0.2 in.). Similarly, when the search unit is placed on surface F, a discernible echo from the 50 mm (2 in.) diam hole indicates a dead zone of less than 10 mm (0.4 in.). Alternatively, the length of the dead zone can be measured by calibrating the time base of the instrument, then measuring the width of the initial-pulse indication at the base of the signal, as illustrated schematically in Fig. 51.

Fig. 51 Schematic showing how dead zone is measured against vertical reference lines. The vertical reference lines represent a unit of vertical thickness.

Sensitivity. The relative sensitivity of an angle-beam search unit in combination with a given instrument can be defined by placing the unit on either surface A or B and reflecting the beam from the side of the 1.5 mm (0.060 in.) diam hole (Fig. 47a). The position of the search unit is adjusted until the echo from the hole is maximum, then the gain of the instrument is adjusted to give the desired indication height.

When no back reflection is expected, the sensitivity of a straight-beam system is defined by placing the search unit on either surface B or F in line with the 1.5 mm (0.060 in.) diam hole. The position of the search unit is adjusted until the echo from the side of the hole is maximum, then the gain of the instrument is adjusted to give the desired indication height.

When a back reflection is expected, a plastic insert can be used in the 50 mm (2 in.) diam hole to gage the sensitivity of a straight-beam system. The plastic material and insert thickness are specified to have the absorption characteristics of 50 mm (2 in.) of steel. With this calibration, the search unit is placed on the side of the insert facing surface C, and the number of echoes and the height of the last echo indication are noted.

Range Setting. The range for a search-unit and instrument system for straight-beam inspection can be set for various distances by use of the IIW block. From surface F to the 2.0 mm (0.080 in.) wide notch is 200 mm (8 in.), from surface A to surface B is 100 mm (4 in.), from surface E to surface A is 91.4 mm (3.60 in.), and from surface C to surface D is 25 mm (1 in.).

Miniature-Block Application. The miniature angle-beam block shown in Fig. 47(b) is used in a somewhat similar manner as the larger IIW block. Both the 25 and 50 mm (1 and 2 in.) radius surfaces provide ways for checking the location of the index mark of a search unit and for calibrating the time base of the instrument in terms of metal distance. The small hole provides a reflector for checking beam angle and for setting the instrument gain.

Reference Plate Application. The use of the ASTM reference plate (Fig. 48) for calibrating ultrasonic equipment is described in ASTM A 503.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection

Detection of Flaws

Ultrasonic inspection has been successfully used to detect flaws in cast and wrought metal parts and in welded, brazed, and bonded joints during research and development, production, and service. Contact inspection is more widely used than immersion inspection, not only because it involves equipment that is portable (allowing field inspection) but also because it is versatile and applicable to a wide range of situations. In contact inspection, however, a substance such as oil, grease, or paste is spread on the surface of the part to act as a couplant; this substance is sometimes difficult to remove after inspection. By contrast, the water used as a couplant in immersion inspection provides good acoustic coupling (even to irregular, rough surfaces such as might occur on unfinished sand castings), but presents no removal problem. Immersion inspection is also especially adaptable to mechanized, production line applications.

The following sections discuss the application of both contact and immersion types of ultrasonic inspection for the detection of flaws in various types of products. In many cases, the inspection procedures used for these products are covered in standards and specifications prepared by various governmental agencies, technical and trade societies, and manufacturers. These standards and specifications usually contain the following three basic elements:

- A description of the inspection method, including details on such variables as ultrasonic frequency, type and diameter of search unit, and type of couplant
- Type and use of calibration and reference standards
- A criterion for rejection, usually expressed as maximum allowable flaw-indication amplitude

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Inspection of Castings

Both contact inspection and immersion inspection are used to detect in castings such flaws as porosity, tears and cracks, shrinkage, voids, and inclusions. Figure 52 illustrates typical ultrasonic indications from four types of flaws found in castings. Although immersion inspection is preferred for castings having rough and irregular surfaces, any one of the inspection techniques previously described can be used. The choice of technique in a specific instance will depend mainly on casting size and shape.

Fig. 52 Ultrasonic indications from four types of flaws found in castings

Because many castings are coarse grained, low-frequency ultrasound may have to be used. Castings of some materials are so coarse grained that extensive scattering makes ultrasonic inspection impractical. These materials include some brasses, stainless steels, titanium alloys, and cast irons. A more extensive discussion is provided in the article "Castings" in this Volume.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Inspection of Primary-Mill Products

Ultrasonic inspection is the most reliable method of detecting internal flaws in forging, rolling, or extrusion billets, in rolling blooms or slabs, and in bar stock. It is capable of detecting relatively small flaws deep within a testpiece. By contrast, eddy current and magnetic particle inspection become less sensitive to internal flaws as the depth of the flaw below the surface increases; detection of internal flaws with these methods is limited to relatively shallow surface layers. Radiography is the only other volumetric method available for inspecting these primary-mill products, but it is slower, more costly, and generally less reliable than ultrasonic inspection for these specifications.

Ultrasonic inspection is used to detect and locate porosity, pipe, internal ruptures, flakes, and nonmetallic inclusions in billets, blooms, slabs, and bar stock of various sizes up to 1.2 m (4 ft) thick in such metals as aluminum, magnesium, titanium, zirconium, carbon steel, stainless steel, high-temperature alloys, and uranium. These products are usually inspected with a straight-beam contact-type search unit, which is often hand held; immersion inspection is also used. One technique for inspecting these product forms is to transmit a sound beam the length of the product; if a strong back reflection is obtained, it is unlikely that there is serious pipe present. However, complete inspection requires testing with the beam transverse to the longitudinal axis. Because complete inspection is relatively slow and tedious, it is sometimes performed only on top cuts, where pipe is most likely to occur. For a higher degree of quality assurance, mechanized contact inspection of an entire lot can be done. Figure 53 shows a typical mechanized setup that uses a wheel-type search unit for the pulse-echo inspection of steel billets. A similar setup uses a water-column search unit instead of the wheel units. Setups for through transmission inspection use a pair of wheel or water-column units.

Inspection of Forgings

Forgings can be ultrasonically inspected for internal flaws such as pipe, internal ruptures, flakes, and nonmetallic inclusions. Inspection is usually done with frequencies of 1 to 5 MHz, with the beam normal to both the surface of the forging and the direction of maximum working; this orientation is best for detecting most flaws in forgings. Angle-beam inspection employing shear waves is sometimes used for rings or hollow forgings.

Contact inspection is performed on most forgings that have fairly uniform dimensions. Because of the difficulty in complete contact inspection of irregularly shaped forgings, immersion inspection may be preferred. Alternatively, contact inspection can be performed at an earlier stage of production before the shape becomes too irregular; however a rough machining of the forging surface is recommended.

Contact inspection is also used for inspecting forgings in service. For example, railroad freight-car-axle journals can be inspected using the special hand-held search unit shown in Fig. 54, which was developed for this purpose. The unit fits on the end of the axle being inspected. Surrounding a centering pin are six straight-beam transducers. The widening sound beams from these transducers give complete coverage of the journal portion of the axle.

Fig. 54 Hand-held straight-beam contact-type search unit for the in-service ultrasonic inspection of railroad freight-car-axle journals

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Inspection of Flat-Rolled Products

Rolled strip, sheet, and plate can be ultrasonically inspected by using either straight-beam or angle-beam pulse-echo techniques for contact or immersion inspection; contact inspection is more widely used. With straight-beam inspection from the top surface of a testpiece, planar discontinuities to which flat-rolled products are susceptible are readily detected, and their locations and limits are easily and accurately determined. However, straight beams cannot be used on strip or sheet too thin to allow resolution of the first back reflection from the initial pulse. Therefore, the inspection of thin products is usually performed with a Lamb wave angle-beam technique.

Straight-beam top inspection of rolled plate is used to detect laminations, excessive stringers of nonmetallic inclusions, and similar flaws. Laminations are particularly detrimental when pieces cut from the plate are to be subsequently welded to form large structural assemblies. Laminations usually occur centered in the thickness of the plate and are usually centered in the as-rolled width of the plate. Laminations do not extend to the surface except at sheared or flame-cut edges and may be difficult to detect visually unless the lamination is gross. For these reasons, ultrasonic inspection is the only reliable way to inspect a plate for laminations.

The straight-beam top inspection of steel plate is usually performed at a beam frequency of 2.25 MHz with search units 20 to 30 mm ($\frac{3}{4}$ to $1\frac{1}{8}$ in.) in diameter. Higher or lower frequencies may be necessitated by grain size, microstructure, or thickness of the material being inspected. The surface of the plate should be clean and free of loose scale that could hinder acoustic transmission. Couplants used for contact inspection include oil, glycerin, or water containing a wetting agent and a rust inhibitor. These are usually applied in a thin layer with a brush.

The contact top inspection of aluminum and other nonferrous plate is usually done with a technique similar to that used for ferrous plate. Frequencies of 1 to 5 MHz, search units $\frac{1}{2}$ to $1\frac{1}{2}$ in. in diameter, and oil couplants are most often used for nonferrous plate.

Prior to inspecting production material, the controls of the ultrasonic instrument are adjusted to obtain a level of sensitivity that will ensure detection of less severe flaws than would be cause for rejection. How this is established is determined by the specific calibration procedure that applies. Those used in plate inspection include test blocks, percentage of back reflection, and loss of back reflection. Test blocks are usually made of a section of plate that is the

same thickness, type, and condition (for example, annealed, pickled, or ground) as the plate to be inspected. The test block will generally contain one or more drilled holes, which are usually flat bottomed. If more than one reference hole is contained in the test block, they will normally be at different depths. The most commonly used depth is midthickness. Instrument controls are adjusted to obtain from the hole a readable echo on the oscilloscope screen. Rejection of material is generally based on the presence of indications exceeding that from the reference hole in the test block. If there are several holes at different depths in the test block, they are used to correct for the effect of metal distance. The depth at which a flaw lies below the entry surface affects the response from the flaw. The test block hole with a depth closest to the depth of the flaw in the plate is used to estimate flaw size. Holes ranging from 3 to 13 mm ($\frac{1}{8}$ to $\frac{1}{2}$ in.) in diameter can be used for reference, depending on desired sensitivity and specified maximum allowable flaw size.

When the percentage of back reflection technique is employed, the search unit is placed over a sound (indication-free) region of the plate, and the instrument controls are adjusted to obtain a readable indication of the first back reflection. For accuracy in determining flaw size, the first back reflection indication displayed on the screen of the ultrasonic instrument is usually kept at less than full screen height and in the linear portion of oscilloscope response. The plate is then scanned by moving the search unit in a uniform manner over the surface of the plate. The plate to be used for nuclear power purposes generally requires a 100% coverage with a small percentage of overlap (for example, 10% of the search-unit diameter) between successive scans. Some specifications call for inspection along grid lines. Rejection is based on the presence of indications that exceed a predetermined percentage of the reference back reflection indication. The percentage of back reflection technique can be used if test blocks are not available or where extreme variation in ultrasonic transmissibility from one lot of material to another exists and it is not feasible to make a test block from each.

The loss of back reflection technique is the technique most often used for the inspection of plate for planar discontinuities, especially laminations. This technique is similar to the percentage of back reflection technique except that rejection is based on complete or partial loss of the back reflection indication. The system is calibrated by placing the search unit over a sound (lamination-free) region of the plate to be inspected. The pattern on the oscilloscope screen is then a series of multiple back reflection indications from the bottom surface of the plate, as shown for the top inspection of 28.4 mm (1.12 in.) thick steel plate in Fig. 55(a). The instrument controls are adjusted to produce a first back reflection height of about 75 to 100% of full screen height. General scanning of the plate is done at this sensitivity level. Minor sensitivity adjustments can be made to accommodate surface roughness, provided no laminations or other flaws are encountered.

(a)

(b)

Fig. 55 Displays of multiple patterns produced during ultrasonic top inspection of steel plate using straight-beam pulse-echo techniques. (a) CRT pattern of back reflection indications from a lamination-free region of a 25 mm (1 in.) thick steel plate. (b) Pattern of indications from a lamination at one-half the plate thickness in an imperfect region of the plate

As the search unit passes over the edge of a lamination during scanning, additional indications appear on the oscilloscope screen approximately midway between the initial pulse and the first back reflection and between the multiple back reflection indications. As the search unit is moved farther over the laminated region, indications of the laminations become stronger until finally the original pattern is replaced by a series of multiple lamination indications spaced at

approximately half the thickness of the plate (Fig. 55b). If the lamination is gross, the number of multiple indications will decrease.

When a flaw indication is observed during general scanning, the gain (sensitivity) of the instrument is adjusted to produce a first back reflection in an adjoining indication-free area of the plate that is $80 \pm 5\%$ of full screen height. Then the indication is scanned in all directions to determine the extent of the flawed region. All flaw indications are evaluated on the basis of maximum obtainable response.

The size of a lamination can be determined by moving the search unit back and forth across the flawed region and, when lamination indications drop to 40% of full screen height, marking the plate at a location corresponding to the center of the search unit. The specification will usually describe acceptance in terms of the maximum size of the region over which complete loss of back reflection can occur. Partial loss of back reflection generally must exceed a certain percentage of the normal back reflection, and this loss usually must be accompanied by the presence of lamination indications. Specifications may require a search unit of minimum diameter for the inspection (for example, a minimum diameter of 25 mm, or 1 in., is often specified for steel). The loss of back reflection technique described above has been used on steel plate from 15 to 75 mm ($\frac{5}{8}$ to 3 in.) thick. With modifications, this technique can be applied to both thinner and thicker material. Further information on the straight-beam top inspection of steel plates is contained in ASTM A 435 and A 578.

Straight-beam edge inspection can be used when large quantities of steel plate with widths of 1.2 to 2.1 m (4 to 7 ft) and thicknesses of 20 to 30 mm ($\frac{3}{4}$ to $1\frac{1}{8}$ in.) are to be inspected. Preliminary screening by inspecting each plate from the edge can reduce the amount of top inspection described above by as much as 80%. Edge inspection can be done while the plate is stacked for storage and requires no handling of individual plates for the inspection. This inspection is rapid and will reveal those plates that are suspect and should be top inspected. Plates that pass the edge inspection need not necessarily be further inspected unless required by specifications.

In edge inspection, an ultrasonic beam is directed from one edge only through the plate perpendicular to the direction of rolling. This technique directs the sound beam at the narrowest dimension of laminations, yet when laminations or other flaws are present there is a partial loss of normal back reflection (often to less than 50% of the back reflection from lamination-free plate). The search unit usually recommended for inspecting steel plate is 22 mm ($\frac{7}{8}$ in.) in diameter and has a plastic wear face. On thin steel plates, where making contact with the edge of the plate is more difficult, a 13 mm ($\frac{1}{2}$ in.) diam search unit can be used. Poor edge condition frequently makes it difficult to obtain good coupling. In most cases, grease will provide sufficient coupling. If the edge is too concave to be filled in with grease, a plastic shoe may help. If none of these techniques brings the back reflection to an acceptable level, the plate should be set aside for top inspection. Even if it takes extra time to make good edge contact, this technique is still more rapid than top inspection.

The screen pattern produced by edge inspection shows a cluster of indications near the search unit that resulted from the high power needed to penetrate the plates; the back reflection will appear as a group of multiple signals that result from partial mode conversion from longitudinal waves to shear waves, as shown in Fig. 56(a) for the edge inspection of 1.5 m (5 ft) wide steel plate. When the back reflection falls below 50% of full screen height, the plate is marked for top inspection. When a lamination is especially severe, it will produce echoes at a point between the back reflection and initial-pulse indications, as shown in Fig. 56(b). On a steel plate 2.4 m (8 ft) long, four checks at equal intervals along one edge are usually sufficient.

Fig. 56 Displays of multiple patterns produced during the ultrasonic edge inspection of steel plate using straight-beam pulse-echo techniques. (a) Pattern from a lamination-free region in a 1500 mm (60 in.) wide steel plate. (b) Pattern of indications from a lamination in the plate. The presence of a lamination has reduced the back reflection indication to less than 50% of full screen height.

Angle-beam inspection can be used to inspect rolled plates. With angle-beam inspection, it is possible to inspect the entire width of the plate merely by moving the search unit along one edge of the plate. However, some specifications require that for total coverage of the plate the search unit be placed on the top surface, directed toward an edge, and moved away from the edge until the opposite edge is reached. Similar scans are repeated with overlapping (for example, 10% of the search-unit diameter) for successive scans. This procedure is continued until the entire plate has been covered. Some specifications call for a second angle-beam inspection in a direction 90° from the first.

The search unit used for the angle-beam inspection of plate is usually one that provides 45 to 60° shear waves in the material being inspected. As with straight-beam inspection, the plate surface should be clean and free of loose scale, and a suitable couplant should be used. Prior to angle-beam inspection of plate, the instrument controls are adjusted to obtain a readable response on the oscilloscope screen from a square notch or V-notch in a test plate. The test plate is generally similar to the plate to be inspected with respect to type, thickness, surface finish, and microstructure. The notch is usually 3 or 5% of the plate thickness in depth, 25 mm (1 in.) long or longer, and approximately twice as wide as it is deep.

The search unit is oriented to a position on the test surface so as to receive the maximum reflected energy from the notch; instrument sensitivity is adjusted to display the notch indication at 50 to 75% of full screen height. Often, a distance-amplitude curve is established by repositioning the search unit at several distances from the notch (for example, at $\frac{1}{2}$, 1, and $1\frac{1}{2}$ skip distances, depending on thickness of the plate) and the various responses noted. This curve is the 100% reference line for reporting flaw-echo amplitudes. When evaluating a flaw to determine whether or not the plate is rejectable, it is important to check at a metal distance comparable to that used in initial calibration using the notch in the test plate.

Angle-beam inspection can detect laps and inclusions and possibly laminations not parallel to the plate surface. However, it is difficult to detect laminations parallel to the plate surface. It is hard to distinguish between a signal from the top of the plate, for example, and a lamination of this type near the top. Therefore, it may be desirable to make a rapid sampling of the plate condition using straight-beam longitudinal waves. If laminations of the type just mentioned are found to be absent, angle-beam shear waves can be used to inspect the entire plate. Of course, if it is necessary to check the plate for cracks on or just beneath the surface, surface waves may be used.

Because straight-beam inspection cannot be used on strip or sheet too thin to allow the back reflection to be resolved from the initial pulse, inspection of these products is accomplished by angle-beam (Lamb wave) inspection. The procedure is much the same as for the angle-beam inspection of plate. The search unit is usually mounted in a fixed position at one edge of the strip or sheet. The sound beam is directed across the width to the far edge while the strip or sheet moves past the search unit. Coupling is maintained by continuously feeding a suitable liquid (alcohol can be used for steel products) ahead of the search unit. The location of a flaw is determined by noting the position of the flaw echo between the initial pulse and edge reflection echo on the oscilloscope screen. An alarm gate is often used to signal the presence of a flaw, thus eliminating the need for constant observation of the screen by an operator.

The mechanized inspection of flat-rolled products has been accomplished by several methods; for example, wheel-type search units have been used for mechanized angle-beam inspection, and water-column search units have been used in transmitting and receiving parts to make printed plan views of the responses from a plate as it travels between the pairs. The immersion inspection of plate is highly adaptable to mechanization; some setups are designed for simultaneous thickness gaging and flaw detection.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Inspection of Extrusions and Rolled Shapes

Flaws in extrusions and in rolled shapes are usually longitudinally oriented, that is, parallel to the direction of working. Both contact and immersion inspection are used to inspect for these flaws, usually employing their longitudinal-beam or angle-beam techniques. In some cases, surface waves are used to detect surface cracks or similar flaws.

Aluminum extrusions may be immersion inspected with C-scan water-tank equipment using the straight-beam pulse-echo technique. The usual types of flaws encountered in this test are laps and seams, but linear porosity may also be found in some products. If a second inspection of a region where flaws are suspected is desired, it is often done by straight-beam contact inspection using water or oil as the couplant.

Cold-extruded steel parts are subject to internal bursts called chevrons. This type of flaw is easily detected either by straight-beam (longitudinal wave) inspection with the search unit contacting the end of the extrusion or by angle-beam (shear wave) inspection with the search unit contacting the side of the extrusion.

In one procedure used to inspect cold extruded automobile-axle shafts for chevrons, a variable-angle water-column search unit was used. The axle shaft being inspected was held horizontally by a fixture in the portable inspection unit shown in Fig. 57(a). The variable-angle water-column search unit that was used produced a sound beam at 1.6 to 2.25 MHz and was adjusted so that the beam entered the shaft at 45° to the shaft axis. This allowed the beam to travel the length of the

shaft (Fig. 57b) and be reflected from the wheel flange. A dual-gated instrument was employed to allow a fail-safe system and to ensure proper inspection of each shaft.

Fig. 57 Ultrasonic inspection of a cold extruded steel automobile-axle shaft for chevrons and internal splits using a portable inspection unit

As the shaft was transferred to the inspection fixture, it closed a limit switch that started the testing sequence. A 5-s time delay after the water column was activated allowed the exclusion of air bubbles and ensured effective coupling of the search unit to the shaft. The instrument then "looked" for the back reflection from the flange in the back reflection gate. If no signal was present, the instrument indicated a no-test condition, and the operator repositioned the shaft and started the sequence a second time. When a back reflection signal was present in the back reflection gate and no signal above a preset amplitude was present in the flaw gate, the instrument indicated an acceptable part. When a signal above the preset amplitude occurred in the flaw gate, as shown in Fig. 57(c), the instrument indicated the presence of damaging chevrons, and the part was automatically marked with paint for rejection.

Another type of internal flaw, a longitudinal split of the core material, was occasionally introduced into axle shaft by an induction-hardening process. The inspection procedure used to detect this type of flaw was the same as for chevrons except that the shaft was rotated during the inspection portion of the testing sequence (Fig. 57d). As the shaft was rotated and the plane of the split assumed a horizontal orientation, the length of the sound beam path was so shortened that the signal moved over into the flaw gate, where it appeared as a flaw indication (Fig. 57e).

Steel bars and pipe are usually contact inspected for internal flaws, using either the straight-beam or the angle-beam technique, or both techniques simultaneously. One method of inspecting round bar is to scan along the bar with a straight-beam search unit having a curved plastic shoe to achieve good contact with the bar. Because the surface of the bar is curved, the sound beam enters the bar at various angles. This may produce both longitudinal and shear waves in the bar and provides for inspection of the entire cross section of the bar.

Another method of inspecting round bar can also be used on pipe. In this method, the bar or pipe is rotated to provide inspection of the entire cross section. Mechanized equipment that uses this method (Fig. 58) is designed to provide inspection simultaneously by both ultrasonic and eddy current techniques. This equipment can inspect bars and pipes from 75 to 300 mm (3 to 12 in.) in diameter and from 3 to 17 m (10 to 56 ft) in length.

Fig. 58 Mechanized equipment for simultaneous ultrasonic and eddy current inspection of round bar or pipe. 1, support frame; 2, drive trolley; 3, carriage; 4, saddle; 5, cable track; 6, manual controls; 7, sensor for signaling end of bar or pipe; 8, eddy current probe; 9, straight-beam ultrasonic search unit; 10, 45° angle-beam ultrasonic search unit; 11, test bar

The equipment consists of a free-standing support frame to which is mounted a motor-driven trolley (on a monorail track that runs the entire length of the support structure, about 21 m, or 70 ft). The trolley, in turn, supports and propels a carriage-and-saddle assembly. The saddle, suspended beneath the carriage, carries three flaw sensors--two ultrasonic search units and one eddy current probe--and is self-aligning when in contact with a pipe or bar during testing. Also mounted on the carriage are a manual control station and an air cylinder that lowers and raises the saddle. A flexible cable track follows the movement of the carriage and saddle assembly. Instrumentation is enclosed in two separate cabinets, and a control console houses all the controls and relays associated with the system. Operation of the equipment is described below.

The bar or pipe to be inspected is placed on a rotator (not shown in Fig. 58) that turns at an adjustable speed. The operator then initiates the test cycle, and the control system activates an air cylinder that lowers the saddle into contact with the rotating part and starts the flow of the water couplant. The trolley and carriage then move the saddle along the rotating test bar or pipe at a speed (also adjustable) that ensures complete inspection of the part.

Ultrasonic inspection is accomplished by two independent water-column search units employing the pulse-echo technique; one unit uses a straight beam and the other an angle beam. Eddy current inspection is performed by a special parallel-rods proximity probe covering approximately a 75 mm (3 in.) scan path. The eddy current instrument has two adjustable inspecting alarm thresholds to provide a capability for inspecting the ends of a part at higher sensitivity than the middle. A chart recorder is also provided to record the magnitude of any flaw signal. If a flaw is detected by any of these sensors, the control system lowers an associated marking device to produce a permanent mark (unique for each sensor) in the region of the flaw. When the end of the bar or pipe is reached, a sensor signals the control system, and the saddle is raised and returned, at higher speed, to the start position.

Steel rails for railroads can be contact inspected in service with special equipment that detects cracks--either transverse cracks emanating from the edges of the railhead or from hydrogen flakes in the center of the railhead, or cracks emanating from fishplate boltholes. Most larger rail-testing equipment employs the pulse-echo method. Often this equipment is mounted on special railroad cars. Most inspection with this equipment is done by angle-beam techniques, but straight-beam inspection is also used. With some equipment, coupling is through an oil film; in other equipment, wheel-type search units are used.

Seamless tubes and pipes can be contact tested on the mechanized equipment shown in Fig. 58, but immersion inspection is used more often. Usually, the tube or pipe is rotated and driven past the immersed search units, which are positioned to produce an angle beam in the wall of the testpiece. The immersion tank has glands on either side through which the part passes during inspection. Further information on the ultrasonic inspection of seamless tubes and pipe is available in the articles "Tubular Products" and "Boilers and Pressure Vessels" in this Volume.

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Inspection of Welded Joints

Welded joints can be ultrasonically inspected using either the straight-beam or the angle-beam technique. Angle-beam inspection is used most often, one reason being that the transducer does not have to be placed on the weld surface, but is typically placed on the relatively smooth base metal surface adjacent to the weld. With angle-beam inspection, the wedge angle is usually selected to produce shear waves in the part being inspected at an optimum angle to detect serious flaws.

The types of flaws usually encountered in welds are porosity, entrapped slag, incomplete penetration, incomplete fusion, and cracks. Serious flaws, such as cracks and incomplete fusion, usually extend longitudinally along the weld and give especially clear signals when the sound beam strikes them at right angles. Spherical porosity will produce a small-amplitude echo, even when the sound beam strikes at an angle to the joint. Slag inclusions may produce stepped indications, which are maximum at right angles to the orientation of the slag. A large inclusion may produce multiple signals as different portions of the inclusion are scanned. The ultrasonic inspection of welds is discussed in the articles "Weldments, Brazed Assemblies, and Soldered Joints" and "Tubular Products" in this Volume.

Inspection of Bonded Joints

If the shape of a joint is favorable, ultrasonic inspection can be used to determine the soundness of joints bonded either adhesively or by any of the various metallurgical methods, including brazing and soldering. Both pulse-echo and resonance techniques have been used to evaluate bond quality in brazed joints.

A babbitted sleeve bearing is a typical part having a metallurgical bond that is ultrasonically inspected for flaws. The bond between babbitt and backing shell is inspected with a straight-beam pulse-echo technique, using a contact-type search unit applied to the outside of the steel shell. A small-diameter search unit is used to ensure adequate contact with the shell through the couplant. Before inspection, the outside of the steel shell and the inside of the cast babbitt liner are machined to a maximum surface roughness of $3.20\ \mu\text{m}$ ($125\ \mu\text{in.}$) (but the liner is not machined to final thickness).

During inspection, the oscilloscope screen normally shows three indications: the initial pulse, a small echo from the bond line (due to differences in acoustical impedance of steel and babbitt), and the back reflection from the inside surface of the liner. Regions where the bond line indication is minimum are assumed to have an acceptable bond. Where the bond line

signal increases, the bond is questionable. Where there is no back reflection at all from the inside surface of the liner (babbitt), there is no bond.

Inspection of other types of bonded joints is often done in a manner similar to that described above for babbitted bearings. An extensive discussion of the ultrasonic inspection of various types of adhesive-bonded joints (including two-component lap joints, three component sandwich structures, and multiple-component laminated structures) is available in the article "Adhesive-Bonded Joints" in this Volume. Additional information can be found in Ref 9 for the immersion inspection of lap joints in Ref 10 for inspecting multiple-component laminated structures using resonance techniques. Reference 11 describes the ultrasonic inspection of a type of laminated structure of which one of the components of the structure was a composite material; the inspection was able to detect flaws in the composite material as well as unbonded regions between the components. Reference 12 deals with the inspection of bonded joints by LLW testing.

Crack Monitoring

Laboratory and in-service monitoring of the initiation and propagation of cracks that are relatively slow growing (such as fatigue cracks, stress-rupture cracks, and stress-corrosion cracks) has been accomplished with ultrasonic techniques. An example of the ultrasonic detection of stress-rupture cracks resulting from creep in reformer-furnace headers is given in the article "Boilers and Pressure Vessels" in this Volume. A relatively new and improved approach for monitoring the growth of cracks is done with ultrasonic imaging techniques.

Monitoring of fatigue cracks in parts during laboratory tests and while in service in the field has been extensively done using ultrasonic techniques. Reference 13 describes the use of surface waves to detect the initiation of cracks in cylindrical compression-fatigue testpieces having a circumferential notch. The surface waves, which were produced by four angle-beam search units on the circumference of each testpiece, were able to follow the contour of the notch and detect the cracks at the notch root. Monitoring the crack-growth rate was accomplished by periodically removing the cracked testpiece from the stressing rig and measuring the crack size by straight-beam, pulse-echo immersion inspection. It was found necessary to break open some of the cracked testpieces (using impact at low temperature) and visually measure the crack to establish an accurate calibration curve of indication height versus crack size.

The use of pulse-echo techniques for monitoring fatigue cracks in pressure vessels in laboratory tests is described in Ref 14. These techniques use several overlapping angle-beam (shear wave) search units, which are glued in place to ensure reproducible results as fatigue testing proceeded.

The in-service monitoring of fatigue cracking of machine components is often accomplished without removing the component from its assembly. For example, 150 mm (6 in.) diam, 8100 mm (320 in.) long shafts used in pressure rolls in papermaking machinery developed fatigue cracks in their 500 mm (20 in.) long threaded end sections after long and severe service. These cracks were detected and measured at 3-month intervals, using a contact-type straight-beam search unit placed on the end of each shaft, without removing the shaft from the machine. When the cracks were found to cover over 25% of the cross section of a shaft, the shaft was removed and replaced. In another case, fatigue cracking in a weld joining components of the shell of a ball mill 4.3 m (14 ft) in diameter by 9.1 m (30 ft) long was monitored using contact-type angle-beam search units. The testing was done at 3-month intervals until a crack was detected; then it was monitored more frequently. When a crack reached a length of 150 mm (6 in.), milling was halted and the crack repaired.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Dimension-Measurement Applications

Ultrasonic inspection methods can be used for measurement of metal thickness. These same methods can also be used to monitor the deterioration of a surface and subsequent thinning of a part due to wear or corrosion and to determine the position of a solid object or liquid material in a closed metallic cavity.

Thickness measurements are made using pulse-echo techniques. Resonance techniques were also used in the past, but have become obsolete. The results can be read on an oscilloscope screen or on a meter, or they can be printed out. Also, the same data signals can be fed through gates to operate sorting or marking devices or to sound alarms. Resonance thickness testing was most often applied to process control inspection where opposite sides of the testpieces are smooth and parallel, such as in the inspection of hollow extrusions, drawn tubes, tube bends, flat sheet and plate, or electroplated parts.

The maximum frequency that can be used for the test determines the minimum thickness that can be measured. The maximum thickness that can be measured depends on such test conditions as couplant characteristics, test frequency, and instrument design and on material type, metallurgical condition, and surface roughness.

Pulse-echo thickness gages with a digital readout (Fig. 59) are widely used for thickness measurement. Pulse-echo testing can measure such great thickness that it can determine the length of a steel reinforcing rod in a concrete structure, provided one end of the rod is accessible for contact by the search unit. Although pulse-echo testing is capable of measuring considerable thicknesses, near-field effects make the use of pulse-echo testing ineffective on very thin materials.

Fig. 59 Hand-held ultrasonic thickness gage

Position measurements of solid parts or liquid materials in closed metallic cavities are usually made with pulse-echo-type equipment. One technique is to look for changes in back reflection intensity as the position of the search unit is changed. In one variation of this technique, the oil level in differential housings was checked to see if the automated equipment used to put the oil in the housing on an-assembly line had malfunctioned. The test developed for this application utilized a dual-gated pulse-echo system that employed a 1.6-MHz immersion-type search unit with a thin, oil-filled rubber gland over its face. The search unit was automatically placed against the outside surface of the housing just below the proper oil level, as shown in Fig. 60(a). With oil at the correct level, sufficient beam energy was transmitted across the boundary between the housing wall and the oil to attenuate the reflected beam so that multiple back reflections were all contained in the first gate (Fig. 60b). The lack of oil at the correct level allowed the multiple back reflections to spill over into the second gate (Fig. 60c). Thus, the test was a fail-safe test that signaled "no test" (no signal in the first gate), "go" (signals in the first gate only), and "no go" (signals in both gates).

(a) Position of search unit for inspection

(b) Oscilloscope display for correct oil level

(c) Oscilloscope display for incorrect oil level

Fig. 60 Method of determining correct oil level in on automobile differential housing by use of an ultrasonic pulse-echo system. See text.

In another position measurement system, a set of two contact-type 4-MHz search units was utilized in a through transmission pitch-catch arrangement to determine the movement of a piston in a hydraulic oil accumulator as both precharge nitrogen-gas pressure and standby oil pressure varied (Fig. 61). The two search units were placed 180° apart on the outside surface of the accumulator wall at a position on the oil side of the piston, as shown in Fig. 61. When a high-energy pulse was sent from the transmitting unit, the beam was able to travel straight through the oil, and a strong signal was picked up by the receiving unit. However, as the search units were moved toward the piston (see locations drawn in phantom in Fig. 61), the sloping sides of the recess in the piston bottom deflected the beam so that very little signal was detected by the receiving unit.

Determination of Microstructural Differences

Ultrasonic methods can be used to determine microstructural differences in metals. For this, contact testing with the pulse-echo technique is used. The testing can be either the measurement of ultrasonic attenuation or the measurement of bulk sound velocity.

The attenuation method is based on the decay of multiple echoes from testpiece surfaces. Once a standard is established, other testpieces can be compared to it by comparing the decay of these echoes to an exponential curve. This test is especially suited for the microstructural control of production parts, in which all that is necessary is to determine whether or not the parts conform to a standard.

An example of the use of ultrasonic attenuation in the determination of differences in microstructure is the control of graphite-flake size in gray iron castings, which in turn controls tensile strength. In one application, a water-column search unit that produced a pulsed beam with a frequency of 2.25 MHz was used to test each casting across an area of the casting wall having uniform thickness and parallel front and back surfaces. A test program had been first carried out to determine the maximum size of graphite flakes that could be permitted in the casting and still maintain a minimum tensile strength of 200 MPa (30 ksi). Then, ultrasonic tests were made on sample castings to determine to what intensity level the second back reflection was lowered by the attenuation effects of graphite flakes larger than permitted. Next, a gate was set on the ultrasonic instrument in the region of the second back reflection, and an alarm was set to signal whenever the intensity of this reflection was below the allowable level. The testing equipment was then integrated into an automatic loading conveyor, where the castings were 100% inspected and passed or rejected before any machining operation.

Velocity Measurements. When considering the compressional and shear wave velocities given in Table 1, there may be small deviations for crystalline materials because of elastic anisotropy. This is important and particularly evident in copper, brass, and austenitic steels. The following example illustrates the variation of sound velocity with changes in the microstructure of leaded free-cutting brass.

Example 3: Measuring the Bulk Sound Velocity in Leaded Free-Cutting Brass.

† Leaded free-cutting brass has a matrix microstructure of α phase with a dispersion of lead particles. Beta-phase stringers may also be present. The lead distribution varies in different heat lots from a total random distribution to confinement at grain boundaries.

This example shows a relationship correlating the sound velocity characteristic to the type of lead distribution in the brass. Two grades of leaded brass are considered: UNS C35300 and C36000. Both alloys are similar in chemical composition, mechanical properties, and sound velocity characteristics.

Four samples with flat parallel surfaces were prepared from 21 mm (0.83 in.) diam bar stock. These cylindrical samples were 17 mm (0.67 in.) in thickness (height). A similar-size velocity standard made from C36000 leaded brass was available. This standard test block had been measured for ultrasound transmission by the National Bureau of Standards (NBS).

The determination of sound velocity involves the measurement of sample thickness and the measurement of transit times with an A-scan display of ultrasonic echoes. The thickness of the samples and the velocity standard block are measured to an accuracy of ± 0.02 mm (± 0.001 in.), and the A-scan display provides the relative time or distance between the interfacial and back echoes for the samples and the velocity standard. If the time sweep on the A-scan display is not accurately calibrated, the velocity standard provides the reference for comparing the relative transit times of the A-scan data. The bulk sound velocity of the samples can then be determined by comparing the A-scan spacing (transit times) of echoes in the sample to the echo spacing in the velocity standard. Further details on the measurement of ultrasonic velocity are available in ASTM E 494-75.

With this general procedure, the back-echo distances on the A-scan oscilloscope display were measured using the electronic gate function control. The frequency used was 10 MHz, with a 75 mm (3 in.) focus transducer. The back-echo spacing on the A-scan display was recorded, and bulk sound velocities calculated. The sound velocity values are listed below:

Identity	Material	Condition	Velocity
----------	----------	-----------	----------

			m/s	ft/s
NBS	C36000	Half hard	4149	13,610
A	C36000	Half hard	3839	12,600
B	C35300	Half hard	4136	13,570
C	C35300	Annealed	4454	14,610
D	C35300	Half hard	4381	14,370

Photomicrographs of samples A, B, C, and D in Fig. 62 show the matrix microstructures and lead distributions. In Fig. 62(a) and 62(b), the dark lead particles are distributed primarily at grain boundaries. These two samples also have lower bulk sound velocity transmission characteristics. Samples C and D have a significantly more random lead distribution within the α -phase grains and higher sound velocity transmission values.

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Corrosion Monitoring

Ultrasonic inspection can be used for the *in situ* monitoring of corrosion by measuring the thickness of vessel walls with ultrasonic thickness gages. The advantage of this method is that internal corrosion of a vessel can be monitored without penetration.

There are, however, some disadvantages. Serious problems may exist in equipment that has a metallurgically bonded internal lining, because it is not obvious from which surface the returning signal will originate. A poor surface finish, paint, or a vessel at high or low temperature may also complicate the use of contact piezoelectric transducers (although this difficulty might be addressed by noncontact *in situ* inspection with an EMA transducer).

Despite these drawbacks, ultrasonic thickness measurements are widely used to determine corrosion rates. To obtain a corrosion rate, a series of thickness measurements is made over an interval of time, and the metal loss per unit time is determined from the measurement samples. Hand-held ultrasonic thickness gages are suitable for these measurements and are relatively easy to use. However, depending on the type of transducer used, the ultrasonic thickness method can overestimate metal thicknesses when the remaining thickness is under approximately 1.3 mm (0.05 in.).

Another corrosion inspection method consists of monitoring back-surface roughness with ultrasonic techniques. The following example describes an application of this method in the monitoring of nuclear waste containers.

Example 4: Ultrasonic Examination of Nuclear Waste Containers to Detect Corrosion.

Before low-level transuranic waste containers are transferred from interim storage (up to 20 years) to long-term storage, the containers are inspected for corrosion. Previously, the most commonly used procedure was visual examination of waste drum external surfaces and a few trial contact ultrasonic thickness measurements. However, visual examination detects only external damage, and sampling with contact ultrasonic thickness readings does not detect subtle changes resulting from minor internal corrosion. Also, the large number of drums to be examined means that manual examination is not compatible with the goal of keeping personnel radiation exposure as low as reasonably achievable.

An automated ultrasonic inspection was developed for monitoring the corrosion in 210 L (55 gal.) nuclear waste containers (carbon steel drums with a nominal wall thickness of 1.4 mm, or 0.055 in.). An initial evaluation was made of both ultrasonic and eddy current methods for assessing container integrity. Potential problems with obtaining the required depth of penetration with eddy currents and the permeability variation in drums resulted in selection of the ultrasonic method.

The ultrasonic system consisted of an eight-channel multiplexed ultrasonic instrument, a drum rotation fixture, bubbler-type search-unit holders, CRT display, strip chart recorder, analog and digital recording, and digital data processing (Ref 15). Eight locations were scanned during drum rotation, and data were taken every 1 mm (0.04 in.) around the circumference as the drum rotated. The search units (10-MHz focused transducers) were designed to tolerate an angle change of $\pm 5^\circ$ and had a maximum beam size of 1.3 mm (0.050 in.) at the focal point to provide for measurements over rough surfaces. The system was able to measure the thickness of steel in the range of 0.5 to 3 mm (0.020 to 0.120 in.).

Figure 63 shows indications from corroded and uncorroded areas. This illustrates the ability of the system to detect back-surface roughness due to corrosion buildup. Correlation with metallography shows that the system can detect oxide buildup of 250 μm (10 mils) and more, as well as deterioration as small as 25 μm (1.0 mil).

Fig. 63 Variations in ultrasonic indications from (a) corroded and (b) uncorroded areas

Ultrasonic Inspection

Revised by Yoseph Bar-Cohen, Douglas Aircraft Company, McDonnell Douglas Corporation; Ajit K. Mal, University of California, Los Angeles; and the ASM Committee on Ultrasonic Inspection*

Stress Measurements

With ultrasonic techniques, the velocity of ultrasonic waves in materials can be measured and related to stress (Ref 16). These techniques rely on the small velocity changes caused by the presence of stress, which is known as an acoustoelastic effect. The technique is difficult to apply because of the very small changes in velocity with changes in stress and because of the difficulty in distinguishing stress effects from material variations (such as texture; see Ref 17). However, with the increased ability to time the arrival of ultrasonic pulses accurately (± 1 ns), the technique has become feasible for a few practical applications, such as the measurement of axial loads in steel bolts and the measurement of residual stress (Ref 5).

The real limitation of this technique is that in many materials the ultrasonic pulse becomes distorted, which can reduce the accuracy of the measurement. One way to avoid this problem is to measure the phase difference between two-tone bursts by changing the frequency to keep the phase difference constant (Ref 5). Small specimens are used in a water bath, and the pulses received from the front and back surfaces overlap.

The presence of stress also rotates the plane of polarization of polarized shear waves, and there is some correlation between the angle of rotation and the magnitude of the stress. Measurement of this rotation can be used to measure the internal stress averaged over the volume of material traversed by the ultrasonic beam.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Introduction

ACOUSTIC EMISSIONS are stress waves produced by sudden movement in stressed materials. The classic sources of acoustic emissions are defect-related deformation processes such as crack growth and plastic deformation. The process of generation and detection is illustrated in Fig. 1. Sudden movement at the source produces a stress wave, which radiates out into the structure and excites a sensitive piezoelectric transducer. As the stress in the material is raised, many of these emissions are generated. The signals from one or more sensors are amplified and measured to produce data for display and interpretation.

Fig. 1 Basic principle of the acoustic emission method

The source of the acoustic emission energy is the elastic stress field in the material. Without stress, there is no emission. Therefore, an acoustic emission (AE) inspection is usually carried out during a controlled loading of the structure. This can be a proof load before service, a controlled variation of load while the structure is in service, a fatigue test, a creep test, or a complex loading program. Often, a structure is going to be loaded anyway, and AE inspection is used because it gives valuable additional information about the performance of the structure under load. Other times, AE inspection is selected for reasons of economy or safety, and a special loading procedure is arranged to meet the needs of the AE test.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Relationship to Other Test Methods

Acoustic emission differs from most other nondestructive testing (NDT) methods in two key respects. First, the signal has its origin in the material itself, not in an external source. Second, acoustic emission detects movement, while most other methods detect existing geometrical discontinuities. The consequences of these fundamental differences are summarized in Table 1.

Table 1 Characteristics of acoustic emission inspection compared with other inspection methods

Acoustic emission	Other methods
Detects movement of defects	Detect geometric form of defects
Requires stress	Do not require stress
Each loading is unique	Inspection is directly repeatable
More material-sensitive	Less material-sensitive
Less geometry-sensitive	More geometry-sensitive
Less intrusive on plant/process	More intrusive on plant/process
Requires access only at sensors	Require access to whole area of inspection
Tests whole structure at once	Scan local regions in sequence
Main problems: noise related	Main problems: geometry related

Often in NDT there is no one method that can provide the whole solution; for cost effectiveness, technical adequacy, or both, it is best to use a combination of methods. Because acoustic emission has features that distinguish it so sharply from other methods, it is particularly useful when used in combination with them.

A major benefit of AE inspection is that it allows the whole volume of the structure to be inspected nonintrusively in a single loading operation. It is not necessary to scan the structure looking for local defects; it is only necessary to connect a suitable number of fixed sensors; which are typically placed 1 to 6 m (4 to 20 ft) apart. This leads to major savings in testing large structures, for which other methods require removal of insulation, decontamination for entry to vessel interiors, or scanning of very large areas.

Typically, the global AE inspection is used to identify areas with structural problems, and other NDT methods are then used to identify more precisely the nature of the emitting defects. Depending on the case, acceptance or rejection can be based on AE inspection alone, other methods alone, or both together.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Range of Applicability

Acoustic emission is a natural phenomenon occurring in the widest range of materials, structures, and processes. The largest-scale acoustic emissions are seismic events, while the smallest-scale processes that have been observed with AE inspection are the movements of small numbers of dislocations in stressed metals. In between, there is a wide range of laboratory studies and industrial testing.

In the laboratory, AE inspection is a powerful aid to materials testing and the study of deformation and fracture. It gives an immediate indication of the response and behavior of a material under stress, intimately connected with strength, damage, and failure. Because the AE response of a material depends on its microstructure and deformation mode, materials differ widely in their AE response. Brittleness and heterogeneity are two major factors conducive to high emissivity. Ductile deformation mechanisms, such as microvoid coalescence in soft steels, are associated with low emissivity.

In production testing, AE inspection is used for checking and controlling welds (Ref 1), brazed joints (Ref 2), thermocompression bonding (Ref 3), and forming operations such as shaft straightening (Ref 4) and punch press operations. In general, AE inspection can be considered whenever the process stresses the material and produces permanent deformation.

In structural testing, AE inspection is used on pressure vessels (Ref 5), storage tanks (Ref 5), pipelines and piping (Ref 6), aircraft and space vehicles (Ref 7), electric utility plants (Ref 7), bridges (Ref 7), railroad tank cars (Ref 8), bucket trucks (Ref 7), and a range of other equipment items. Acoustic emission tests are performed on both new and in-service equipment. Typical uses include the detection of cracks, corrosion, weld defects, and material embrittlement.

Procedures for AE structural testing have been published by The American Society of Mechanical Engineers (ASME), the American Society for Testing and Materials (ASTM), and other organizations. Successful structural testing comes about when the capabilities and benefits of AE inspection are correctly identified in the context of overall inspection needs and when the correct techniques and instruments are used in developing and performing the test procedure (Ref 9).

Acoustic emission equipment is highly sensitive to any kind of movement in its operating frequency range (typically 20 to 1200 kHz). The equipment can detect not only crack growth and material deformation but also such processes as solidification, friction, impact, flow, and phase transformations. Therefore, AE techniques are also valuable for:

- In-process weld monitoring (Ref 10)
- Detecting tool touch and tool wear during automatic machining (Ref 10)
- Detecting wear and loss of lubrication in rotating equipment (Ref 10), and tribological studies (Ref 11)
- Detecting loose parts and loose particles (Ref 12)
- Detecting and monitoring leaks, cavitation, and flow (Ref 12, 13)
- Monitoring chemical reactions, including corrosion processes (Ref 14), liquid-solid transformations, and phase transformations (Ref 14)

When these same processes of impact, friction, flow, and so on, occur during a typical AE inspection for cracks or corrosion, they constitute a source of unwanted noise. Many techniques have been developed for eliminating or discriminating against these and other noise sources. Noise has always been a potential barrier to AE applicability. This barrier is constantly being explored and pushed outward, bringing previously impractical projects into the realm of feasibility.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Acoustic Emission Waves and Propagation

The primitive wave released at the AE source is illustrated in Fig. 2. The displacement waveform is basically a steplike function corresponding to the permanent change associated with the source process. The corresponding velocity and stress waveforms are basically pulselike. The width and height of the primitive pulse depend on the dynamics of the source process. Source processes such as microscopic crack jumps and precipitate fractures are often completed in a few microseconds or fractions of a microsecond, so the primitive pulse has a correspondingly short duration. The amplitude and energy of the primitive pulse vary over an enormous range from submicroscopic dislocation movements to gross crack jumps. The primitive wave radiates from the source in all directions, often having a strong directionality depending on the nature of the source process, as shown in Fig. 3. Rapid movement is necessary if a significant amount of the elastic energy liberated during deformation is to appear as an acoustic emission.

Fig. 2 Primitive AE wave released at a source. The primitive wave is essentially a stress pulse corresponding to a permanent displacement of the material.

Fig. 3 Angular dependence of acoustic emission radiated from a growing microcrack. Most of the energy is directed in the 90 and 270° directions, perpendicular to the crack surfaces.

The form of the primitive wave is profoundly changed during propagation through the medium, and the signal emerging from the sensor has little resemblance to the original pulse. This transformation of the AE waveform is important both to the researcher interested in source function analysis and to the practical NDT inspector interested in testing structures. The researcher who wants to determine the original source waveform uses broadband sensors and performs a detailed analysis of the early part of the received signal. This is an important but very demanding line of inquiry. It may take an hour of computer time to process a single waveform. Most materials-oriented researchers, along with NDT inspectors, are interested in broader statistical features of the AE activity and do not need to know the precise details of each source event. They use narrowband sensors and electronic equipment that measures only a few features of the received waveform but is able to process hundreds of signals per second. The salient wave propagation factors are different for these two lines of work, as discussed below.

Factors in Source Function Analysis. The relationship between the source pulse and the resulting movement at the point of detection has been intensively studied during the last 10 to 15 years. Research groups at the NDT Centre at Harwell, UK (Ref 15), the National Bureau of Standards (Ref 16), Cornell University (Ref 17), and the University of Tokyo (Ref 18) have led the attack on this surprisingly difficult problem. A long-term goal of these studies has been to learn how to calculate a description of the source event from observation of the output of a distant sensor.

The difficulty of the problem is indicated in Fig. 4, which shows the vertical component of the surface movement at point B, resulting from the abrupt application of a vertical force at point A on a semi-infinite body. Even with this simple geometry and source function, the resulting waveform is quite complicated. In the case of a plate, it is more complicated yet, because the second surface also plays its role in the elasto-dynamics of the wave propagation process. In plates, the motion at the point of detection depends strongly on the ratio of source distance to plate thickness.

Fig. 4 Displacement waveform produced by an abrupt application of a downward force at point A. The waveform can be viewed as either a "snapshot" of surface displacement (in which case x = position) or as a graph of the displacement at point B as a function of time (x = time).

In addition, the source function is not instantaneous, it will in fact be a force dipole and/or double couple rather than a point force, its orientation is in general unknown, and horizontal as well as vertical components of motion need to be considered. With these complications, it has understandably taken many years of effort to develop mathematical theory, computational tools, and experimental techniques equal to the task of calculating the source function.

In recent years, the leading laboratories have attained the ability to quantify crack growth increments, orientations, and time characteristics in some of the simpler specimen geometries ordinarily encountered (Ref 19). High-fidelity sensors must be used, and the analysis involves only the first part of the AE waveform, which is recorded in full detail with a high-performance transient recorder. This effort in the characterization of the source pulse has been one of the leading areas of AE research, and it can be expected eventually to yield returns in applied NDT.

Factors in Source Location and Typical AE Measurements. Whereas source function analysis utilizes only the first part of the AE waveform, mainstream AE technology accepts the waveform in its entirety. The later part of this waveform is made up of many components reaching the sensor by a variety of paths. Figure 5 illustrates this principle, but shows only a few of the indefinitely large number of possible paths by which the wave can reach the sensor. Typically, the highest peak in the waveform is produced, not by the first component, but by the constructive interference of several of the later components. The AE wave bounces around the testpiece, repeatedly exciting the sensor until it finally decays away. This decay process may take 100 μ s in a highly damped, nonmetallic material or tens of milliseconds in a lightly damped, metallic material--much longer than the source event, which is usually finished in a few microseconds or less.

Fig. 5 Three possible paths from source to sensor in a water-filled pipe. 1, direct path; 2, spiral path; 3, waterborne path

It is important to understand that the shape of the received waveform is fundamentally the result of these wave propagation processes. Other important aspects of wave propagation in typical AE testing are attenuation and wave velocity. Attenuation is the loss of signal amplitude due to geometric factors and material damping as the wave travels through the material (Ref 20). Attenuation governs detectability at a distance and is therefore an important factor in choosing sensor positions and spacing. Acoustic emission procedures typically call for attenuation measurements to be made before a test and specify permissible sensor spacing based on these measurements.

Wave velocity is an additional factor to be considered when AE technology is used for source location. Source location is an important technique that is widely used both in laboratory studies and in structural testing. It is particularly significant in testing large structures, for which AE inspection is used to identify active regions for conclusive follow-up inspection with other NDT methods. Large cost savings have been realized through this combination of global AE inspection and focused inspection by other methods.

There are several strategies for source location. Zone location places the source within a broad area. Point location places the source precisely, by calculating from the relative arrival times of the AE wave at several sensors. Wave velocity is involved in these calculations. The attainable accuracy is governed by wave propagation processes and depends on such factors as geometry, plate thickness, and contained fluids. In effect, these factors render the wave velocity uncertain and this leads to errors in source location. In favorable cases, the attainable accuracy is better than 1% of the sensor spacing; in unfavorable cases, worse than 10%. The wave propagation effects underlying these variations are reviewed in Ref 20.

Acoustic Emission Sensors and Preamplifiers*

The key element in an AE resonant sensor is a piezoelectric crystal (transducer) that converts movement into an electrical voltage. The crystal is housed in a suitable enclosure with a wear plate and a connector, as shown in Fig. 6. The sensor is excited by the stress waves impinging on its face, and it delivers an electrical signal to a nearby preamplifier and then to the main signal-processing equipment. The preamplifier can be miniaturized and housed inside the sensor enclosure, facilitating setup and reducing vulnerability to electromagnetic noise.

Fig. 6 Typical construction of an AE resonant sensor

sensor is excited by a broadband transient pulse, it rings like a bell at its own natural frequencies of oscillation. Therefore, the electrical signal at the sensor output is the product of this ringing, thus compounding the effects of multiple paths and multiple wave modes by which the wave travels from source to sensor. A typical AE signal from a piezoelectric sensor is shown in Fig. 7; the radical difference between this observed signal and the simple waveform at the source (Fig. 2) cannot be overemphasized.

Sensor Response. One of the most sought-after properties in an AE sensor is high sensitivity. Although high-fidelity, flat frequency response sensors are available, most practical AE testing employs resonant-type sensors that are more sensitive, as well as less costly, than the flat frequency response type. These sensors have one or more preferred frequencies of oscillation, governed by crystal size and shape. These preferred frequencies actually dominate the waveform and spectrum of the observed signal in typical AE testing.

The sensitivity calibration of AE sensors was the subject of a substantial developmental program at the National Bureau of Standards (NBS) through the late 1970s. This program has led to the routine availability of NBS-traceable plots showing the absolute sensitivity of AE sensors in volts per unit velocity as a function of frequency (Ref 21).

Acoustic Emission Waveform Transformation. In addition to the wave propagation factors discussed earlier, the transformation of a single AE waveform is further compounded by the sensor response. When a resonant

Fig. 7 Typical AE burst-type waveform recorded from a flat-bottom storage tank with a transient recorder

Frequency Response. By selecting a resonant sensor from the wide range available, one can effectively choose the monitoring frequency. This is a useful feature that allows the inspector to make a suitable trade-off between the desired detection range and the prevailing noise environment. In practice, the vast majority of AE testing is well performed with sensors that are resonant at about 150 kHz.

Preamplifier Response. The signals generated by the sensor are amplified to provide a higher, more usable voltage. This is accomplished with a preamplifier, which is placed close to (or even inside) the sensor so as to minimize pickup of electromagnetic interference. The preamplifier has a wide dynamic range and can drive the signal over a long length of cable so that the main instrumentation can be placed hundreds of meters from the testpiece if necessary.

The preamplifier typically provides a gain of 100 (40 dB) and includes a high-pass or bandpass filter to eliminate the mechanical and acoustical background noise that prevails at low frequencies. The most common bandpass is 100 to 300 kHz, encompassing the 150 kHz resonant frequency of the most commonly used sensor. Other operating frequencies can be used, but there are limitations. At lower frequencies, there are increasing problems with mechanical background noise. At higher frequencies, the wave attenuates (damps out) more rapidly, and the detection range of the sensor will be smaller. Choice of operating frequency is therefore a trade-off between noise and detection range. Lower frequencies are used on pipelines, where detection range is at a premium, and in geological work because rocks and soils are highly attenuating. Higher frequencies are used to test steam lines in electricity generating stations, where background noise is unusually high.

Attainable Sensitivity. Preamplifiers inevitably generate electronic noise, and it is this noise that sets the ultimate limit to the smallest movement detectable with AE equipment. The smallest signal that can be detected is about 10 μV at the transducer output, corresponding to a surface displacement of about 25 pm (1×10^{-6} $\mu\text{in.}$) for a typical high-sensitivity sensor. This sensitivity is more than enough for most practical NDT applications.

Installation. Typically, the sensor is coupled to the testpiece with a fluid couplant and is secured with tape, an adhesive bond, or a magnetic hold-down device. In some applications, however, the AE sensor may be mounted on a waveguide, as in Example 1.

After the sensor is installed and connected to the monitoring equipment, system performance is checked by "lead break" before monitoring begins. This involves the breaking of a lead pencil near the sensor to verify the response from an acoustic signal. Properly performed, the lead break delivers a remarkably reproducible signal that closely matches the "point impulse loading" source discussed above (see the section "Factors in Source Function Analysis" in this article).

Example 1: Acoustic Waveguide Sensors Used in Monitoring the Cooling of Molten Vitrified Nuclear Waste.

Acoustic emission monitoring was used to help correlate cracking in vitrified high-level waste with cooling procedures. There was a need for a method capable of performing in an environment consisting of approximately 900 °C (1650 °F) temperatures and 500 Gy/h (50,000 rad/h) gamma radiation for the continuous monitoring of vitrified waste in canisters during cooling to detect glass cracking. Waveguide sensors about 4.6 m (15 ft) long were used; one end was submerged in the glass, and a sensing crystal and preamplifier were positioned on the other end. The signal from the sensor was passed through coaxial cables to the outside of the hot cell, where it was received by an AE monitor system for analysis. At the end of the testing, the AE sensors had been in the environment for 120 days, and the accumulated dose of gamma radiation had reached 14×10^5 Gy (14×10^7 rad). The sensors were still functioning properly.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Instrumentation Principles

During an AE test, the sensors on the testpiece produce any number of transient signals. A signal from a single, discrete deformation event is known as a burst-type signal. This type of signal has a fast rise time and a slower decay, as illustrated in Fig. 7. Burst-type signals vary widely in shape, size, and rate of occurrence, depending on the structure and the test conditions. If there is a high rate of occurrence, the individual burst-type signals combine to form a continuous emission. In some cases, AE inspection relies on the detection of continuous emission (see the sections "Mechanisms of AE Sources" and "Leak Testing" in this article).

The instrumentation of an AE inspection provides the necessary detection of continuous emissions or detectable burst-type emissions. Typically, AE instrumentation must fulfill several other requirements:

- The instrumentation must provide some measure of the total quantity of detected emission for correlation with time and/or load and for assessment of the condition of the testpiece
- The system usually needs to provide some statistical information on the detected AE signals for more detailed diagnosis of source mechanisms or for assessing the significance of the detected signals
- Many systems can locate the source of detectable burst-type emissions by comparing the arrival times of the wave at different sensors. This is an important capability of great value in testing both large and small structures
- The systems should provide a means for discriminating between signals of interest and noise signals from background noise sources such as friction, impact, and electromagnetic interference

Instruments vary widely in form, function, and price. Some are designed to function automatically in automated production environments. Others are designed to perform comprehensive data acquisition and extensive analysis at the hands of skilled researchers. Still others are designed for use by technicians and NDT inspectors performing routine tests defined by ASME codes or ASTM standards.

Signal Detection and Emission Counts. After sensing and preamplification, the signal is transmitted to the main instrument, where it is further amplified and filtered. Next is the critical step of detecting the signal. This is accomplished with a comparator circuit, which generates a digital output pulse whenever the AE signal exceeds a fixed threshold voltage. The relationship between signal, threshold, and threshold-crossing pulses is shown in Fig. 8. The threshold level is usually set by the operator; this is a key variable that determines test sensitivity. Depending on instrument design, sensitivity may also be controlled by adjusting the amplifier gain.

Fig. 8 Principle of AE signal detection and threshold-crossing counts

One of the oldest and simplest ways to quantify AE activity is to count the threshold-crossing pulses generated by the comparator (Fig. 8). These acoustic emission counts are plotted as a function of time or load, either as an accumulating total or in the form of a count rate histogram. The all-hardware AE systems of the early 1970s could draw these count and count rate displays on *x-y* recorders as the test proceeded, and much of the early AE literature presents results in this form. Figure 9, a typical plot of this type, shows cumulative counts as a function of applied load during a rising-load test on a precracked specimen of high-strength steel. The vertical scale is 10,000 counts full-scale. The vertical steps on the first parts of the plot are individual AE events. The larger events score several hundred counts each. By 35 kN (8000 lbf), 10,000 counts have been accumulated. The pen resets to the bottom of the graph, and resumes plotting. As the load rises, the AE rate increases, and the individual events are no longer discernible on the plot. As the specimen approaches failure, there are multiple resets of the pen corresponding to the generation of hundreds of thousands of AE counts.

Fig. 9 Acoustic emission from a welded three-point bend specimen of 12% Ni maraging steel. Steps in the curve are discrete, burst-type emissions caused by plastic zone growth and later, crack front movement.

Hit-Driven AE Systems. All-hardware systems reached an apex of development in the late 1970s, but they were eventually superseded by computer-based systems. The development of AE technology coincided with the development of computers, and computers were probably used earlier for AE inspection than for any other NDT method. Computers were first used for AE multichannel source location systems around 1970. Although source location was the first task (and a very advanced one), computers soon came into use for the more general purposes of AE data storage, analysis, and display. At the same time, personnel involved in AE inspection became interested in other signal features of burst-type emissions beyond the threshold-crossing counts (see the section "Signal Measurement Parameters" in this article).

These trends led to a new principle of AE instrumentation that has dominated the technology ever since. This principle involves the measurement of key parameters of each hit, that is, each AE signal that crosses the threshold. A digital description of each hit is generated by the front-end hardware and is passed in sequence with other hit descriptions through a computer system, which provides data storage, a variety of graphical displays, and replay for posttest analysis.

A generic block diagram is shown in Fig. 10, and a typical modern system is shown in Fig. 11. The larger, multichannel systems divide the data-processing tasks among many microprocessors. In the system shown in Fig. 11, for example, a separate microprocessor serves each pair of signal measurement channels. The highest priority for this microprocessor is to read the results of each signal measurement as soon as the measurement process is completed, so that the measurement circuitry can be reset for the next event. The front-end microprocessor can rapidly store several hundred hit descriptions in its buffer, pending further processing. With this parallel processing architecture, added channels will automatically bring added data processing power. With the front-end buffers supplemented by other, even larger buffers in the later stages of the microcomputer network, the system has the versatility to absorb sudden surges of AE activity and to handle widely varying data rates in an optimum manner (Ref 22).

Signal Measurement Parameters. The five most widely used signal measurement parameters are counts (Fig. 8), amplitude, duration, rise time, and the measured area under the rectified signal envelope (MARSE) (Fig. 12). Some tests make do with fewer parameters, and some tests use others, such as true energy, counts-to-peak, average frequency, or spectral moment. However, the five principal parameters have become well standardized and accepted through the market processes of the last 10 years.

Fig. 12 Commonly measured parameters of a burst-type acoustic emission signal

Along with these signal parameters, the hit description passed to the computer typically includes important external variables, such as the time of detection, the current value of the applied load, the cycle count (if it is a cyclic fatigue test), and the current level of continuous background noise. The length of the total hit description is usually between 20 and 40 bytes.

Amplitude, A , is the highest peak voltage attained by an AE waveform. This is a very important parameter because it directly determines the detectability of the AE event. Acoustic emission amplitudes are directly related to the magnitude of the source event, and they vary over an extremely wide range from microvolts to volts. Of all the conventionally measured parameters, amplitude is the one best suited to developing statistical information in the form of distribution functions (Ref 23). The amplitudes of acoustic emissions are customarily expressed on a decibel (logarithmic) scale, in which 1 μV at the transducer is defined as 0dBae, 10 μV is 20dBae, 100 μV is 40dBae, and so on.

Counts, N , are the threshold-crossing pulses (sometimes called ringdown counts) discussed above. This is one of the oldest and easiest ways of quantifying the AE signal. Counts depend on the magnitude of the source event, but they also depend strongly on the acoustic properties and reverberant nature of the specimen and the sensor.

MARSE, sometimes known as energy counts, E , is the measured area under the rectified signal envelope. As a measure of the AE signal magnitude, this quantity has gained acceptance and is replacing counts for many purposes, even though the required circuitry is relatively complex. MARSE is preferred over counts because it is sensitive to amplitude as well as duration, and it is less dependent on threshold setting and operating frequency. Total AE activity must often be measured by summing the magnitudes of all the detected events; of all the measured parameters, MARSE is the one best suited to this purpose.

Duration, D , is the elapsed time from the first threshold crossing to the last. Directly measured in microseconds, this parameter depends on source magnitude, structural acoustics, and reverberation in much the same way as counts. It is valuable for recognizing certain long-duration source processes such as delamination in composite materials (Ref 24), and it can be useful for noise filtering and other types of signal qualification.

Rise time, R , is the elapsed time from the first threshold crossing to the signal peak. Governed by wave propagation processes between source and sensor, this parameter can be used for several types of signal qualification and noise rejection.

Multichannel Considerations. Measurement of the signal proceeds simultaneously on every channel that detects (is hit by) the AE wave. Acoustic emission systems are available in sizes from 1 channel to over 100 channels, depending on the size and complexity of the structure to be tested. Typical laboratory systems have 2 to 6 channels, while most structural tests are accomplished with 12 to 32 channels.

An individual AE event may hit just one channel or it may hit many channels, depending on the strength of the event, the wave attenuation in the structure, and the sensor spacing. Therefore, an early task for the multichannel system is to determine whether a group of closely spaced hits on different channels is from the same source event. Depending on the system design, this can be accomplished either in hardware or in software. The second, third, and later hits from a source event can be either retained for the purposes of source location or discarded to keep the data clean and simple. After this task of event/hit identification has been performed, the system can deal in event descriptions as well as hit descriptions. The event description usually includes channel identification and relative timing information for all the channels involved, along with the signal characteristics of the first hit and perhaps the other hits as well.

The stream of hit (or event) descriptions is passed through a central processor that coordinates the tasks of data storage, display, and operator communications. In larger systems, these tasks can be divided among several processors. In many systems, the entire stream of hit descriptions is stored to disk; this provides unlimited posttest analysis capability. Full data storage is a vital aspect of applied AE technology. It reduces dependence on the on-site operator for ultimate test results, allowing him to concentrate on the vital task of correct data collection (Ref 11).

Data Displays. A software-based, hit-driven AE system can produce many types of graphic displays. The operator is not limited to what can be observed during the test, because the results can be refined, filtered, and redisplayed in any manner during the posttest analysis.

Broadly, AE data displays can be classed as:

- History plots that show the course of the test from start to finish
- Distribution functions that show statistical properties of the emission
- Channel plots showing the distribution of detected emissions by channel
- Location displays that show the position of the AE source
- Point plots showing the correlation between different AE parameters
- Diagnostic plots showing the severity of AE indications from different parts of the structure

Some of these generic display types are illustrated in Fig. 13.

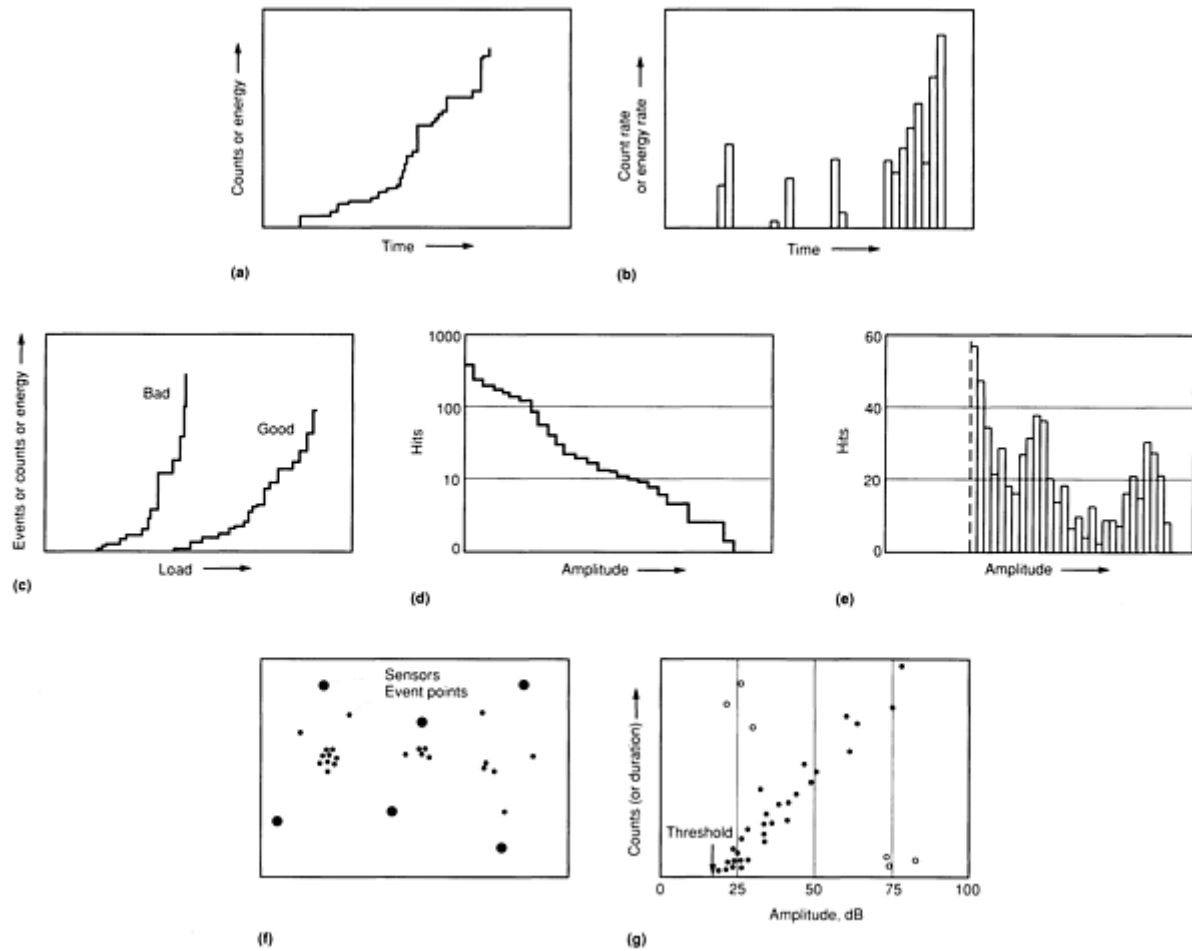

Fig. 13 Typical AE data displays. (a) History plot of the cumulative count or energy. (b) History plot of the count rate or energy rate. (c) History plot of AE data versus load. (d) Cumulative amplitude distribution showing the number of hits that exceeded an amplitude. (e) Differential amplitude distribution showing the number of hits of a particular amplitude. (f) Planar source location display. (g) Point plot of counts (or duration) versus amplitude

Figures 13(a) and 13(b) show history plots of AE data versus time in cumulative and rate form, respectively. A cumulative plot is the more convenient format for reading off a total emission quantity, while a rate plot highlights the changes in activity that occur during the test.

Figure 13(c) is a history plot of AE data versus load. This is the most fundamental plot because it directly relates cause to effect. This type of plot is especially useful for separating good parts from bad; bad parts characteristically begin to emit at lower loads and give more emission than good parts at all load levels. This basic plot of AE data versus load is also the best way to display the Kaiser and Felicity effects, as shown in Fig. 14.

Fig. 14 Basic AE history plot showing Kaiser effect (BCB), Felicity effect (DEF), and emission during hold (GH)

Figures 13(d) and 13(e) show the cumulative and differential forms, respectively, of the amplitude distribution function. The x -axis shows amplitude, and the y -axis shows how many hits had that amplitude (differential form) or exceeded it (cumulative form). The differential amplitude distribution (Fig. 13e) is useful for distinguishing between deformation mechanisms and for observing changes in AE intensity as the test proceeds. The cumulative form (Fig. 13d) is more useful for quantitative modeling and for assessing how the detectability of AE will be affected by changes in test sensitivity. The amplitude distribution is a standard AE display, and the underlying theory is well developed (Ref 23). Distribution functions using the other signal measurement parameters are also employed for special purposes.

Figure 13(f) is a planar source location display. This display is basically a map of the structure, with the computed location of each emission event shown as a single point in the appropriate position. Sensor locations are shown as large dots, providing a reference frame. The eye is drawn to clusters of located events, which correspond to the most active sources, typically structurally significant defects.

Figure 13(g) is a point plot of counts (or duration) versus amplitude. Each hit is shown as one point on the display, and its position shows information about the size and shape of the waveform. This type of display is used for data quality evaluation, specifically for identifying some commonly encountered types of unwanted noise (Ref 25). Acoustic emission signals from impulsive sources typically form a diagonal band running across this display. Noise signals from electromagnetic interference fall below the main band (circled area, lower right, Fig. 13g) because they are not prolonged by acoustic reverberation. Noise signals from friction and leaks fall above the main band (circled area, upper left, Fig. 13g) because the source process is extended in time, not a short impulse. This is only one of the many point plots that have proved useful in practical AE testing.

The typical software-based system can generate many displays simultaneously in memory while the test is running, presenting them to the operator upon demand. In addition to these graphic displays, the system may present tabulated data and/or listings of the individual event or hit descriptions.

Special-Purpose AE Systems. The software-based, hit-driven AE system has the architecture of choice for application development and general-purpose laboratory and structural testing, but not all AE systems require this kind of computational power and versatility of display. Once the needs of the test have been defined, simpler equipment is often appropriate for routine application.

Production testing can often be done with a basic, all-hardware instrument that simply measures counts or energy and trips an alarm when the emission exceeds a predetermined quantity. Automatic self-checking for good sensor contact can be incorporated into the function of such an instrument.

Resistance weld monitoring and feedback control is accomplished with all-hardware systems that have special gates, timers, and interfaces to synchronize the AE monitoring with the operation of the weld controller. Other types of weld monitoring instruments incorporate pattern-recognition algorithms for automatically recognizing and classifying specific kinds of weld defects.

Leak testing is a major and relatively simple application of AE instrumentation (see the section "Structural Test Applications" in this article). Leak testing can be performed with instruments that measure only the root mean square (rms) voltage of the continuous emission from a leak. Sometimes, detectability is enhanced by the occurrence of burst-type signals from particle impact or structural degradation of the local material. Small size is a major advantage when the instrument has to be carried around an industrial complex or power generating plant.

Specific Applications. Instrument manufacturers have also developed special instruments for specific, well-established applications, such as bucket truck testing and tank car testing. These instruments are based on the applicable codes or standard procedures for performing the test. Simplification of hardware and software leads to a lower-cost instrument. Customized software provides more positive guidance and fewer operator choices, so that a lower level of skill can be used on-site and the test can be performed reliably and economically.

Noise

Precautions against interfering noise are an integral part of AE technology. Enormous progress has been made since the early days when students worked at night, using specially constructed loading machines in underground laboratories to avoid disruption of their experiments by street traffic and people moving nearby. With current technology, many tests can be performed without special measures, and a wide range of techniques have been developed to make AE inspection applicable in extremely noisy environments.

A basic starting point is the selection of an appropriate frequency range for AE monitoring. The acoustic noise background is highest at low frequencies. The 100 to 300 kHz range has proved suitable for perhaps 90% of all AE testing. In noisy environments (an electric power plant, for example), higher frequencies, such as 500 kHz, have been

necessary to reduce the noise detected from fluid flow. Because higher frequencies bring reduced detection range, there is an inherent trade-off between detection range and noise elimination.

Acoustic noise sources include fluid flow in pumps and valves, friction processes such as the movement of structures on their supports, and impact processes such as rain and wind-blown cables striking the structure. Electrical and electromagnetic noise sources include ground loops, power switching circuits, radio and navigation transmitters, and electrical storms.

Noise problems can be addressed in many ways. First, it may be possible to stop the noise at the source. Second, it may be possible to eliminate an acoustic source by applying impedance-mismatch barriers or damping materials at strategic points on the structure. Electrical noise problems, which are often the result of poor grounding and shielding practices, can be eliminated by proper technique or by using differential sensors or sensors with built-in preamplifiers. If these measures are inadequate, the problem must be dealt with by hardware or software in the AE instrument itself.

Sensitivity adjustments, including floating-threshold techniques, can be very effective as long as they do not also cause the loss of essential AE data. Methods for selective acceptance and recording of data based on time, load, or spatial origin are well developed. Beyond this, because noise sources often give characteristically different waveforms, they can often be separated from true acoustic emissions by computer inspection of the measured signal characteristics (Ref 25). This can be accomplished immediately after measurement (front-end filtering), during the display process (graphical filtering), or after the test by playing the data through a posttest filtering program or advanced waveform analysis package.

Through the development and application of these techniques, AE inspection has been brought into service in increasingly demanding environments, and this trend is expected to continue. Examples of difficult applications in which noise elimination was key to the successful use of AE inspection include the on-line monitoring of welding (Ref 1, 26) and the detection of fatigue crack growth in flying aircraft (Ref 7).

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Load Control and Repeated Loadings

Because acoustic emission is produced by stress-induced deformation of the material, it is highly dependent on the stress history of the structure. Emission/stress/time relationships also depend on the material and on the type of deformation producing the emission. Some materials respond almost instantly to applied stress, emitting and then quickly stabilizing. Other materials take some time to settle down after a load is applied; this is readily observed in materials that show viscoelastic properties, such as resin-matrix composites. In other cases, a constant load may produce ongoing damage, and the structure may never stabilize. An example of this is hydrogen-induced cracking, which may proceed under constant load to failure, with continual emission.

Acoustic emission testing is often carried out under conditions of rising load. The first load application will typically produce much more emission than subsequent loadings. In fact, for instantaneously plastic materials, subsequent loadings should produce no emissions at all until the previous maximum load is exceeded. This behavior was first reported by Kaiser in 1950 (Ref 27) and has been a leading influence in the development of AE test methodology. Dunegan (Ref 28) showed that for materials that obey the Kaiser effect, emission on a repeat loading will indicate that structural damage occurred between the first loading and the repeat. This became the conceptual basis of much of the AE testing of the 1970s, when the first AE field test organizations undertook periodic inspection of pressure vessels and other structures.

Recent test strategies pay much attention to emission that occurs at loads below the previous maximum and to emission that continues when the load is held at a constant level. The evidence is that structurally significant defects will tend to exhibit these behaviors, while emission related to stabilization of the structure, such as the relief of residual stress, will tend not to recur when the structure is loaded again.

Figure 14 is a generic illustration of these contrasting behaviors. Emission is observed upon initial loading from A to B, but not upon unloading (B to C). Upon reapplying the load, there is no emission (line is horizontal) until B is reached again; this is the Kaiser effect. The load is increased to D, with more emission, and another unload-reload cycle is applied. This time, because of the higher stress levels, significant defects begin to emit at point F, below the previous maximum load. This behavior is known as the Felicity effect. It can be quantified with the Felicity Ratio (FR):

$$FR = \frac{\text{Load at which emission begins again}}{\text{Previous maximum load}}$$

Technically, the Kaiser effect can be construed as a Felicity Ratio of 1.0 or greater. Systematic decreases in the Felicity Ratio as material approaches failure have been well documented for fiber-reinforced plastics (Ref 29) and a Felicity Ratio less than 0.95 is cause for rejection of an FRP tank or pressure vessel tested by AE inspection according to ASME Article 11 (Ref 30). Under ASME Article 12 (Ref 31) for the AE testing of metal pressure vessels, it is in some cases admissible to ignore AE data from the first loading of a vessel and to consider only AE data from a second loading. The basis for this is that much emission on the first loading comes from local yielding (structurally insignificant), while only the significant defects will emit on the second loading (Felicity Ratio < 1).

Figure 14 also illustrates the graphical appearance of emission continuing during a load-hold period (G to H). The Felicity effect and the occurrence of emission during load holds may share a common underlying explanation; both are associated with the unstable nature of structurally significant defects. Emission during load holds has been known since the early years of AE inspection (Ref 28) and was incorporated in FRP evaluation criteria in the mid 1970s. In the late 1980s, emission during hold has been made the entire basis of Monsanto's successful procedure for the AE testing of railroad tank cars (Ref 8). In this interesting development, data analysis is greatly simplified because the background noise sources present during rising load are much less obtrusive during the load-hold periods.

Careful attention must be paid to the loading schedule if AE testing is to be successful. Procedures for an AE test typically specify the loads that must be applied (relative to the working load or design load) and the upper and lower limits on the loading rate. Fiber-reinforced plastic tanks and vessels must be conditioned by a period at reduced load before the AE test is conducted (Ref 30). An AE test can be invalidated if the structure is inadvertently loaded beforehand to the AE test pressure. For success in dealing with these points, there must be good communication and coordination between the personnel loading the structure and those collecting the AE data.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Acoustic Emission in Materials Studies^{*}

Acoustic emission is a remarkable tool for studying material deformation because the information it provides is both detailed and immediate. With its sensitivity to microstructure and its intimate connection with failure processes, AE inspection can give unique insights into the response of material to applied stress. Acoustic emission analysis is most useful when used in conjunction with other diagnostic techniques, such as stress-strain measurements, microscopy, crack-opening-displacement measurements and potential drop (for crack growth), or ultrasonic damping measurements (for dislocation studies). Acoustic emission complements these techniques and offers additional information on the dynamics of the underlying deformation processes, their interplay, and the transitions from one type of deformation to another.

Many materials studies involve the development of a test approach for eventual field application. Such work can be valuable, but it is subject to the difficulty of simulating defect emissivities and other field conditions in the laboratory. Laboratory tests are often done with simple uniaxial stresses applied parallel to the rolling direction, while materials in industrial service are often subjected to complex biaxial or triaxial stress fields. In such cases, the acoustic emissions from the laboratory tests will not be a good model of the acoustic emissions from materials in industrial service.

Mechanisms of AE Sources. Needless to say, acoustic emissions are not generated by the reversible, homogeneous alteration of interatomic spacings that constitutes elastic deformation. Acoustic emissions are only generated when some abrupt and permanent change takes place somewhere in the material. Mechanisms that produce acoustic emissions in metals include the movement and multiplication of dislocations; slip; twinning; fracture and debonding of precipitates, inclusions, and surface layers; some corrosion processes; microcrack formation and growth; small and large crack jumps; and frictional processes during crack closure and opening.

The amount of AE energy released depends primarily on the size and speed of the local deformation process. The formation and movement of a single dislocation does produce an AE stress wave, but it is not a large enough process to be detected in isolation. However, when millions of dislocations are forming and moving at the same time during yielding of a tensile specimen, the individual stress waves overlap and superimpose to give a detectable result. The result is a continuous excitation of the specimen and sensor that is detectable as soon as the voltage it produces becomes comparable with the background noise. The higher the strain rate and the larger the specimen, the larger this signal becomes. This so-called continuous emission is different from burst-type emission in that the individual source events are not discernible. Continuous emission is best measured with rms or energy rate measuring circuitry.

Continuous emission from the plastic deformation of steels, aluminum alloys, and many other metals has been extensively studied, and there have been many detailed findings relating acoustic emissions to dislocation activity and precipitates, microstructure, and materials properties (Ref 32). Such studies can yield valuable insights for alloy and material development. Most studies have focused primarily on continuous emission during and after yield; burst-type emissions sometimes observed in the nominally elastic region are less well explained.

The following example illustrates the dependence of continuous emission on microstructure. The fracture of small-scale precipitates (in this case, pearlite lamellae) generates continuous emission, which can be related to the microstructure that results from heat treating.

Example 2: Relation of Acoustic Emissions With the Optimum Heat Treating of Ferritic/Pearlitic Steel.

Figure 15 illustrates the dependence of continuous acoustic emissions on the microstructure of a deep-drawing ferritic/pearlitic steel subjected to a spheroidizing heat treatment to improve its formability. Data are shown from representative underannealed, optimally annealed, and overannealed conditions. Figure 15 shows AE energy rate as a function of time from dog-bone tensile specimens pulled to failure in a screw-driven test machine. All the graphs display peaks around the yield region, a common feature in the high-sensitivity tensile testing of unflawed specimens. Figure 15 also shows a second, shallow peak at higher strain levels.

(a)

(b)

(c)

Fig. 15 Acoustic emission energy rate (expressed as the mean square of sensor voltage) and load versus time. Optimum formability corresponds to the lowest emissivity in a deep-drawing steel subjected to spheroidization heat treatment. (a) Underannealed: 80% pearlite, 20% spheroids. (b) Optimally annealed: 100% spheroids. (c) Overannealed: 30% elongated spheroids and doglegs

The interesting result is that the optimally annealed specimen shows a much smaller peak (gives much less emission) than the other two specimens. The explanation is found by carefully relating AE behavior to microstructural deformation processes. It is known that dislocations can pile up against pearlite lamellae during plastic deformation, eventually causing the lamellae to fracture. This fracture of pearlite lamellae is believed to be the cause of the first peaks in Fig. 15.

With the test material in the underannealed condition, microscopy reveals the presence of many untransformed pearlite lamellae that can intercept the moving dislocations, so the peak is high. With the test material in the optimally annealed condition, microscopy shows that virtually all the lamellae have been transformed to spheroids. These have a smaller cross-sectional area and present less of an obstacle to the moving dislocations, so deformation can proceed without breaking pearlite. Ductility is enhanced, and there is very little emission from this optimally annealed material.

With the test material in the overannealed condition, microscopy shows that additional carbon has come out of solution, growing the spheroids and forming doglegs at the grain boundaries. These larger particles interfere more strongly with dislocation motion and produce larger emissions when fractured, so the emission peak is strong again. It is an interesting result that the optimum material condition is the condition of lowest emissivity, suggesting that AE inspection could be used for inspection and quality control of this material as well as for research.

Acoustic emission from crack growth is of the greatest interest for practical NDT applications of the AE phenomenon. By virtue of the stress concentrations in their vicinity, cracks and other defects will emit during rising load, while unflawed material elsewhere is still silent. Acoustic emissions from crack initiation and growth have been extensively reported in the literature. Many of these reports deal with specialized forms of crack growth, such as fatigue, stress-corrosion cracking, and hydrogen embrittlement (Ref 33).

It is useful to distinguish between AE signals from the plastic zone at the crack tip and AE signals from movement of the crack front itself. Growth of the plastic zone typically produces many emissions of rather low amplitude. These emissions are typically ascribed to the fracture of precipitates and inclusions (for example, manganese sulfide stringers in steels), and the triaxial nature of the stress field is implicated in the emissivity of these sources.

Acoustic emissions from crack front movement depend critically on the nature of the crack growth process. Microscopically rapid mechanisms such as brittle intergranular fracture and transgranular cleavage are readily detectable, even when the crack front is only advancing one grain at a time at subcritical stress levels. Slow, continuous crack growth mechanisms such as microvoid coalescence (ductile tearing) and active path corrosion are not detectable in themselves, but if general yield has not occurred, they may be detectable through associated plastic zone growth. Quantitative theory, which explains why some processes are detectable and others are not, was developed by Wodley and Scruby (Ref 33). The possibility of silent crack growth in ductile materials caused much consternation when it was first recognized in laboratory conditions, but it has not been a deterrent in real-life NDT, in which emission from defects is characteristically enhanced by environmental embrittlement, emissive corrosion products, crack face friction, or emissive nonmetallic materials entrained in the defect during the fabrication process.

Many fracture mechanics models have been developed to relate acoustic emissions to crack growth parameters. An important early approach was to relate acoustic emissions to the plastic zone size with the hope of estimating directly the stress intensity factor at defects found in the field (Ref 34, 35). Other models relate acoustic emissions to crack tip movement in situations of cyclic fatigue (Ref 33) or stress-corrosion cracking (Ref 36) for various materials. These models are commonly framed as power-law relationships, with the acoustic emission described by conventional parameters such as threshold-crossing counts, N . In the more recent but difficult technique of source function analysis discussed in the section "Acoustic Emission Waves and Propagation" in this article, individual crack growth increments can be quantified in absolute terms by computer-intensive analysis of the early portion of the AE waveform.

Nonmetallic layers on metal surfaces also exhibit acoustic emissions for potential NDT applications. Examples of acoustic emissions from nonmetallic layers include:

- The acoustic emission from high-temperature oxidation (Ref 37)
- The extensive study of acoustic emissions from room-temperature corrosion processes (Ref 38, 39)
- The use of acoustic emissions to optimize the performance of ceramic coatings used in high-temperature components (Ref 40)

Metal-Matrix Composites. The following example illustrates one application involving the testing of a metal-matrix composite.

Example 3: Acoustic Emissions From the Microcracking of the Brittle Reaction Zones of Two Metal-Matrix Composites.

During the tensile testing of two metal-matrix composites, microcracking of the brittle interphase between the fibers and the matrix produced distinguishable peaks in AE count rates well before ultimate failure from ductile failure of the matrix. This may suggest a potential application of AE inspection for the real-time monitoring of structures made of these or similar metal-matrix composites to provide indications of structural problems before critical damage occurs.

The materials tested were metal-matrix composites that consisted of a titanium (Ti-6Al-4V) matrix reinforced with continuous, large-diameter silicon carbide (SiC, \approx 0.142 mm, or 0.0056 in., in diameter) or boron carbide coated boron (B(B₄C), \approx 0.145 mm, or 0.0057 in., in diameter) fibers (with fiber volume fractions of 0.205 and 0.224, respectively). Standard straight-edge tensile test coupons were used. Specimens were cut with the fibers either parallel or perpendicular to the load axis (longitudinal or transverse tension specimens, respectively). Steel end tabs were used, and all surfaces were sanded and cleaned.

Specimens were tested to failure in a servohydraulic testing machine operated at constant crosshead displacement. For each test, a single AE transducer was coupled to the midpoint of the specimen (within the gage section) with vacuum grease, and the acoustic count rate was measured as a function of the longitudinal displacement (strain). After each test, the fracture surface was examined with optical and scanning electron microscopes to determine the fracture processes that occurred.

The values given in Table 2 for rupture or failure strains of the fibers and the brittle reaction compounds formed at the fiber/matrix interface during the hot pressing process were used to find the correlations between fracture processes and AE count rates, with differences in the AE count rates between the two materials related to the differences in their brittle components. As shown in Fig. 16(a), for longitudinal tension specimens of B(B₄C)/Ti-6Al-4V, there was a distinguishable rise in the AE count rate near the rupture strain of titanium diboride and a peak near the rupture strain for boron carbide. The final peak resulted from ultimate fiber failure. For transverse tension specimens, Fig. 16(b) and 16(c) show large peaks in AE count rate near the rupture strains of the major brittle components (titanium diboride in B(B₄C)/Ti-6Al-4V and titanium carbide in SiC/Ti-6Al-4V). There were also minor peaks near the rupture strains of the other brittle components. The larger brittle reaction zone in B(B₄C)/Ti-6Al-4V relative to SiC/Ti-6Al-4V results in the larger area for the AE count rate plot. The ultimate failure in the transverse specimens consisted largely of ductile matrix failure with lower AE count rates (relative to the microcracking).

Table 2 Brittle phase mechanical properties

Metal-matrix composite	Brittle compound	Failure strain, %
B(B ₄ C)/Ti-6Al-4V	Titanium diboride	0.25
	Boron carbide	0.57
	Boron	0.80

SiC/Ti-6Al-4V	Titanium carbide	0.28
	Titanium silicide	0.66
	Silicon carbide	0.91

Fig. 16 Area plot of AE count rate versus strain. (a) Longitudinal tension test of a B(B₄C)/Ti-6Al-4V specimen. (b) Transverse tension test of a B(B₄C)/Ti-6Al-4V specimen. (c) Transverse tension test of a SiC/Ti-6Al-4V specimen

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Use of AE Inspection in Production Quality Control

In a small but important class of applications, AE inspection is applied during a manufacturing process to check the quality of the product or one of its components before final assembly and/or delivery. Of the production testing applications discussed in the section "Range of Applicability" in this article, common application of AE inspection in production quality control is the monitoring of welding and shaft straightening processes. Other efforts have been directed toward the inspection of integrated circuits. In the early 1970s, for example, an entire satellite launch mission failed because of a loose particle inside the cavity of a single integrated circuit. As a result, integrated circuits for critical applications are now routinely tested by particle impact noise detection technology, an inexpensive derivative of AE testing (Ref 12). During the manufacturing process, other types of flaws in integrated circuits can also be effectively controlled with AE inspection. Acoustic emissions from bonding processes and from ceramic substrate cracking were investigated by Western Electric researchers during the 1970s and were used as accept/reject criteria for parts on automated assembly lines (Ref 3).

The AE monitoring of welding processes has been part of the technology since its early days. Slag-free, more-automated weld techniques such as resistance welding, laser and electron beam welding, and gas tungsten arc and gas metal arc welding are the easiest to monitor. In the case of resistance welding, AE monitoring is carefully synchronized to the weld cycle, and the various phases of the weld process are treated separately. Emission during solidification and cooling is correlated with nugget size and therefore with weld strength, while high-amplitude signals from expulsions can be used to switch off the weld current at the optimum time to avoid overwelding and to save power and electrode life. In the case of gas tungsten arc and gas metal arc welding, real-time computer algorithms have been developed to recognize the characteristic AE signatures of particular types of defects and to report these defects while the weld is being made. These procedures are effective even in the presence of substantial background noise. Gas tungsten arc welded injector tubes for the space shuttle are among the welded components routinely monitored by AE inspection in the production environment.

Shaft straightening is another production process that lends itself to quality control by AE monitoring. Forged shafts are routinely straightened in special machinery that detects any imperfections in alignment and applies suitable bending forces to correct them. The quality of the product is threatened by microcracking of the hardened surface of the shaft during the bending process. Acoustic emission inspection detects this very effectively and is incorporated into the machinery to warn personnel and to halt the process when potentially damaging microcracking occurs (Ref 4).

In welding and shaft straightening, the stresses that activate acoustic emissions are already present in the normal production processes (in welding, they are thermal stresses). In other cases, the stress is applied for the express purpose of AE testing. This is akin to the loadings routinely applied for the AE inspection of new and in-service pressure vessels and other large structures. Examples include the production testing of brazed joints (Ref 2), and the proof testing of welds in steel ammunition-belt links described in the following example.

Example 4: Acoustic Emission Inspection of Projection Welds in 1050 Steel Ammunition-Belt Links.

The ammunition-belt link shown in Fig. 17(a) was made of 0.81 mm (0.032 in.) thick 1050 steel strip. The steel was preformed into link halves that were joined by two projection welds on each side where the sections overlapped. Although the welding schedules were carefully controlled to produce good resistance welds, there was a significant potential for producing some faulty welds in the mass-produced links. In a good weld, a weld nugget is formed that is usually stronger than the base metal in tension; that is, the base metal will tear before the weld will break. In a poor weld, the joint interface is literally just stuck together, and a moderate force, particularly one imposed by impact, will cause the joint to

fracture at the interface. A preliminary feasibility investigation showed that poor welds produced more acoustic emission under load than good welds, even though the load was insufficient to break a poor weld.

Fig. 17 Ammunition-belt link, of 1050 steel, joined by four projection welds that were inspected by AE monitoring during proof testing in the fixture shown. Dimensions given in inches. Source: Ref 41

Proof-Testing Equipment. A mechanical link tester (Fig. 17b) was designed to apply both a shear load and a bending load to the ammunition-belt link at the welded joints. This simulated the service load that would be imposed on the link.

Initially, piezoelectric sensors were attached to each link before testing to monitor acoustic emissions. This was the simplest and most direct method of confirming feasibility. Because attaching sensors directly to the link was not feasible for production testing, piezoelectric sensors were embedded in the spreader arms of the link-test fixtures in an area adjacent to the welded joints in the link.

A spreader force of 270 N (60 lbf) on the link provided a link-spreader-arm interface pressure of about 35 MPa (5 ksi), which provided good coupling of acoustic information across the interface. The sliding action of the spreader mechanism produced a wide-frequency noise range that could not be electronically filtered without also filtering the acoustic emission. This problem was overcome by gating out the noise from moving parts of the link-stressing mechanism and monitoring for acoustic emission during static stressing of the link after the spreader arms had reached full displacement. A microswitch was installed in the fixture to turn on the AE monitoring system in proper relation to operation of the spreader arm.

Acceptance Levels. The form of signal energy analysis that produced the best results consisted of electronically integrating for the area under the half wave rectified envelope of the emission signal in terms of volts amplitude and time duration. The analyzer used for the production application produced a dc voltage proportional to the total AE energy measured. The system sensitivity was adjusted so that an energy analog output voltage of 10 V represented the division point between a good and a bad projection weld in a link. If the welded joint generated enough acoustic emission to produce a 10-V energy output, the link was rejected. If the value was less than 10 V, the link was accepted. The selective ejection function of the mechanical tester was designed to eject the links into the accept or reject container based on an electronic switching function that was controlled by the output voltage of the emission analyzer.

The monitoring system was calibrated by introducing an artificial signal into sensors in the spreader arms, where it was detected and processed by the monitoring system. A 10-V, 10- μ s pulse was fed into these sensors from a pulse generator. The resulting signal was reproducible, was a reasonable simulation of the real data, and was simple to generate. Monitoring by acoustic emission was the only available nondestructive method that could perform the necessary 100% inspection of these projection resistance welds.

Acoustic Emission Inspection

Adrian A. Pollock, Physical Acoustics Corporation

Structural Test Applications

Acoustic emission inspection has been successfully applied in the structural testing of aircraft, spacecraft, bridges, bucket trucks, buildings, dams, military vehicles, mines, piping systems, pipelines, pressure vessels, railroad tank cars, rotating machinery, storage tanks, and other structures. The typical goal of an AE structural test is to find defects and to assess or ensure structural integrity. Acoustic emission inspection has been described as condition monitoring of static plant (Ref 42), which is parallel to the vibration monitoring techniques that are effectively used to monitor the condition of rotating plant. Both of these methods are useful for predicting failures (Ref 43) and reducing maintenance costs.

Key to structural testing with AE inspection are the stress concentrations that cause defects and other areas of weakness to emit while the rest of the structure is silent. Acoustic emission inspection thus high-lights the regions that threaten the integrity of the structure. As a whole-structure test using fixed sensors, AE inspection is normally complemented by other NDT methods that are used to follow up the AE findings and to assist in determining the type, severity, and acceptability of the AE sources.

A major advantage of AE inspection is that it does not require access to the whole examination area. Removal of external insulation or internal process fluids, typically a major expense associated with other NDT methods, is not required for the AE test. In fact, this procedure can be avoided altogether if the AE test indicates that the structure is in good condition.

For AE inspection to function reliably as a whole-structure test, the structure must be loaded in such a way as to stimulate emission from all structurally significant defects. Continuous monitoring in service is a possible test approach that has been applied, for example, to aircraft (Ref 7) and nuclear reactors. This approach guarantees appropriate stressing, but it is difficult because a small amount of emission from defect growth must be separated from a large amount of noise over a long time period. More commonly, the AE test is conducted over the course of a few minutes or hours, during which the structure is stimulated by applying a controlled stress (Ref 44). In most cases, this is satisfactorily accomplished by going somewhat above the normally apparent service loads (for example, 110% of the working pressure for an in-service pressure vessel, 200% of the rated load for an aerial manlift device). However, there are cases in which this approach will not work. For example, if defects are being induced in service by thermal stresses rather than mechanical stresses, an applied mechanical loading may not give a good match to the stress field that is causing the defects to grow in service. The defects, effectively unstressed, may not emit. To overcome this problem, inspectors testing steam lines in electric power plants have conducted AE monitoring during thermal overloads and cool-downs and have reported better success from this type of stressing.

In performing a successful AE test, careful attention must be paid to the type, magnitude, and rate of the applied stimulation (loading). Previously applied stresses will have a very strong influence on the emission that will be observed, as discussed in the section "Load Control and Repeated Loadings" in this article. Precautions must be taken to avoid inadvertent loadings of the structure. Many tests have been spoiled when site personnel, eager to ensure that the pressure system is leaktight, have taken the vessel up to the test pressure before the arrival of the AE inspectors. Accurate load measurement and the ability to hold load at a constant value are other requirements that may demand special attention from site personnel.

Load history is less important for leak testing because leak testing relies primarily on the detection of turbulent flow through the leak orifice. Major structural test applications of acoustic leak testing include flat-bottom storage tanks and nuclear reactor components. In the case of nuclear reactor components, millions of dollars have been saved through the selected use of AE instrumented inspection technology as an alternative to hydrotesting (Ref 45).

Data evaluation procedures depend on the context and content of the test. In one-of-a-kind and developmental testing, the skill and experience of the investigator are of prime importance. This fact inhibited the widespread use of AE inspection until standard test procedures started to become available in the late 1970s. The development of standard test procedures made it possible for AE tests to be efficiently conducted by regular NDT inspectors (given the proper training), while the more innovative investigators moved on to the development of new application areas. Some of the well-developed and standardized structural test applications of AE inspection will be briefly summarized below.

Bucket Trucks. The AE inspection of aerial manlift devices (bucket trucks) was pioneered by the author for Georgia Power Company in 1976 and was carried forward into routine practice by independent testing laboratories and several electric utilities in the years that followed. The ASTM F-18 Committee on Electrical Protective Equipment for Workers published the Standard Practice on the subject in 1985 (Ref 46).

First intended for use on the fiberglass boom sections of insulated bucket trucks, the method was soon extended to cover the pedestal, pins, and other metal components. An estimated 70,000 to 100,000 AE tests have been conducted up to 1988. Bucket trucks can develop problems through accidents, overloads, and fatigue in service. A thorough, regular inspection and test program can identify potential problems before they cause injuries or downtime (Ref 47).

Acoustic emission inspection is a major part of the structural integrity evaluation that complements functional tests of the bucket truck. Of all inspection methods, it is the most effective for detecting problems in fiberglass components, while for metal parts and 100% structural coverage, it serves as a cost-saving screening test that directs the inspector's attention to problem areas. The AE test is preceded by a visual inspection, and any AE indications are normally followed up with magnetic particle, dye penetrant, or ultrasonic inspection.

The AE test typically requires 12 to 16 sensors. System performance is checked by lead break before monitoring begins (see the section "Installation" in this article). Monitoring begins with a noise-check period, followed by two loadings to a predetermined proof load. Emissions during rising load, load hold and load release are separately recorded.

Data evaluation procedures are difficult to spell out because of the wide variety of possible noise and AE sources and the wide range of bucket truck constructions. The experienced inspector uses his knowledge of the truck as he evaluates high- and low-amplitude emission on the different channels during the different stages of the test. Aware of possible noise sources, he looks for indications that may lead to confirmation of damaged fiberglass, cracked metal components, or maintenance problems such as lack of lubrication in visually inaccessible areas.

Using an AE instrument specially designed for economical bucket truck testing, an experienced test crew can perform five to ten AE tests in a single day. When the required visual, operational, ultrasonic, magnetic particle, and dye penetrant testing operations are also performed, typically two to three trucks can be inspected per day.

Jumbo Tube Trailers. Acoustic emission inspection for testing jumbo tube trailers was developed by Blackburn and legitimized in lieu of hydrotest by a Department of Transportation exemption granted in 1983 (Ref 48). These tube trailers carry large volumes of industrial gases on the public highways, typically at a pressure of 18,200 kPa (2640 psi). Fatigue cracks can grow in service, but the hydrotest will not detect these cracks unless they actually cause rupture of the tube. The AE test will detect the cracks while they are still subcritical, during a 10% overpressure applied during the normal filling operation. The AE test is therefore more meaningful than the hydrotest. The AE test is also less expensive and avoids disassembly of the trailer and contamination of the internals with water.

The trailer typically holds 12 tubes, which are all tested at the same time. The AE test requires just two sensors on each 10 m (34 ft) long tube; wave propagation and attenuation characteristics are very favorable in this structure, and AE sources can be accurately located. If ten or more valid events are located within a 200 mm (8 in.) axial distance on the cylindrical portion of the tube, ultrasonic inspection is carried out and the tube is accepted or rejected based on the ultrasonic evaluation of flaw depth. The accept/reject criteria are based on a conservative fracture mechanics analysis of in-service fatigue crack growth. Between March 1983 and March 1988 about 1700 jumbo tubes were AE tested, and the method has been further extended to other shippers of compressed gas and other tube types.

Fiberglass Tanks, Pressure Vessels, and Piping. In the 1970s, the chemical industry was experiencing worldwide failures of fiberglass storage tanks and pressure vessels. Causes included inadequate design and fabrication, mishandling during transportation, and misuse of this relatively unfamiliar material. The situation was aggravated by the lack of a viable inspection method.

An AE test methodology was pioneered by Monsanto, resulting in elimination of the tank failure problem (Fig. 18). The method came into widespread acceptance through the formation and activities of the Committee for Acoustic Emission in Reinforced Plastics (CARP), which is currently affiliated with the American Society for Nondestructive Testing. The written procedure developed by CARP and first published by the Society for the Plastics Industry in 1982 was the basis for the introduction of AE inspection into the ASME Boiler and Pressure Vessel Code in 1983 (Ref 30, 49). An estimated 5000 tests have been carried out using this procedure as of 1988. The work of CARP was also extended to cover methodology for testing fiberglass piping (Ref 50).

Fig. 18 Failures of FRP tanks. An FRP tank failure problem was eliminated by 100% AE inspection starting in 1979. The isolated failures in 1982 and 1984 occurred after these tanks had failed the AE test, and damage-preventive measures were taken.

The AE test typically requires 8 to 30 sensors, depending on the size of the vessel or tank. High-frequency (typically 150 kHz) channels are used to cover regions of known high stress, such as knuckles, nozzles, and manways; low-frequency (typically 30 kHz) channels having a larger detection range are used to complete the coverage of less critical regions. In the case of a storage vessel, the test is typically conducted during filling with process fluid after an appropriate conditioning period with the contents at a reduced level. In the case of a pressure vessel, appropriate overpressure is applied. The loading is conducted in several stages, with load-hold emission, Felicity Ratio, and other accept/reject criteria evaluated at each stage. System performance checks and background noise checks are part of the test procedure.

Metal Pressure Vessels and Storage Tanks. In the 1970s, many research and engineering organizations and test companies were active in the AE testing of metal pressure vessels. A 1979 survey estimated that about 600 pressure vessels had been tested by AE inspection on a production basis up to that time, mostly in the petroleum, chemical, and nuclear industries (Ref 51). (Although tests on pipes, heat exchanger tubing, and miscellaneous components were much

more numerous, pressure vessels have always been a focal point for AE testing.) Much of this testing was done with *ad hoc*, undocumented procedures that relied heavily on the individual experience of the teams performing the work. The main emphasis was usually placed on source location, technically a most attractive feature of AE testing. Located sources would be graded according to their AE activity and/or intensity, and the vessel owner would be advised regarding which areas to inspect with other NDT methods. Many structural defects were successfully identified with these methods.

A significant maturing of the technology took place when Fowler at Monsanto engaged on a systematic program of methods development, using the results of follow-up inspection to refine and improve the AE data analysis procedures. Starting in 1979, this program included destructive tests on decommissioned vessels, field tests on many hundreds of in-service vessels and tanks, and development of analytical procedures for recognizing and eliminating extraneous noise (Ref 25). The program de-emphasized the calculation of source location (which requires several sensors to be hit) because in practice many AE events hit only one sensor. To use all the AE hits, zone location was employed instead of point location. The outcome of this program was a comprehensive test procedure backed by detailed case histories and available to licensees under the trademark MONPAC. This procedure has been applied to approximately 2000 metal vessels and storage tanks as of 1988 Ref 8.

A typical MONPAC test result is shown in Fig. 19. Here a 30-year old ethylene storage vessel was AE tested on-line, raising the pressure by turning off a compressor. Results are presented in the form of an unfolded map of the vessel, with the evaluation of appropriate zones on the map being displayed in color codes (Fig. 19 only shows the color as a dark region). The zone evaluations indicated "no significant emissions," so a hazardous and possibly deleterious internal inspection was avoided (Ref 42).

Fig. 19 Display of MONPAC test results for an ethylene storage vessel. In this case, no significant emissions were detected, and there were only minor indications from zones 3, 6, and 8. The need to take the vessel off-line for other forms of inspection was avoided.

Other MONPAC tests have found external and internal corrosion, stress-corrosion cracking, weld cracking, lack of fusion, lack of penetration, and embrittled material. Plant shutdowns have been shortened through early diagnosis of major

problems, or have been eliminated through positive demonstration of structural integrity. Savings achieved through this method run to tens of millions of dollars.

An AE methodology for metal vessel testing has also been introduced into the ASME Boiler and Pressure Vessel Code as of the December 1988 Addendum (Ref 31). The article states requirements for written test procedure, personnel qualification, equipment, system calibration, preexamination measurements, background noise check, and vessel pressurization. An illustrative loading schedule and sensor layouts are included. Evaluation criteria are to be supplied, class by class, by the referencing code section; they will be based on emission during load hold, count rate, number of hits, large amplitude hits, MARSE, and activity trends. This entry into the ASME Code represents a major milestone in the establishment and maturity of AE technology.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Introduction

RADIOLOGY is the general term given to material inspection methods that are based on the differential absorption of penetrating radiation--either electromagnetic radiation of very short wavelength or particulate radiation--by the part or testpiece (object) being inspected. Because of differences in density and variations in thickness of the part or differences in absorption characteristics caused by variations in composition, different portions of a testpiece absorb different amounts of penetrating radiation. These variations in the absorption of the penetrating radiation can be monitored by detecting the unabsorbed radiation that passes through the testpiece.

The term radiography often refers to the specific radiological method that produces a permanent image on film (conventional radiography) or paper (paper radiography or xeroradiography). In a broad sense, however, radiography can also refer to other radiological techniques that can produce two-dimensional, plane-view images from the unabsorbed radiation. Recently, the American Society of Testing and Materials (ASTM) defined radioscopy as the term to describe the applications when film or paper is not used and defined radiology as the general term covering both techniques.

However, the term radioscopy has not received wide acceptance yet, and this article considers the following two techniques as radiographic inspection (with x-rays or γ -rays):

- *Film or paper radiography*: A two-dimensional latent image from the projected radiation is produced on a sheet of film or paper that has been exposed to the unabsorbed radiation passing through the testpiece. This technique requires subsequent development of the exposed film or paper so that the latent image becomes visible for viewing
- *Real-time radiography (also known as radioscopy)*: A two-dimensional image can be immediately displayed on a viewing screen or television monitor. This technique does not involve the creation of a latent image; instead, the unabsorbed radiation is converted into an optical or electronic signal, which can be viewed immediately or can be processed in near real time with electronic and video equipment

The principal advantage of real-time radiography over film radiography is the opportunity to manipulate the testpiece during radiographic inspection. This capability allows the inspection of internal mechanisms and enhances the detection of cracks and planar defects by manipulating the part to achieve the proper orientation for flaw detection. Moreover, part manipulation in real-time radiography simplifies three-dimensional (stereo) dynamic imaging and the determination of flaw location and size. In film radiography, however, the position of a flaw within the volume of a testpiece cannot be determined exactly with a single radiograph; depth parallel to the radiation beam is not recorded. Consequently, other film techniques, such as stereoradiography, triangulation, or simply making two or more film exposures (with the radiation beam being directed at the testpiece from a different angle for each exposure), must be used to locate flaws more exactly within the testpiece volume.

Although real-time radiography enhances the detection and location of flaws by allowing the manipulation of the testpiece during inspection, another important radiological technique with enhanced flaw detection and location capabilities is computed tomography. Unlike film and real-time radiography, computed tomography (CT) involves the generation of cross-sectional views instead of a planar projection. The CT image is comparable to that obtained by making a radiograph of a physically sectioned thin planar slab from an object. This cross-sectional image is not obscured by overlying and underlying structures and is highly sensitive to small differences in relative density. Moreover, CT images are easier to interpret than radiographs (see the article "Industrial Computed Tomography" in this Volume).

All of the terms and techniques in the preceding discussion refer to radiological inspection with penetrating electromagnetic radiation in the form of x-rays or γ -rays. Other forms of radiation include subatomic particles that are generated during nuclear decay. The most commonly known subatomic particles are α particles, β particles, and neutrons, all of which are emitted from the nuclei of various atoms during radioactive decay. Beta particles and neutrons are sufficiently penetrating to be useful for radiography, but neutrons are more widely used. More information on neutron radiography is available in the article "Neutron Radiography" in this Volume.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Uses of Radiography

Radiography is used to detect the features of a component or assembly that exhibit a difference in thickness or physical density as compared to surrounding material. Large differences are more easily detected than small ones. In general, radiography can detect only those features that have an appreciable thickness in a direction parallel to the radiation beam. This means that the ability of the process to detect planar discontinuities such as cracks depends on proper orientation of the testpiece during inspection. Discontinuities such as voids and inclusions, which have measurable thickness in all directions, can be detected as long as they are not too small in relation to section thickness. In general, features that exhibit a 1% or more difference in absorption compared to the surrounding material can be detected.

Although neither is limited to the detection of internal flaws, radiography and ultrasonics are the two generally used nondestructive inspection methods that can satisfactorily detect flaws that are completely internal and located well below the surface of the part. Neither method is limited to the detection of specific types of internal flaws, but radiography is more effective when the flaws are not planar, while ultrasonics is more effective when the flaws are planar. In comparison to other generally used nondestructive methods (for example, magnetic particle, liquid penetrant, and eddy current inspection), radiography has three main advantages:

- The ability to detect internal flaws
- The ability to detect significant variations in composition
- Permanent recording of raw inspection data

Applicability. Radiographic inspection is extensively used on castings and weldments, particularly where there is a critical need to ensure freedom from internal flaws. For example, radiography is often specified for the inspection of thick-wall castings and weldments for steam-power equipment (boiler and turbine components and assemblies) and other high-pressure systems. Radiography can also be used on forgings and mechanical assemblies, although with mechanical assemblies radiography is usually limited to inspection for condition and proper placement of components or for proper liquid-fill level in sealed systems. Certain special devices are more satisfactorily inspected by radiography than by other methods. For example, radiography is well suited to the inspection of semiconductor devices for voids in the element mount area, in the case seal area, and in plastic molding compounds used to encapsulate some devices. Radiography is also used to inspect for cracks, broken wires, foreign material, and misplaced and misaligned elements. High-resolution real-time imaging with microfocus x-ray sources has made it possible to use radiography as a failure analysis tool for semiconductors and other electronic components. Real-time imaging allows analysis from a variety of angles, while microfocus adds the capability of detecting flaws as small as 0.025 mm (0.001 in.) in the major dimension. New uses of radiography have also occurred with the inspection of composites. In such applications, the sensitivity is maximized with the use of high-intensity, low-energy radiation.

The sensitivity of x-ray and γ -ray radiography to various types of flaws depends on many factors, including type of material, type of flaw, and product form. (Type of material in this context is usually expressed in terms of atomic number—for example, metals having low atomic numbers are classified as light metals, and those having high atomic numbers are heavy metals.) Table 1 indicates the general degree of suitability of the three main radiographic methods for the detection of discontinuities in various product forms and applications.

Table 1 Comparison of suitability of three radiographic methods for the inspection of light and heavy metals

(a) G, good; F, fair; P, poor; U, unsatisfactory.

- (b) Includes only visible cracks. Minute surface cracks are undetectable by radiographic inspection methods.
- (c) Radiation beam must be parallel to the cracks, laps, or flakes. In real-time radiography, the testpiece can be manipulated for proper orientation.
- (d) When calibrated using special thickness gages

Radiography can be used to inspect most types of solid material, with the possible exception of materials of very high or very low density. (Neutron radiography, however, can often be used in such cases, as discussed in the article "Neutron Radiography" in this Volume.) Both ferrous and nonferrous alloys can be radiographed, as can nonmetallic materials and composites.

There is wide latitude both in the material thickness that can be inspected and in the techniques that can be used. Numerous special techniques and special devices have been developed for the application of radiography to specific inspection problems, including even the inspection of radioactive materials. Most of these specialized applications are not discussed in this article, but several can be found in articles in this Volume that deal with the use of radiography in the inspection of specific product forms.

In some cases, radiography cannot be used even though it appears suitable from Table 1, because the part is accessible from one side only. Radiography typically involves the transmission of radiation through the testpiece, in which case both sides of the part must be accessible. However, radiographic and radiometric inspection can also be performed with Compton scattering, in which the scattered photons are used for imaging. With Compton scattering, inspection can be performed when only one side is accessible. Another method of inspecting a region having one inaccessible side is to use probes with a microfocus x-ray tube (see the section "Microfocus X-Ray Tubes" in this article).

Limitations. Compared to other nondestructive methods of inspection, radiography is expensive. Relatively large capital costs and space allocations are required for a radiographic laboratory, although costs can be reduced when portable x-ray or γ -ray sources are used in film radiography. Capital costs can be relatively low with portable units, and space is required only for film processing and interpretation. Operating costs can be high; sometimes as much as 60% of the total inspection time is spent in setting up for radiography. With real-time radiography, operating costs are usually much lower, because setup times are shorter and there are no extra costs for processing or interpretation of film.

The field inspection of thick sections can be a time-consuming process because the effective radiation output of portable sources may require long exposure times of the radiographic film. Radioactive (γ -ray) sources are limited in their output primarily because high-activity sources require heavy shielding for the protection of personnel. This limits field usage to sources of lower activity that can be transported. The output of portable x-ray sources may also limit the field inspection of thick sections, particularly if a portable x-ray tube is used. Portable x-ray tubes emit relatively low-energy (300 keV) radiation and are limited in the radiation output. Both of these characteristics of portable x-ray tubes combine to limit their application to the inspection of sections having the absorption equivalent of 75 mm (3 in.) of steel. Instead of portable x-ray tubes, portable linear accelerators and betatrons provide high-energy (>1 MeV) x-rays for the radiographic field inspection of thicker sections.

Certain types of flaws are difficult to detect by radiography. Cracks cannot be detected unless they are essentially parallel to the radiation beam. Tight cracks in thick sections may not be detected at all, even when properly oriented. Minute discontinuities such as inclusions in wrought material, flakes, microporosity, and microfissures may not be detected unless they are sufficiently segregated to yield a detectable gross effect. Laminations are nearly impossible to detect with radiography; because of their unfavorable orientation, delaminations do not yield differences in absorption that enable laminated areas to be distinguished from delaminated areas.

It is well known that large doses of x-rays or γ -rays can kill human cells, and in massive doses can cause severe disability or death. Protection of personnel--not only those engaged in radiographic work but also those in the vicinity of radiographic inspection--is of major importance. Safety requirements impose both economic and operational constraints on the use of radiography for inspection.

Principles of Radiography

Three basic elements of radiography include a radiation source, the testpiece or object being evaluated, and a sensing material. These elements are shown schematically in Fig. 1. The testpiece in Fig. 1 is a plate of uniform thickness containing an internal flaw that has absorption characteristics different from those of the surrounding material. Radiation from the source is absorbed by the testpiece as the radiation passes through it; the flaw and surrounding material absorb different amounts of radiation. Thus, the intensity of radiation that impinges on the sensing material in the area beneath the flaw is different from the amount that impinges on adjacent areas. This produces an image, or shadow, of the flaw on the sensing material. This section briefly reviews the general characteristics and safety principles associated with radiography.

Fig. 1 Schematic of the basic elements of a radiographic system showing the method of sensing the image of an internal flaw in a plate of uniform thickness

Radiation Sources

Two types of electromagnetic radiation are used in radiographic inspection: x-rays and γ -rays. X-rays and γ -rays differ from other types of electromagnetic radiation (such as visible light, microwaves, and radio waves) only in their wavelengths, although there is not always a distinct transition from one type of electromagnetic radiation to another (Fig. 2). Only x-rays and γ -rays, because of their relatively short wavelengths (high energies), have the capability of penetrating opaque materials to reveal internal flaws.

Fig. 2 Schematic of the portion of the electromagnetic spectrum that includes x-rays, γ -rays, ultraviolet and visible light, and infrared radiation showing their relationship with wavelength and photon energy

X-rays and γ -rays are physically indistinguishable; they differ only in the manner in which they are produced. X-rays result from the interaction between a rapidly moving stream of electrons and atoms in a solid target material, while γ -rays are emitted during the radioactive decay of unstable atomic nuclei.

The amount of exposure from x-rays or γ -rays is measured in roentgens (R), where 1 R is the amount of radiation exposure that produces one electrostatic unit (3.33564×10^{-10} C) of charge from 1.293 mg (45.61×10^{-6} oz) of air. The intensity of an x-ray or γ -ray radiation is measured in roentgens per unit time.

Although the intensity of x-ray or γ -ray radiation is measured in the same units, the strengths of x-ray and γ -ray sources are usually given in different units. The strength of an x-ray source is typically given in roentgens per minute at one meter (RMM) from the source or in some other suitable combination of time or distance units (such as roentgens per hour at one meter, or RHM). The strength of a γ -ray source is usually given in terms of the radioactive decay rate, which has the traditional unit of a curie ($1 \text{ Ci} = 37 \times 10^9$ disintegrations per second). The corresponding unit in the Système International d'Unités (SI) system is a gigabecquerel ($1 \text{ GBq} = 1 \times 10^9$ disintegrations per second).

The spectrum of radiation is often expressed in terms of photon energy rather than as a wavelength. Photon energy is measured in electron volts, with 1 eV being the energy imparted to an electron by an accelerating potential of 1 V. Figure 2 shows the radiation spectrum in terms of both wavelength and photon energy.

Production of X-Rays. When x-rays are produced from the collision of fast-moving electrons with a target material, two types of x-rays are generated. The first type of x-ray is generated when the electrons are rapidly decelerated during collisions with atoms in the target material. These x-rays have a broad spectrum of many wavelengths (or energies) and are referred to as continuous x-rays or by the German word *bremsstrahlung*, which means braking radiation. The second type of x-ray occurs when the collision of an electron with an atom of the target material causes a transition of an orbital electron in the atom, thus leaving the atom in an excited state. When the orbital electrons in the excited atom rearrange themselves, x-rays are emitted that have specific wavelengths (or energies) characteristic of the particular electron rearrangements taking place. These characteristic x-rays usually have much higher intensities than the background of *bremsstrahlung* having the same wavelengths.

Production of γ -Rays. Gamma rays are generated during the radioactive decay of both naturally occurring and artificially produced unstable isotopes. In all respects other than their origin, γ -rays and x-rays are identical. Unlike the broad-spectrum radiation produced by x-ray sources, γ -ray sources emit one or more discrete wavelengths of radiation, each having its own characteristic photon energy (or wavelength).

Many of the elements in the periodic table have either naturally occurring radioactive isotopes or isotopes that can be made radioactive by irradiation with a stream of neutrons in the core of the nuclear reactor. However, only certain isotopes are extensively used for radiography (see the section "Gamma-Ray Sources" in this article).

Image Conversion

The most important process in radiography is the conversion of radiation into a form suitable for observation or further signal processing. This conversion is accomplished with either a recording medium (usually film) or a real-time imaging medium (such as fluorescent screens or scintillation crystals). The imaging process can also be assisted with the use of intensifying or filtration screens, which intensify the conversion process or filter out scattered radiation.

Recording media provide a permanent image that is related to the variations in the intensity of the unabsorbed radiation and the time of exposure. With a recording medium such as film, for example, an invisible latent image is formed in the areas exposed to radiation. These exposed areas become dark when the film is processed (that is, developed, rinsed, fixed, washed, and dried), with the degree of darkening (the photographic density) depending on the amount of exposure to radiation. The film is then placed on an illuminated screen so that the image formed by the variations in photographic density can be examined and interpreted.

Real-time imaging media provide an immediate indication of the intensity of radiation passing through a testpiece. With fluorescent screens, for example, visible light is emitted with a brightness that is proportional to the intensity of the incident x-ray or γ -ray radiation. This emitted light can be observed directly, amplified, and/or converted into a video signal for presentation on a television monitor and subsequent recording. The various types of imaging systems are described in the section "Real-Time Radiography" in this article.

Intensifying and filtration screens are used to improve image contrast, particularly when the radiation intensity is low or when the radiation energy is high. The screens are useful at higher energies because the sensitivity of films and fluorescent screens decreases as the energy of the penetrating radiation increases. The various types of screens are discussed in the section "Image Conversion Media" in this article.

Image Quality and Radiographic Sensitivity

The quality of radiographs is affected by many variables, and image quality is measured with image-quality indicators known as penetrameters. These devices are thin specimens made of the same material as the testpiece; they are described in more detail in the section "Identification Markers and Penetrameters (Image-Quality Indicators)" in this article. When placed on the testpiece during radiographic inspection, the penetrameters measure image contrast and, to a limited extent, resolution. Detail resolution is not directly measured with penetrameters, because flaw detection depends on the nature of the flaw, its shape, and orientation to the radiation beam.

Image quality is governed by image contrast and resolution, which are also sometimes referred to as radiographic contrast and radiographic definition. These two factors are interrelated in a complex way and are affected by several factors described in the sections "Radiographic contrast" and "Radiographic definition" in this article. In real-time systems, image contrast and resolution are also described in terms of the detective quantum efficiency (DQE) (also known as the quantum detection efficiency, or QDE) and the modulation transfer function (MTF), respectively. These terms, which are also used in computed tomography, are defined in the text and in Appendix 2 of the article "Industrial Computed Tomography" in this Volume.

Radiographic sensitivity, which should be distinguished from image quality, generally refers to the size of the smallest detail that can be seen on a radiograph or to the ease with which the images of small details can be detected. Although radiographic sensitivity is often synonymous with image quality in applications requiring the detection of small details, a distinction should be made between radiographic sensitivity and radiographic quality. Radiographic sensitivity refers more to detail resolvability, which should be distinguished from spatial resolution and contrast resolution. For example, if the density of an object is very different from the density of the surrounding region, the flaw might be resolved because of the large contrast, even if the flaw is smaller than the spatial resolution of the system. On the other hand, when the contrast is small, the area must be large to achieve resolvability.

Radiographic contrast refers to the amount of contrast observed on a radiograph, and it is affected by subject contrast and the contrast sensitivity of the image-detecting system. Radiographic contrast can also be affected by the unsharpness of the detected image. Figure 3, for example, shows how contrast is affected when the sharp edge of a step is blurred

because of unsharpness. If the unsharpness is much smaller than d in Fig. 3, then the contrast is not reduced and the edges in the image are easily defined. However, if d is much smaller than the unsharpness, then the contrast is reduced. If the unsharpness is too large, the image cannot be resolved.

Fig. 3 Effect of geometric unsharpness on image contrast. (a) Flaw size, d , is larger than the unsharpness, then full contrast occurs. (b) Flaw size, d , is smaller than the unsharpness, then contrast is reduced.

Subject contrast is the ratio of radiation intensities transmitted by various portions of a testpiece. It depends on the thickness, shape, and composition of the testpiece; the intensity of the scattered radiation; and the spectrum of the incident radiation. It does not depend on the detector, the source strength, or the source-to-detector distance. However, it may depend on the testpiece-to-detector distance because the intensity of scattered radiation (from within the testpiece) impinging upon a detector is almost eliminated when projective enlargement approaches a magnification factor of three (see the section "Enlargement" in this article).

In general, a radiograph should be made with the lowest-energy radiation that will transmit adequate radiation intensities to the detector, because long wavelengths tend to improve contrast. However, radiation energies that are too low produce excessive amounts of scattered radiation that washes out fine detail. On the other hand, energies that are too high, although they reduce scattered radiation, may produce images having contrast that is too low to resolve small flaws. For each situation, there is an optimum radiation energy that produces the best combination of radiographic contrast and definition, or the greatest sensitivity.

The amount of subject contrast can be modeled as follows. If there is a change in thickness, Δx , of a testpiece with a uniform attenuation coefficient, μ , then the subject contrast (without scattering) is equal to $\mu\Delta x$. Similarly, if there is a change in the attenuation coefficient, $\Delta\mu$, over a distance X , then the subject contrast (without scatter) is equal to $X\Delta\mu$. If there is scattering, the subject contrast is reduced such that:

$$\text{Subject contrast} = \frac{\mu\Delta x \text{ (or } X\Delta\mu\text{)}}{1 + I_S/I_D} \quad (\text{Eq 1})$$

where I_S is the intensity of the scattered radiation and I_D is the intensity of the direct (or primary) radiation passing through the testpiece. The scattering may occur from within the testpiece (Fig. 4a) or from the surroundings (Fig. 4b and c). The various mechanisms of scattering and attenuation are described in the section "Attenuation of Electromagnetic Radiation" in this article.

Fig. 4 Schematic of the three types of scattered radiation encountered when using x-rays and γ -rays

Contrast sensitivity refers to the ability of responding to and displaying small variations in subject contrast. Contrast sensitivity depends on the characteristics of the image detector and on the level of radiation being detected (or on the amount of exposure for films). The relationship between the contrast sensitivity and the level of radiation intensity (or film exposure) can be illustrated by considering two extremes. At low levels of radiation intensity, the contrast sensitivity of the detectors is reduced by a smaller signal-to-noise ratio, while at high levels, the detectors become saturated. Consequently, contrast sensitivity is a function of dynamic range.

In film radiography, the contrast sensitivity is:

$$\text{Contrast sensitivity \%} = \frac{2.3\Delta D}{G_D} \cdot 100 \quad (\text{Eq 2})$$

where ΔD is the smallest change in photographic density that can be observed when the film is placed on an illuminated screen. The factor G_D is called the film gradient or film contrast. The film gradient is the inherent ability of a film to record a difference in the intensity of the transmitted radiation as a difference in photographic density. It depends on film type, development procedure, and film density. For all practical purposes, it is independent of the quality and distribution of the transmitted radiation (see the section "Film Radiography" in this article).

Contrast sensitivity in real-time systems is determined by the number of bits (if the image is digitized) and the signal-to-noise ratio (which is affected by the intensity of the radiation and the efficiency of the detector). The factors affecting the contrast sensitivity and signal-to-noise ratio of real-time systems are discussed in the section "Modern Image Intensifiers" in this article. The best contrast sensitivity of digitized images from fluorescent screens is about 8 bits (or 256 gray levels).

Another way of specifying the contrast sensitivity of fluorescent screens is with a gamma factor, which is defined by the fractional unit change in screen brightness, $\Delta B/B$, for a given fractional change in the radiation intensity, $\Delta I/I$. Most fluorescent screens have a gamma factor of about one, which is not a limiting factor. At low levels of intensity, however,

the contrast is reduced because of quantum mottle (see the section "Screen Unsharpness" in this article) just as unsharpness reduced the contrast in the example illustrated in Fig. 3.

Dynamic range, or latitude, describes the ability of the imaging system to produce a suitable signal over a range of radiation intensities. The dynamic range is given as the ratio of the largest signal that can be measured to the precision of the smallest signal that can be discriminated. A large dynamic range allows the system to maintain contrast sensitivity over a wide range of radiation intensities or testpiece thicknesses. Film radiography has a dynamic range of up to 1000:1, while digital radiography with discrete detectors can achieve 100,000:1. The latitude, or dynamic range, of film techniques is discussed in the section "Exposure Factors" in this article.

Radiographic definition refers to the sharpness of a radiograph. In Fig. 5(a), for example, the radiograph exhibits poor radiographic definition even when the contrast is high. Better radiographic definition is achieved in Fig. 5(b), even though the contrast is lower.

Fig. 5 Radiographs with poor and improved radiographic definition. (a) Advantage of a higher radiographic contrast is offset by poor definition. (b) Despite lower contrast, better detail is obtained with improved definition. Source: Ref 1

The degree of radiographic definition is usually specified in line pairs per millimeter or by the minimum distance by which two features can be physically distinguished. The factors affecting radiographic definition are geometric unsharpness and the unsharpness (or spatial resolution) of the imaging system. The net effect of these two unsharpnesses is not directly additive, because the combination of the two unsharpnesses is complex. For most practical radiography, the total unsharpness, U_T , is:

$$U_T^2 = U_g^2 + U_d^2 \quad (\text{Eq 3})$$

where U_g is the geometric unsharpness and U_d is the unsharpness or spatial resolution of the image-detecting system. Another important type of unsharpness occurs when in-motion radiography is performed. This type of unsharpness, termed motion unsharpness, is discussed in the section "In-Motion Radiography" in this article. Geometric unsharpness is usually the largest contributor to maximum unsharpness in film radiography, while the unsharpness of fluorescent screens in real-time radiography often overshadows the effect of geometric unsharpness.

Distortion and Geometric Unsharpness. Because a radiograph is a two-dimensional representation of a three-dimensional object, the radiographic images of most testpieces are somewhat distorted in size and shape compared to actual testpiece size and shape. The mechanisms of geometric unsharpness and distortion are described in the section "Principles of Shadow Formation" in this article. The severity of unsharpness and distortion depends primarily on the

source size (focal-spot size for x-ray sources), source-to-object and source-to-detector distances, and position and orientation of the testpiece with respect to source and detector.

Film unsharpness specifies the spatial resolution of the film and must not be confused with film graininess. Film unsharpness and film graininess must be treated as two separate parameters.

Film unsharpness depends not only on the film grain size and the development process but also on the energy of the radiation and the thickness and material of the screens. When a quantum of radiation sensitizes a silver halide crystal in a film, adjacent crystals may also be sensitized if the quantum has sufficient energy to release electrons during the absorption by the first crystal. Consequently, a small volume of crystals would be sensitized, thus producing a small disk instead of a point image. Figure 6 illustrates an experimental curve of film unsharpness versus radiation energy. The screens used will also affect the unsharpness with the production of electrons.

Fig. 6 Experimental curve of film unsharpness, U_f , against x-ray energy (filtered sources). Source: Ref 2

Screen Unsharpness. In addition to the spatial resolution established by the video or image-processing equipment, the spatial resolution of real-time systems is also affected by screen unsharpness. Screen unsharpness depends not only on the grain size and thickness of the screen but also on the detection efficiency and the energy and intensity of the radiation. Statistical fluctuations (quantum mottle) of screen brightness becomes more significant at low levels of screen brightness, and this can occur when either the radiation intensity or the detection efficiency is lowered. Nevertheless, screen unsharpness due to statistical fluctuation can be eliminated with the image-processing operation of frame summation, which makes an image representing the amount of radiation exposure during the frame-summing interval.

Projective Magnification With Microfocus X-Ray Sources. Even though the imaging systems have limits in their spatial resolution, detail of the testpiece can be enlarged by projective magnification (see the section "Enlargement" in this article). This process of image magnification minimizes the limits of graininess and unsharpness caused by the imaging system. With microfocus x-ray sources, a resolution greater than 20 line pairs per millimeter (or a spatial resolution of 0.002 in.) can be achieved.

Detail Perceptibility of Images. Studies have shown that the perceptibility of image details depends principally on the product: $MTF^2 \cdot DQE$; where MTF is the modulation transfer function and DQE is the detective quantum efficiency of the imaging system. These terms, as previously mentioned in this section, are described in the article "Industrial Computed Tomography" in this Volume.

Radiation Safety

The principles of radiation safety have evolved from experience in health physics, which is the study of the biological effects of ionizing radiation. There are two main aspects of safety: monitoring radiation dosage and protecting personnel. This section summarizes the major factors involved in both. More detailed information on radiation safety is available in the Selected References at the end of this article.

Radiation Units. Ordinarily, x-ray and γ -ray radiation is measured in terms of its ionizing effect on a given quantity of atoms. The roentgen, as described in the section "Radiation Sources" in this article, is a unit derived on this basis for x-rays and γ -rays. However, even though the amount of x-ray and γ -ray exposure can be quantified in the roentgen unit, the effects of radiation on the human body also depend on the amount of energy absorbed and the type of radiation. Consequently, the roentgen equivalent man (rem) unit and the SI-based sievert (Sv) unit have been developed for the purposes of radiation safety. As described below, these two units include safety factors assigned to the absorbed energy dose of a particular type of radiation (where the absorbed energy dose is measured either in the radiation absorbed dose, or rad, unit or the SI-based gray unit).

Rem and Rad Units. The specification of radiation in rems is equal to the product of the rad and a factor known as the relative biological effectiveness (rbe). The rbe (as established by the U.S. Government) is 1.0 for x-rays, γ -rays, or β particles; 5.0 for thermal neutrons; 10 for fast neutrons; and 20 for α particles. One rad represents the absorption of 100 ergs of energy per gram of irradiated material; it applies to any form of penetrating radiation.

Sievert and Gray Units. A sievert is the SI-based version of the rem unit. The same rbe factors are used, but the sievert unit is derived from the absorbed dose specified in the SI-based gray (Gy) unit. Because 1 Gy represents the absorption of one joule of energy per kilogram of material, then 1 Gy = 100 rads and 1 Sv = 100 rem.

Units for X-Rays and γ -Rays. Because 1 R (which applies only to the ionizing effect of x-rays or γ -rays) corresponds to the absorption of only about 83 ergs per gram of air, the unit of 1 R can be considered equal to 0.01 Gy (1 rad) for radiation-safety measurements. With this approach, then, the measurement of x-ray and γ -ray dose in roentgens can be considered equivalent to direct measurement of dose in rems because the rbe is equal to one. This considerably simplifies the process of monitoring dose levels.

Maximum Permissible Dose. Current practice in health physics specifies a threshold value of accumulated dose above which an individual should not be exposed. The value of this threshold, or maximum permissible dose, increases at the rate of 0.05 Sv/yr (5 rem/yr) for all persons over the age of 18. This so-called banking concept is based on experience and assumes that no person will be exposed to penetrating radiation before the age of 18. The total amount of radiation absorbed by any individual should never exceed his continually increasing accumulated permissible dose; furthermore, no individual should be exposed to more than 0.12 Sv (12 rem) in any given year, regardless of other factors. For administrative purposes, maximum permissible dose rate is evaluated for each individual on a quarterly or weekly basis.

The applicable dose rates are 0.0125 Sv ($1\frac{1}{4}$ rems) per calendar quarter, or about 1 millisievert (1 mSv, or 100 mrem) per week.

Radiation Protection. The two main factors in radiation protection are controlling the level of radiation exposure and licensing the facility. The main criterion in controlling radiation exposure is the philosophy outlined in Regulatory Guide 8.10 of the United States Nuclear Regulatory Commission, which specifies the objective of reducing radiation exposures to a level as low as reasonably achievable. The licensing process involves the issuance of permission for operating a radiographic facility; permission may be required from federal, state, and local governments.

The federal licensing program is concerned with those companies that use radioactive isotopes as sources. However, in some localities, state and local agencies exercise similar regulatory prerogatives. To become licensed under any of these programs, a facility or operator must show that certain minimum requirements have been met for the protection of both operating personnel and the general public from excessive levels of radiation. Although local regulations may vary in the degree and type of protection afforded, certain general principles apply to all.

First, the amount of radiation that is allowed to escape from the area over which the licensee has direct and exclusive control is limited to an amount that is safe for continuous exposure. In most cases, total dose values of 0.02 mSv (2 mrem) in 1 h, 1 mSv (100 mrem) in 7 consecutive days, and 5 mSv (500 mrem) in a calendar year can be considered safe. These values correspond to those adopted by the federal government for radioactive sources and are also applicable under most local regulations. For purposes of control, unrestricted areas within a given facility are often afforded the same status as

areas outside the facility. An unrestricted area is usually defined as an area where employees are not required to wear personal radiation-monitoring devices and where there is unrestricted access by either employees or the public.

Second, main work areas are shielded in accordance with applicable requirements. Some facilities must be inspected by an expert in radiation safety in order to qualify for licensing; it is usually recommended that the owner consult an expert when planning a new facility or changes in an older facility to ensure that all local requirements are met. Appropriate shielding usually consists of lead or thick concrete on all sides of the main work area. The room in which the actual exposures are made is the most heavily shielded and may be lined on all sides with steel or lead. Particular attention is given to potential paths of leakage such as access doors and passthroughs and to seemingly unimportant paths of leakage such as the nails and screws that attach lead sheets to walls and doors.

Third, portable radiation sources are used in strict accordance with all regulations. In most cases, safe operation is ensured by a combination of:

- Movable shielding (usually lead)
- Restrictions on the intensity and direction of radiation emitted from the source during exposure
- Exclusion of all personnel from the immediate area during exposure

The best protection is afforded by distance because radiation intensity decreases in proportion to the square of the distance from the source. As long as personnel stay far enough away from the source while an exposure is being made, portable sources can be used with adequate safety.

Finally, access to radiographic work areas, including field sites and radioactive-source storage areas, must at all times be under the control of competent and properly trained radiographers. Radiographers must be responsible for admitting only approved personnel into restricted work areas and must ensure that each individual admitted to a restricted work area carries appropriate devices for monitoring absorbed radiation doses. In addition to keeping records of absorbed dose for all monitored personnel, radiographers must maintain accurate and complete records of radiation levels in both restricted and adjacent unrestricted areas.

Radiation Monitoring. Every safety program must be controlled to ensure that both the facility itself and all personnel subject to radiation exposure are monitored. Facility monitoring is generally accomplished by periodically taking readings of radiation leakage during the operation of each source under maximum-exposure conditions. Calibrated instruments can be used to measure radiation dose rates at various points within the restricted area and at various points around the perimeter of the restricted area. This information, in conjunction with knowledge of normal occupancy, is used to evaluate the effectiveness of shielding and to determine maximum duty cycles for x-ray equipment.

To guard against the inadvertent leakage of large amounts of radiation from a shielded work area, interlocks and alarms are often required. Basically, an interlock disconnects power to the x-ray source if an access door is opened. Alarms are connected to a separate power source, and they activate visible and/or audible signals whenever the radiation intensity exceeds a preset value, usually 0.02 mSv/h (2 mrem/h).

All personnel within the restricted area must be monitored to ensure that no one absorbs excessive amounts of radiation. Devices such as pocket dosimeters and film badges are the usual means of monitoring, and often both are worn. Pocket dosimeters should be direct reading. One disadvantage of the remote-reading type is that it must be brought to a charger unit to be read. Both types are sensitive to mechanical shock, which could reduce the internal charge, thus implying that excessive radiation has been absorbed. If this should happen, the film badge should be developed immediately and the absorbed dose evaluated.

Under normal conditions, pocket dosimeters are read daily, and the readings are noted in a permanent record. At less frequent intervals, but at least monthly, film badges are developed and are evaluated by comparison with a set of reference films. Because of various factors, the values of absorbed radiation indicated by dosimeters and film badges may differ. This is particularly true at low dose rates and with high radiation energies (1 MeV or more). However, the accuracy of both dosimeters and film badges increases with increasing dose, and at dose rates near the maximum allowable dose of 0.0125 Sv ($1\frac{1}{4}$ rem) per calendar quarter, the readings usually check within $\pm 20\%$.

Access Control. Permanent facilities are usually separated from unrestricted areas by shielded walls. Sometimes, particularly in on-site radiographic inspection, access barriers may consist only of ropes. In such cases, the entire perimeter around the work area should be under continual visual surveillance by radiographic personnel. Signs that carry the international symbol for radiation must be posted around any high-radiation area. This helps to inform bystanders of the potential hazard, but should never be assumed to prevent unauthorized entry into the danger zone. In fact, no interlock, no radiation alarm, and no other safety device should be considered a substitute for constant vigilance on the part of radiographic personnel.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

X-Ray Tubes

X-ray tubes are electronic devices that convert electrical energy into x-rays. Typically, an x-ray tube consists of a cathode structure containing a filament and an anode structure containing a target--all within an evacuated chamber or envelope (Fig. 7). A low-voltage power supply, usually controlled by a rheostat, generates the electric current that heats the filament to incandescence. This incandescence of the filament produces an electron cloud, which is directed to the anode by a focusing system and accelerated to the anode by the high voltage applied between the cathode and the anode. Depending on the size of the focal spot achieved, x-ray tubes are sometimes classified into three groups:

- Conventional x-ray tubes with focal-spot sizes between 2 by 2 mm (0.08 by 0.08 in.) and 5 by 5 mm (0.2 by 0.2 in.)
- Minifocus tubes with focal-spot sizes in the range of 0.2 mm (0.008 in.) and 0.8 mm (0.03 in.)
- Microfocus tubes with focal-spot sizes in the range of 0.005 mm (0.0002 in.) and 0.05 mm (0.002 in.)

The design of conventional and microfocus x-ray tubes is discussed in the following section.

Fig. 7 Schematic of the principal components of an x-ray unit

When the accelerated electrons impinge on the target immediately beneath the focal spot, the electrons are slowed and absorbed, and both bremsstrahlung and characteristic x-rays are produced. Most of the energy in the impinging electron beam is transformed into heat, which must be dissipated. Severe restrictions are imposed on the design and selection of materials for the anode and target to ensure that structural damage from overheating does not prematurely destroy the target. Anode heating also limits the size of the focal spot. Because smaller focal spots produce sharper radiographic images, the design of the anode and target represents a compromise between maximum radiographic definition and maximum target life. In many x-ray tubes, a long, narrow, actual focal spot is projected as a roughly square effective focal spot by inclining the anode face at a small angle (usually about 20°) to the centerline of the x-ray beam, as shown in Fig. 8.

Fig. 8 Schematic of the actual and effective focal spots of an anode that is inclined at 20° to the centerline of the x-ray beam

Tube Design and Materials

The cathode structure in a conventional x-ray tube incorporates a filament and a focusing cup, which surrounds the filament. The focusing cup, usually made of pure iron or pure nickel, functions as an electrostatic lens whose purpose is to direct the electron beam toward the anode. The filament, usually a coil of tungsten wire, is heated to incandescence by an electric current produced by a relatively low voltage, similar to the operation of an ordinary incandescent light bulb. At incandescence, the filament emits electrons, which are accelerated across the evacuated space between the cathode and the anode. The driving force for acceleration is a high electrical potential (voltage) between anode and cathode, which is applied during exposure.

The anode usually consists of a button of the target material embedded in a mass of copper that absorbs much of the heat generated by electron collisions with the target. Tungsten is the preferred material for traditional x-ray tubes used in radiography because its high atomic number makes it an efficient emitter of x-rays and because its high melting point enables it to withstand the high temperatures of operation. Gold and platinum are also used in x-ray tubes for radiography, but targets made of these metals must be more effectively cooled than targets made of tungsten. Other materials are used, particularly at low energies, to take advantage of their characteristic radiation. Most high-intensity x-ray tubes have forced liquid cooling to dissipate the large amounts of anode heat generated during operation.

Tube envelopes are constructed of glass, ceramic materials or metals, or combinations of these materials. Tube envelopes must have good structural strength at high temperatures to withstand the combined effect of forces imposed by atmospheric pressure on the evacuated chamber and radiated heat from the anode. The shape of the envelope varies with

the cathode-anode arrangement and with the maximum rated voltage of the tube. Electrical connections for the anode and cathode are fused into the walls of the envelope. Generally, these are made of metals or alloys having thermal-expansion properties that match those of the envelope material.

X-ray tubes are inserted into metallic housings that contain an insulating medium such as transformer oil or an insulating gas. The main purpose of the insulated housing is to provide protection from high-voltage electrical shock. Housings usually contain quick disconnects for electrical cables from the high-voltage power supply or transformer. On self-contained units, most of which are portable, both the x-ray tube and the high-voltage transformer are contained in a single housing, and no high-voltage cables are used.

Microfocus X-Ray Tubes. Developments in vacuum technology and manufacturing processes have led to the design and manufacture of microfocus x-ray systems. Some of these systems incorporate designs that allow the opening of the tube head and the replacement of component parts, such as targets and filaments (Fig. 9). A vacuum is generated by the use of a roughing pump and turbomolecular pumps that rapidly evacuate and maintain the system to levels as low as 0.1×10^{-3} Pa (10^{-6} torr). Electrostatic or magnetic focusing and x-y deflection are used to provide very small focal spots and to guide the beam to various locations on the target. Focal-spot sizes are adjustable from 0.005 to 0.2 mm (0.0002 to 0.008 in.). If the target becomes pitted in one area, the beam can be deflected to a new area, extending the target life. When the target, filament, or other interior component is no longer useful in producing the desired focal-spot size or x-ray output, the tube can be opened and the component replaced at minimal cost. The tube can then be evacuated to operating levels in a few minutes or hours, depending on the length of time the tube is open to the atmosphere and the amount of contamination present.

Fig. 9 Schematic of a microfocus x-ray tube

These systems are available with voltages varying from 10 to 360 kV at beam currents from 0.01 to 2 mA. To avoid excessive pitting of the target, the beam current is varied according to the desired focal-spot size and/or kilovolt level (Fig. 10).

Fig. 10 Maximum ratings for no burn-in with 200-kV cathode/120-kV anode for electron beam widths of $\approx 10 \mu\text{m}$ (0.4 mil)

Microfocus x-ray systems having focal spots that approach a point source are useful in obtaining very high resolution images. A radiographic definition of 20 line pairs per millimeter (or a spatial resolution of 0.002 in.), using real-time radiography has been achieved with microfocus x-ray sources. This high degree of radiographic definition is accomplished by image enlargement, which allows the imaging of small details (see the section "Enlargement" in this article).

Microfocus x-ray systems have found considerable use in the inspection of integrated circuits and other miniature electronic components. Microfocus x-ray systems with specially designed anodes as small as 13 mm (0.5 in.) in diameter and several inches long also enable an x-ray source to be placed inside otherwise inaccessible areas, such as aircraft structures and piping. The imaging medium is placed on the exterior, and this allows for the single-wall inspection of otherwise uninspectable critical components. Because of the small focal spot, the source can be close to the test area with minimal geometric unsharpness (see the section "Principles of Shadow Formation" in this article for the factors that influence geometric unsharpness).

X-Ray Tube Operating Characteristics

There are three important electrical characteristics of x-ray tubes:

- The filament current, which controls the filament temperature and in turn the quantity of electrons that are emitted
- The tube voltage, or anode-to-cathode potential, which controls the energy of impinging electrons and therefore the energy or penetrating power, of the x-ray beam
- The tube current, which is directly related to filament temperature and is usually referred to as the milliamperage of the tube

The strength, or radiation output, of the beam is approximately proportional to milliamperage, which is used as one of the variables in exposure calculations. This radiation output, or R-output, is usually expressed in roentgens per minute (or hour) at 1 m (as mentioned in the section "Radiation Sources" in this article).

X-Ray Spectrum. The output of a radiographic x-ray tube is not a single-wavelength beam, but rather a spectrum of wavelengths somewhat analogous to white light. The lower limit of wavelengths, λ_{\min} , in manometers, at which there is an abrupt ending of the spectrum, is inversely proportional to tube voltage, V . This corresponds to an upper limit on photon energy, E_{\max} , which is proportional to the tube voltage, V :

$$E_{\max} = aV \quad (\text{Eq 4})$$

where $a = 11 \text{ eV/volt}$.

Figure 11 illustrates the effect of variations in tube voltage and tube current on photon energy and the intensity (number of photons). As shown in Fig. 11(a), increasing the tube voltage increases the intensity of radiation and adds higher-energy photons to the spectrum (crosshatched area, Fig. 11a). On the other hand, as shown in Fig. 11(b), increasing the tube current increases the intensity of radiation but does not affect the energy distribution.

Fig. 11 Effect of (a) tube voltage and (b) tube current on the variation of intensity with wavelength for the

bremsstrahlung spectrum of an x-ray tube. See text for discussion.

The energy of the x-rays is important because higher-energy radiation has greater penetrating capability; that is, it can penetrate through greater thickness of a given material or can penetrate denser materials than can lower-energy radiation. This effect is shown in Fig. 12, which relates the penetrating capability to tube voltage. An applied voltage of about 200 kV can penetrate steel up to 25 mm (1 in.) thick, while almost 2000 kV is needed when the thickness to be penetrated is 100 mm (4 in.).

Fig. 12 Effect of tube voltage on the penetrating capability of the resulting x-ray beam

As previously stated, most of the energy in the electron stream is converted into heat rather than into x-rays. The efficiency of conversion, expressed in terms of the percentage of electron energy that is converted into x-rays, varies with electron energy (or tube voltage), as shown in Fig. 13. At low electron energies (tube voltages of about 100 to 200 kV), conversion is only about 1%; about 99% of the energy must be dissipated from the anode as heat. However, at high electron energies (above 1 MeV), the process is much more efficient, varying from about 7% conversion efficiency at 1 MeV to 37% at 5 MeV. Therefore, in addition to producing radiation that is more penetrating, high-energy sources produce greater intensity of radiation for a given amount of electrical energy consumed.

Fig. 13 Effect of tube voltage or electron energy on the efficiency of energy conversion in the target of an x-ray source

The R-output of an x-ray tube varies with tube voltage (accelerating potential), tube current (number of electrons impinging on the target per unit time), and physical features of the individual equipment. Because of the last factor, the R-

output of an individual source also varies with position in the radiation beam, position usually being expressed as the angle relative to the central axis of the beam.

Effect of Tube Voltage. Both the mean photon energy and the R-output of an x-ray source are altered by changes in tube voltage. The effect of tube voltage on the variation of intensity (R-output) is shown in Fig. 11(a). The overall R-output varies approximately as the square root of tube voltage. The combined effect of greater photon energy and increased R-output produces, for film radiography, a decrease in exposure time of about 50% for a 10% increase in tube voltage. The effect is similar with other permanent-image recording media, as in paper radiography and xeroradiography.

Effect of Tube Current. The spectral distribution of wavelengths is not altered by changes in tube current; only the R-output (intensity) varies (Fig. 11b). Because tube current is a direct measure of the number of electrons impinging on the target per unit of time, and therefore the number of photons emitted per unit of time at each value of photon energy, R-output varies directly with tube current. This leads to the so-called reciprocity law for radiographic exposure, expressed as:

$$it = \text{constant} \qquad \qquad \qquad (\text{Eq 5})$$

where i is the tube current (usually expressed in milliamperes) and t is the exposure time.

The reciprocity law (Eq 5) is valid for any recording medium whose response depends solely on the amount of radiation impinging on the testpiece, regardless of the rate of impingement (radiation intensity). For example, the reciprocity law is valid for most film and paper radiography and most xeroradiography but not for fluoroscopic screens or radiometric detectors, both of which respond to radiation intensity rather than to total amount of radiation. However, radiographic films, when used with fluorescent screens, exhibit reciprocity law failure because the response of film emulsions varies with the rate of impingement of photons of visible light (screen brightness) and with total exposure. If tube current is decreased and exposure time is increased according to the reciprocity law, a fluorescent screen will emit the same amount of light (same number of photons) but at a lower level of brightness over a longer period of time. The lower brightness level will result in lower film density compared to an equivalent exposure made with a higher tube current.

Deviations from reciprocity law are usually small for minor changes in tube current, causing little difficulty in resolving testpiece features or interpreting radiographs made on screen-type film. However, when the tube current is changed by a factor of four or more, there may be a 20% or more deviation from reciprocity law, and it will be necessary to compensate for the effect of screen brightness on film density.

In most cases, when tube voltage is maintained constant, exposures made in accordance with the reciprocity law should produce identical film densities. This assumes that tube voltage does not vary with tube current. Heavy-duty equipment designed for stationary installations contains electrical circuitry (current stabilizers and voltage compensators) that tend to maintain R-output in accordance with the reciprocity law. However, equipment intended for on-site use is often designed to minimize weight, size, and cost and does not contain such complex circuitry. Consequently, the R-output and x-ray spectrum of many portable or transportable machines vary with tube current. These types of machines may exhibit apparent reciprocity law failure at both ends of the useful range of tube currents. For example, at currents approaching the maximum rated current, the tube voltage tends to be depressed because of the heavy electrical load on the transformer. This produces lower values of both R-output and mean photon energy than would normally be expected. Conversely, at very low tube currents, the tube voltage may actually exceed the calibrated value because the transformer is more efficient. This produces higher values of both R-output and mean photon energy than are normally expected. These deviations from expected values are not always indicated on the monitoring instruments attached to x-ray machines.

Because of deviations from reciprocity law caused by equipment characteristics, it is often desirable to prepare exposure charts (usually graphs) for each x-ray unit. Such charts or graphs should be based on film exposure data at several values of tube voltage within the useful kilovoltage range of the unit. Use of these charts for determining exposure times, especially at abnormally high or low tube currents, will help to avoid unsatisfactory image quality.

Effect of Electrical Waveform. In all x-ray tubes that are powered by transformer circuits, the waveform of the tube voltage affects R-output. X-ray tubes are direct current (dc) devices, yet almost all power supplies are driven by alternating current (ac). If ac power is supplied directly to the x-ray tube, the tube itself will provide half-wave rectification. Many low-power x-ray machines use self-rectifying x-ray tubes. As illustrated in Fig. 14(a), half-wave rectification results in a sinusoidal variation of instantaneous tube voltage with time, except that no tube current flows

(and there is no effective tube voltage) during the portion of each cycle when the anode is electrically negative, and consequently there is no emission of x-rays during that portion of the cycle.

Fig. 14 Waveforms for accelerating potential (tube voltage) and tube current for four generally used types of x-ray-tube circuits. (a) Half-wave rectified circuit and (b) full-wave rectified circuit, in which tube voltage is equal to the peak voltage of the electrical transformer. (c) Villard-type circuit and (d) constant-potential circuit, in which tube voltage is twice the peak voltage of the transformer

In a full-wave-rectified circuit (Fig. 14b), the instantaneous tube voltage varies sinusoidally from zero to peak voltage (kVp) and back to zero, then repeats the sinusoidal pattern during the second half of each cycle. This effectively doubles the time during which x-rays are emitted on each cycle, thus doubling the R-output compared to half-wave-rectified equipment.

In Villard-circuit equipment, the electrical input to the x-ray tube varies sinusoidally, but as Fig. 14(c) shows, the zero potential occurs at the minimum instantaneous tube voltage rather than at midrange. Consequently, the accelerating potential across the tube has a peak value (kVp) that is twice the peak voltage of the transformer; for example, 2-MeV electrons can be produced with transformer rated at 1 MVp. X-rays produced by Villard-circuit equipment are harder (that is, of higher mean photon energy) than x-rays produced by rectified equipment having a transformer that operates at the same peak voltage. Villard circuits exhibit a variation in instantaneous tube current that parallels the variation in instantaneous tube voltage.

A modified Villard circuit, also known as a Greinacher circuit or a constant-potential circuit, produces an accelerating potential and instantaneous tube current that are nearly constant, varying only slightly with time, as shown in Fig. 14(d). The chief value of constant-potential equipment lies in the fact that its R-output is about 15% higher than for a full-wave-rectified unit of equivalent tube voltage. This means that a nominal 15% reduction in exposure times can be achieved by using constant-potential instead of rectified equipment.

Heel Effect. X-ray tubes exhibit a detrimental feature known as the heel effect. When the direction in which x-rays are emitted from the target approaches the anode heel plane, the intensity of radiation at a given distance from the focal spot is less than the intensity of the central beam because of self-absorption by the target. Figure 15(a) shows the heel effect schematically, and Fig. 15(b) is a graph of the variation of intensity as a function of angle of emergence relative to the anode heel plane. The direction of the central beam is at 20° —for this particular tube design, an angle equal to the anode heel angle.

Fig. 15 Heel effect in a typical conventional x-ray tube having an anode face inclined 70° to the tube axis (20° anode heel angle). (a) Diagram showing relation of useful beam (crosshatched region) to tube components. (b) Graph of beam intensity (expressed as a percentage of the intensity of the central beam) as a function of angle of emergence relative to the anode heel plane

Radiographs of large-area testpieces that are made at relatively short source-to-detector distances will exhibit less photographic density (film) or less brightness (real-time) in the region where the incident radiation is less intense because of the heel effect. This can lead to errors in interpretation unless the heel effect is recognized. The consequences of heel effect can be minimized by using a source-to-detector distance that ensures that the desired area of coverage is entirely within the useful beam emanating from the x-ray tube or by making multiple exposures with a reduced area of coverage for each exposure.

The heel effect also influences image sharpness when there is some geometric enlargement. The projected size of the focal spot is reduced near the "heel," which reduces the geometric unsharpness of the radiographic image nearest the heel. Conversely, the radiographic image is less sharp on the cathode side of the radiation beam.

Stem Radiation. In an x-ray tube, electrons that produce the useful x-rays are known as primary electrons. The kinetic energy of the primary electrons is converted partly to radiation and partly to heat when these electrons collide with the target. However, some of the primary electrons collide with other components inside the tube envelope, giving rise to slower-moving electrons known as secondary electrons or stray electrons. Some of these stray electrons bounce around inside the tube and eventually strike the anode. This produces x-rays, called stem radiation, that are of relatively long wavelength because of the low kinetic energy of the stray electrons that produced them. Stem radiation, which is about $\frac{1}{200}$ as intense as the useful beam, is produced all over the anode surface, not only at the focal spot. Because stem radiation is projected from a comparatively large area instead of emanating only from the focal spot, it invariably causes image unsharpness.

Some x-ray tubes are designed to eliminate this phenomenon by the use of hollow-end anodes called hooded anodes (Fig. 16). Hooded anodes reduce stem radiation both by shielding the target from some of the stray electrons and by absorbing much of the radiation produced by stray electrons that enter through the open end of the anode cavity.

Fig. 16 Schematic of an x-ray tube having a hooded anode to minimize stem radiation

Tube Rating. X-ray tubes produce a great amount of heat. At 100-kV tube voltage, only about 1% of the electrical energy is converted to x-rays; the remaining 99% is converted to heat. Heat removal constitutes the most serious limitation on x-ray tube design. The size of the focal spot and the design of the anode are the main factors that determine the rating of a particular x-ray tube. A tube rating is a limiting or maximum allowable combination of tube voltage (kilovoltage) and tube current (milliamperage).

Most industrial tubes are rated for continuous service at the maximum tube current that will give reasonable target life at maximum tube voltage. Therefore, if a tube has a continuous rating of 10 mA at 150-kV constant potential, the rating is 1500 W. Any product of kilovoltage and milliamperage equal to 1500 will not exceed the heat limit on the anode. The tube should be able to operate continuously at 20 mA and 75 kV, 30 mA and 50 kV, and so on.

However, another limitation on operating characteristics is that, to sustain the same tube current, the filament must be heated to a higher temperature at low tube voltages than at higher tube voltages. Therefore, the tube current at low voltage must be limited to achieve satisfactory service life. Figure 17 shows a tube-rating chart for continuous operation in which the total length of time for each exposure is not a factor in determining operating conditions. On the left side of the chart, at low tube voltages, operating conditions are determined by filament life; on the right side of the chart, at high tube voltages, anode heating (focal-spot loading) limits operating conditions. Any combination of tube voltage and tube current below the curve can be used without impairing the service life of either anode or filament. In practice, unless there are special considerations, values approaching the continuous-duty rating are ordinarily used to minimize exposure time.

Fig. 17 Tube-rating chart for a typical beryllium-window tube with a 0.3 mm (0.012 in.) focal spot. Tube rating is for continuous operation with a full-wave-rectified single-phase power supply. Below 22.5 kVp, tube current is limited by desired filament life; above 34.5 kVp, tube current is limited by focal-spot loading. Filament voltage is 1.7 to 2.6 V, and filament current is 3.2 to 4.0 A.

Some tube manufacturers use an alternative form of rating (intermittent rating), in which the time involved in making a particular film (or paper) exposure enters into the rating. As illustrated in Fig. 18(a), for each combination of tube current and tube voltage there is a maximum exposure time that must not be exceeded. Longer exposure times can cause the target to melt. Normally, there is a minimum waiting time between exposures for tubes rated for intermittent operation. For the tube rating shown in Fig. 18(a), the waiting time is specified as 5 s when maximum exposure times are used. Some manufacturers have developed rating systems in which the minimum waiting time can be calculated.

(a)

(b)

Fig. 18 Tube-rating chart (a) and cooling chart (b) for a typical industrial x-ray tube having a 1.5 mm (0.06 in.) focal spot. Tube rating is for intermittent operation with a full-wave-rectified single-phase power supply; a minimum 5-s waiting time between exposures is specified. Cooling chart is for an oil-filled housing without an air circulator. When housing is fitted with an optional air circulator (fan), cooling times are reduced to one-half

the values determined from the chart.

Tubes that are rated for intermittent operation can accumulate only a certain amount of heat, then they must be allowed to cool before additional exposures are made. Figure 18(b) is the cooling chart used in conjunction with the tube-rating chart in Fig. 18(a). According to the cooling chart, the tube can store 500,000 units of heat (one heat unit equals $1 \text{ mA} \cdot 1 \text{ kVp} \cdot 1 \text{ s}$). Therefore, if a series of exposures is to be made at 70 kVp, 30 mA, and 5 s, each exposure will expend energy equal to 10,500 heat units. The number of successive film exposures that can be made, with a 5-s wait between exposures, is 47 (500,000 heat units divided by 10,500 heat units per exposure). After the 47th exposure, the tube must be allowed to cool according to the cooling curve in Fig. 18(b). The tube can be allowed to cool for any length of time, and then another exposure can be made as long as the additional exposure does not increase the stored heat above 500,000 heat units. After the tube has reached its capacity for heat storage, waiting times between successive exposures must be in accordance with the cooling curve. In this case, as shown in Fig. 18(b), 2 h would be required (or 1 h with an optional air circulator) for the tube to cool completely.

Inherent Filtration. In the radiography (film or real-time) of thin or lightweight materials, which requires low-energy radiation, filtration by the glass walls of the x-ray tube becomes a problem. Ninety-five percent of a 30-kV x-ray beam is absorbed by the glass walls of an ordinary x-ray tube. Consequently, in a tube used to radiograph thin or lightweight materials, a beryllium window is fused into the glass wall in the path of the x-ray beam. Beryllium is one of the lightest of metals and is more transparent to x-rays than any other metal. The beryllium-window tube has a minimum of inherent filtration and allows most of the very low energy x-rays to escape from the tube, as shown by the comparison with an ordinary oil-insulated glass tube in Fig. 19. The results are quite noticeable with both film and real-time radiography, particularly in contrast improvement. This effect is sometimes noticeable even beyond 150 kV. Very costly 250- or 300-kV tubes with beryllium windows are sometimes used when thin, light materials as well as thick, dense materials must be inspected with the same apparatus. In beryllium-window tubes designed for very low voltage work, the window can be as thin as 0.25 mm (0.010 in.). Consequently, to avoid rupture due to external pressure on the evacuated tube, thin beryllium windows are also of small diameter; this restricts the size of the x-ray beam and the corresponding field diameter.

Fig. 19 Comparison of the R-output of a beryllium-window tube with that of an ordinary oil-insulated glass x-ray tube

In general, the higher the tube voltage, the larger the tube must be, and consequently the thicker the glass walls must be to support the internal elements and to withstand external atmospheric pressure. Furthermore, as the tube voltage increases, there is more likely to be high-voltage arcing from the tube to various parts of the housing. High-voltage tubes are generally surrounded by oil, which not only insulates the tube from the housing but also is often the primary means of extracting heat from the anode. In some tube assemblies, the oil surrounding the tube may be 50 mm (2 in.) thick or more. Both the oil surrounding the tube and the window in the housing that allows the useful beam of radiation to escape act as filters, particularly affecting the long-wavelength portion of the emitted radiation. Above about 200 kV, inherent filtration by components of the tube assembly is less important, primarily because inherent filtration by the testpiece would not allow the long-wavelength portion of the spectrum to reach the film anyway.

High-Energy X-Ray Sources

Above about 400 kV, the conventional design of an x-ray tube and its high-voltage iron-core transformer becomes cumbersome and large. Although x-ray machines with iron-core transformers have been built for 600 kV (maximum), there are no commercial versions operating above 500 kV. For higher-energy x-rays, other designs are used. Some of the machine designs for the production of high-energy x-rays include:

- Linear accelerators
- Betatrons
- Van de Graaff generators
- X-ray tubes with a resonant transformer

Linear accelerators, which produce high-velocity electrons by means of radio-frequency energy coupled to a waveguide, have extended industrial radiography to about 25-MeV photon energy. Betatrons, which accelerate electrons by magnetic induction, are used to produce 20- to 30-MeV x-rays. Portable linear accelerators and betatrons are also used in field inspection. The electron energy of portable units is of the order of 1.5 MeV for portable linear accelerators and 2 to 6 MeV for portable betatrons. Van de Graaff generators and x-ray tubes with resonant transformers are less widely used in industrial radiography. The Van de Graaff generator is an electrostatic device that operates from 500 kV to about 6 MV. X-ray tubes with resonant transformers were developed in the 1940s, and some units are still in operation. The output of these units is limited to about 4000 keV (4 MeV) in maximum photon energy that can be produced. Above these energies, the efficiency of resonant transformers is somewhat impaired. The radiation spectrum is broad, containing a large amount of radiation produced at much lower energies than the maximum. In addition, the accelerating potential fluctuates, which makes focusing of the electron beam difficult and creates a focal spot that is much larger than desired for optimum radiographic definition.

In terms of penetrating capability, expressed as the range of steel thickness that can be satisfactorily inspected, Table 2 compares high-energy sources with conventional x-ray tubes. The maximum values in Table 2 represent the thicknesses of steel that can be routinely inspected using exposures of several minutes' duration and with medium-speed film. Thicker sections can be inspected at each value of potential by using faster films and long exposure times, but for routine work the use of higher-energy x-rays is more practical. Sections thinner than the minimum thicknesses given in Table 2 can be penetrated, but radiographic contrast is not optimum.

Table 2 Penetration ranges of x-ray tubes and high-energy sources

Maximum accelerating potential	Penetration range in steel	
	mm	in.
X-ray tubes		
150 kV	Up to 15	Up to $\frac{5}{8}$
250 kV	Up to 40	Up to $1\frac{1}{2}$

400 kV	Up to 65	Up to $2\frac{1}{2}$
1000 kV (1 MV)	5-90	$\frac{1}{4}$ - $3\frac{1}{2}$
High-energy sources		
2.0 MeV	5-250	$\frac{1}{4}$ - 10
4.5 MeV	25-300	1-12
7.5 MeV	60-460	$2\frac{1}{4}$ - 18
20.0 MeV	75-610	3-24

R-Output of High-Energy Sources. The R-output of a pulsed x-ray generator such as a linear accelerator or betatron depends on several factors, including pulse length and frequency of pulse repetition, although the output of x-ray generators of similar type and design varies approximately as $V^{2.7}$. For high-energy sources, electron beam current generally is not a satisfactory measure of R-output, and comparisons of beam current with the tube current of conventional x-ray tubes have little meaning. In fact, even the measurement of R-output is complicated and difficult, especially for energies exceeding 3 MeV. It is often more realistic to estimate the output of high-energy sources from film exposure data.

In terms of effective output, linear accelerators have the highest beam strength; machines with estimated outputs as high as 25,000 RMM have been built. Betatrons, although capable of producing higher-energy radiation than linear accelerators, are limited in beam strength to about 500 RMM. By contrast, 200 RMM is about the maximum output of conventional rectified, Villard-circuit or constant-potential equipment, of resonant-transformer-based machines, or of machines powered by an electrostatic Van de Graaff generator. Portable betatrons and linear accelerators have an R-output in the range of 1 to 3 RMM.

With most high-energy sources (in which the x-ray beam is emitted from the back side of the target in approximately the same direction of travel as the impinging stream of electrons), the combined effects of self-absorption and electron scattering within the target itself produce a variation in intensity with angle relative to the axis of the central beam that parallels the heel effect in conventional x-ray tubes. The magnitude of the effect varies with electron energy and is extremely pronounced at energies exceeding 2 MeV. The variation of R-output with angle of emergence, shown in Fig. 20 for three values of electron energy, is of considerable practical importance because this effect can severely limit the area of coverage, especially for short source-to-detector distances. The calculated angles between the central beam and the focus of points of half intensity (that is, where the intensity is one-half that of the central beam), as well as the corresponding field diameters at 1 m (3.3 ft), are given in Table 3 for several values of electron energy, assuming normal incidence of the electrons on the target.

Table 3 Half intensity and field diameter at various electron energy values

Electron energy, MeV	Angle to half intensity, degrees	Field diameter at 1 m (3.3 ft)	
		mm	in.

5	11	380	15.0
10	7	244	9.6
18	5	174	6.9
31	3.4	119	4.7
50	1.9	66	2.6

Fig. 20 Variation of R-output with angle of emergence relative to the central beam of a high-energy source. Curves were calculated for x-rays emitted at three levels of electron energy from back side of tungsten target, assuming electron impingement normal to target surface.

As Table 3 indicates, the useful field produced by a parallel stream of electrons with energy above 10 MeV is inconveniently small for most applications. Fortunately, many high-energy sources employ some form of device to focus the electron beam on the target so that a converging beam rather than a parallel beam of electrons strikes the target. Originally intended to achieve a reduced focal-spot size, beam convergence has the secondary effect of increasing the angle to half intensity, thus increasing the effective field at any focal distance. For most high-energy sources, the effect of electron beam convergence is to at least double the field diameter.

In addition to electron beam convergence, almost all high-energy sources are equipped with a field compensator, which further increases the effective field size. A field compensator is a metallic filter that is thicker in the center than it is at the edges. By progressively absorbing less radiation with increasing angle of emergence relative to the central beam, a field compensator can almost double the effective field size. The intensity of the entire beam of radiation is reduced by a field compensator, but even a reduction in central beam intensity of about 35% does not seriously increase film exposure times for most applications. In fact, the increase in effective field size usually more than compensates for the loss of intensity.

There is one type of application in which the inherent variation in intensity with angle of emergence is beneficial. A solid sphere or solid cylinder varies continuously in thickness across a diametral plane. When incident radiation from a uniform-intensity source penetrates a solid sphere or cylinder parallel to a diametral plane, there is a progressive variation in transmitted intensity, because of thickness variations, which leads to underexposure of the central area of the radiograph and overexposure along the edges, often resulting in unsatisfactory definition. With a nonuniform radiation field, however, inherent variations in penetrated thickness are at least partly counter-balanced by variations in incident intensity across the radiation field, which results in a much better resolution of testpiece detail.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Gamma-Ray Sources

Gamma rays are high-energy electromagnetic waves of relatively short wavelength that are emitted during the radioactive decay of both naturally occurring and artificially produced unstable isotopes. In all respects other than their origin, γ -rays and x-rays are identical. Unlike the broad-spectrum radiation produced by an x-ray tube, γ -ray sources emit one or more discrete wavelengths of radiation, each having its own characteristic photon energy.

The two most common radioactive isotopes used in radiography are iridium-192 and cobalt-60. Ytterbium-169 has also gained a measure of acceptability in the radiography of thin materials and small tubes, especially boiler tubes in power plants. Cesium-137, although not used in radiography, has been useful in radiometry and computed tomography.

Radiation Characteristics of γ -Ray Sources. Because gamma radiation is produced by the radioactive decay of unstable atomic nuclei, there is a continuous reduction in the intensity of emitted radiation with time as more and more unstable nuclei transform to stable nuclei. This reduction follows a logarithmic law, and each radioactive isotope has a characteristic half-life, or amount of time that it takes for the intensity of emitted radiation to be reduced by one-half. The term half-life should not be misinterpreted as meaning that the intensity of emitted radiation will be zero at the end of the second half-life. Rather, the intensity remaining at the end of a second half-life will be one-half the intensity at the end of the first half-life, or one-fourth of the initial intensity. The intensity at the end of the third half-life will be one-eighth of the initial intensity, and so on.

As described in the section "Radiation Sources" in this article, the strength of γ -ray sources is the source activity given in the units of gigabecquerel or curies. If the source activity is known at any given time, a table of radioactive-decay factors for the specific radioactive isotope (or the corresponding logarithmic decay formula) can be used to calculate source activity at any subsequent time. Then, radiation intensity, which is usually measured in roentgens per hour, can be found by multiplying source activity by the specific γ -ray constant given in roentgens per hour per gigabecquerel (or curie). Although radiation output is constant for a given isotope, large-size sources emit slightly less radiation per gigabecquerel (curie) than small-size sources; that is, large-size sources have somewhat lower effective output. The difference between calculated radiation output and effective radiation output is the result of self-absorption within the radioactive mass, in which γ -rays resulting from decay of atoms in the center of the mass are partly absorbed by the mass itself before they can escape. Most source manufacturers measure source activity in units of effective gigabecquerel (or curies), which is the net of self-absorption.

Specific activity, commonly expressed as gigabecquerels (curies) per gram or gigabecquerels (curies) per cubic centimeter, is a characteristic of radioactive sources that expresses their degree of concentration. A source that has a high specific activity will be smaller than another source of the same isotope and activity that has a lower specific activity. Generally, sources of high specific activity are more desirable because they have lower self-absorption and provide less geometric unsharpness in the radiographs they produce than sources of low specific activity.

The more important characteristics of γ -ray sources are summarized in Table 4. Source activity and specific activity are not listed, because these characteristics vary according to the physical size of the source, the material and design of its encapsulation, and the degree of concentration at the time the source was originally produced.

Table 4 Characteristics of γ -ray sources used in industrial radiography

γ -ray source	Half-life	Photon energy, MeV	Radiation output, RHM/Ci ^(a)	Penetrating power, mm (in.) of steel
Thulium-170	128 days	0.054 and 0.084 ^(b)	0.003	$13 \left(\frac{1}{2} \right)$
Iridium-192	74 days	12 rays from 0.21-0.61	0.48	75 (3)
Cesium-137	33 years	0.66	0.32	75 (3)
Cobalt-60	5.3 years	1.17 and 1.33	1.3	230 (9)

(a) Output for typical unshielded, encapsulated sources; RHM/Ci, roentgens per hour at 1 m per curie.

(b) Against strong background of higher-MeV radiation.

Physical Characteristics of γ -Ray Sources. Radioactive sources, which are usually metallic but may be salts or gases adsorbed on a block of charcoal, are encapsulated in a protective covering, usually a thin stainless steel sheath or a thicker sheath of aluminum. Encapsulation prevents abrasion, spillage, or leakage of the radioactive material; reduces the likelihood of loss or accidental mishandling; and provides a convenient means by which wires, rods, or other handling devices can be attached to the source.

Gamma-ray sources are housed in protective containers made of lead, depleted uranium, or other dense materials that absorb the γ -rays, thus providing protection from exposure to the radiation. Two basic types of containers are generally used. One type incorporates an inner rotating cylinder that contains the isotope and is rotated toward a conical opening in the outer cylinder to expose the source and allow the escape of radiation. This type is often referred to as a radioisotope camera. The second type incorporates a remote-controlled mechanical or pneumatic positioner that moves the encapsulated radioactive source out of the container and into a predetermined position where it remains until exposure is completed; the source is then returned to the protective container, again by remote control. This type is more versatile than the first type and is much more extensively used. Remote control of the positioner allows the operator to remain at a safe distance from the source while manipulating the capsule out of and into the protective container.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Attenuation of Electromagnetic Radiation

X-rays and γ -rays interact with any substance, even gases such as air, as the rays pass through the substance. It is this interaction that enables parts to be inspected by differential attenuation of radiation and that enables differences in the intensity of radiation to be detected and recorded. Both these effects are essential to the radiographic process. The attenuation characteristics of materials vary with the type, intensity, and energy of the radiation and with the density and atomic structure of the material.

The attenuation of electromagnetic radiation is a complex process. Because of their electromagnetic properties, x-rays and γ -rays are affected by the electric fields surrounding atoms and their nuclei. It is chiefly interaction with these electric fields that causes the intensity of electromagnetic radiation to be reduced as it passes through any material.

The intensity of radiation varies exponentially with the thickness of homogeneous material through which it passes. This behavior is expressed as:

$$I = I_0 \exp (-\mu t) \quad (\text{Eq 6})$$

where I is the intensity of the emergent radiation, I_0 is the initial intensity, t is the thickness of homogeneous material, and μ is a characteristic of the material known as the linear absorption coefficient. The coefficient μ is constant for a given situation, but varies with the material and with the photon energy of the radiation. The units of μ are reciprocal length (for example, cm^{-1}).

The absorption coefficient of a material is sometimes expressed as a mass absorption coefficient (μ/ρ), where ρ is the density of the material. Alternatively, the absorption coefficient can be expressed as an effective absorbing area of a single atom; this property, called the atomic absorption coefficient (μ_a) or cross section, is equal to the linear absorption coefficient divided by the number of atoms per unit volume. The cross section, usually expressed in barns (1 barn = 10^{-24} cm^2), indicates the probability that a photon of radiation will interact with a given atom.

Atomic Attenuation Processes

Theoretically, there are four possible interactions between a photon (quantum) of electromagnetic radiation and material. Also, there are three possible results that an interaction can have on the photon. Thus, there are 12 possible combinations of interaction and result. However, only four of these have a high enough probability of occurrence to be important in the attenuation of x-rays or γ -rays. These four combinations are photoelectric effect, Rayleigh scattering, Compton scattering, and pair production.

The photoelectric effect is an interaction with orbital electrons in which a photon of electromagnetic radiation is consumed in breaking the bond between an orbital electron and its atom. Energy in excess of the bond strength imparts kinetic energy to the electron.

The photoelectric effect generally decreases with increasing photon energy, E , as $E^{-3.5}$, except that, at energies corresponding to the binding energies of electrons to the various orbital shells in the atom, there are abrupt increases in absorption. These abrupt increases are called absorption edges and are given letter designations corresponding to the electron shells with which they are associated. At photon energies exceeding an absorption edge, the photoelectric effect again diminishes with increasing energy.

For elements of low atomic number, the photoelectric effect is negligible at photon energies exceeding about 100 keV. However, the photoelectric effect varies with the fourth to fifth power of atomic number; thus, for elements of high atomic number, the effect accounts for an appreciable portion of total absorption at photon energies up to about 2 MeV.

Rayleigh scattering, also known as coherent scattering, is a form of direct interaction between an incident photon and orbital electrons of an atom in which the photon is deflected without any change in either the kinetic energy of the photon or the internal energy of the atom. In addition, no electrons are released from the atom. The angle between the path of the deflected photon and that of the incident radiation varies inversely with photon energy, being high for low-energy photons and low for high-energy photons. There is a characteristic photon energy, which varies with atomic number, above which Rayleigh scattering is entirely in the forward direction and no attenuation of the incident beam can be detected.

Rayleigh scattering is most important for elements of high atomic number and low photon energies. However, Rayleigh scattering never accounts for more than about 20% of the total attenuation.

Compton scattering is a form of direct interaction between an incident photon and an orbital electron in which the electron is ejected from the atom and only a portion of the kinetic energy of the photon is consumed. The photon is scattered incoherently, emerging in a direction that is different from the direction of incident radiation and emerging with reduced energy and a correspondingly lower wavelength. The relationship of the intensity of the scattered beam to the intensity of the incident beam, scattering angle, and photon energy in the incident beam is complex, yet is amenable to

theoretical evaluation. Compton scattering varies directly with the atomic number of the scattering element and varies approximately inversely with the photon energy in the energy range of major interest.

Pair production is an absorption process that creates two 0.5-MeV photons of scattered radiation for each photon of high-energy incident radiation consumed; a small amount of scattered radiation of lower energy also accompanies pair production. Pair production is more important for heavier elements; the effect varies with atomic number, Z , approximately as $Z(Z + 1)$. The effect also varies approximately logarithmically with photon energy.

In pair production, a photon of incident electromagnetic radiation is consumed in creating an electron-positron pair that is then ejected from an atom. This effect is possible only at photon energies exceeding 1.02 MeV because, according to the theory of relativity, 0.51 MeV is consumed in the creation of the mass of each particle, electron, or positron. Any energy of the incident photon exceeding 1.02 MeV imparts kinetic energy to the pair of particles.

The positron created by pair production is destroyed by interaction with another electron after a very short life. This destruction produces electromagnetic radiation, mainly in the form of two photons that travel in opposite directions, each photon having an energy of about 0.5 MeV. Most of the electrons created by pair production are absorbed by the material, producing bremsstrahlung of energy below 0.5 MeV.

Total absorption is the sum of the absorption or scattering effects of the four processes. The atomic absorption coefficient can be expressed as:

$$\mu_a = \sigma_{pe} + \sigma_R + \sigma_C + \sigma_{pr} \quad (\text{Eq 7})$$

where σ_{pe} is the attenuation due to the photoelectric effect, σ_R is that due to Rayleigh scattering, σ_C is that due to Compton scattering, and σ_{pr} is that due to pair production.

From calculated atomic absorption coefficients, the mass absorption coefficient can be determined by multiplying μ_a by Avogadro's number, N , and dividing by the atomic weight of the element, A :

$$\frac{\mu}{\rho} = \frac{\mu_a N}{A} \quad (\text{Eq 8})$$

Figure 21 shows the variation of the mass absorption coefficient for uranium as a function of photon energy and indicates the amount of total absorption that is attributable to the various atomic processes over the entire range of 10 keV to 100 MeV. Tables of cross sections and absorption coefficients for 40 of the more usually encountered elements at various photon energies from 0.01 to 30 MeV are presented in Ref 1. Absorption coefficients can be evaluated for alloys, compounds, and mixtures by calculating a weighted-average mass absorption coefficient in proportion to the relative abundance of the constituent elements by weight.

Fig. 21 Calculated mass absorption coefficient for uranium as a function of photon energy (solid line) and contributions of various atomic processes (dashed lines). Rayleigh scattering is the difference between total scattering and Compton scattering.

Effective Absorption of X-Rays

The preceding discussion of mass absorption and atomic absorption characteristics is based on the assumption of so-called narrow-beam geometry, in which any photon that is scattered, no matter how small the angle, is considered absorbed. Experimentally, narrow-beam geometry is approximated by interposing a strong absorber such as lead between the material being evaluated and the radiation detector, then allowing the beam of attenuated radiation to pass through a small hole in the absorber to impinge on the detector. Only total absorption can be determined experimentally; however, it has been shown that the sum of calculated absorption coefficients for the various atomic processes correlates closely with experimentally determined narrow-beam absorption coefficients for a wide variety of materials and photon energies.

Broad-Beam Absorption. The evaluation of absorption coefficients under narrow-beam geometry is mainly a convenience that simplifies theoretical calculations. Whenever there is a measurable width to the radiation beam, narrow-beam conditions no longer exist, and absorption must be evaluated under so-called broad-beam geometry. Under broad-beam geometry, photons that are scattered forward at small angles are not lost, but increase the measured intensity of the attenuated beam. Therefore, the broad-beam absorption coefficient of any material is less than the narrow-beam absorption coefficient.

There are many degrees of broad-beam geometry, depending on the portion of the attenuated-beam intensity that is comprised of scattered radiation. However, broad-beam absorption characteristics are usually determined in such a manner that variations in the areas of either the radiation beam or the testpiece have no effect on the intensity of the transmitted radiation. Therefore, broad-beam absorption coefficients are useful because the ordinary radiographic arrangement (in which the film or screen is placed in close proximity to the testpiece) effectively duplicates this condition.

Effect of Radiation Spectrum. The theoretical assessment of absorption characteristics is based on an assumption of monoenergetic radiation (radiation having a single wavelength). As Fig. 11 shows, the actual output of an x-ray tube is not monoenergetic; for example, 200-kV x-rays have an upper limit of 200 keV of photon energy and are comprised of a broad spectrum of x-rays having lower photon energies. Even if an incident beam were monoenergetic, it would soon contain x-rays of lower photon energies because of Compton scattering. Therefore, in addition to the effect of broad-beam geometry, the effective absorption coefficients of materials are further modified by the multienergetic character of impinging radiation. The correction of calculated absorption coefficients for the known wavelength distribution of a beam of x-rays is time consuming but not impossible.

Empirical values of absorption coefficients based on broad-beam experiments are the values that are most useful in exposure calculations, because these values are corrected for both broad-beam geometry and the variation of intensity with photon energy in the incident radiation. Published values of calculated absorption coefficient are based on narrow-beam geometry. If these values are used to estimate radiographic exposures, the estimates may be inaccurate, especially for low-to-medium energy radiation from an x-ray tube and for relatively thick testpieces.

Scattering Factor. The ratio of the intensity of scattered radiation, I_s , to the intensity of direct radiation, I_D , impinging on the detector is known as the scattering factor and is important in determining image quality. Scattered radiation does not reveal characteristics of the testpiece; it only reduces radiographic contrast, obscuring detail and reducing radiographic sensitivity. The scattering factor is a function of photon energy and the thickness, density, and material type (μ/ρ) of the testpiece. Figure 22 illustrates an example of experimental values for the build-up factor ($1 + I_s/I_D$) with steel.

Fig. 22 Experimental values of build-up factor for different thicknesses of steel and different x-ray energies. Source: Ref 2

Because radiation of low photon energy is scattered more than radiation of high photon energy, it is desirable to use relatively high-energy radiation for optimum radiographic subject contrast. This can be accomplished by either raising the voltage of the x-ray tube, which moves the entire bremsstrahlung spectrum to higher photon energies, or by interposing a filter between the source and the testpiece, which effectively raises photon energy by selectively absorbing or scattering the long wavelength portion of the spectrum. The optimum choice of filter material and thickness varies with different combinations of testpiece material and thickness, film or detector type, and bremsstrahlung spectrum as determined by the type of x-ray tube and tube voltage used. Also, the optimum combinations of filter material and thickness, and tube current and exposure time, must be evaluated on the basis of a compromise between image quality and costs. Generally, filters made of metals having high atomic numbers (lead, for example) produce a cleaner image because of a reduction in the amount of scattered radiation. However, such filters also cause a large reduction in the intensity of the radiation beam, which leads to greater expense because of the need for longer exposure times with films or more sensitive detector systems in real-time radiography. Also, because long wavelength radiation is absorbed preferentially, there is a reduction in the ability to image very small flaws.

Raising the voltage of the x-ray tube, which is sometimes restricted by equipment limitations, does not necessarily involve a compromise between image quality and costs. In fact, high-voltage x-ray equipment is frequently capable of producing higher-quality radiographs at reduced cost. Image quality is improved primarily by reducing the proportion of the image background that is directly attributable to scattered radiation. For example, 80% or more of the photographic density of a given film may be attributed to non-image-forming scattered radiation when low-voltage (soft) x-rays are

employed. On the other hand, for a 100 mm (4 in.) thick steel testpiece, only about 40% of the photographic density is caused by scattered radiation when the incident beam is 1.3-MeV radiation and only about 15% with 20-MeV x-rays.

Radiographic Equivalence. The absorption of x-rays and γ -rays by various materials becomes less dependent on composition as radiation energy increases. For example, at 150 keV, 25 mm (1 in.) of lead is equivalent to 350 mm (14 in.) of steel, but at 1000 keV, 25 mm (1 in.) of lead is equivalent to only 125 mm (5 in.) of steel. Approximate radiographic absorption equivalence factors for several metals are given in Table 5. When film exposure charts are available only for certain common materials (such as steel or aluminum), exposure times for other materials can be estimated by determining the film exposure time for equal thickness of a common material from the chart, then multiplying by the radiographic equivalence factor for the actual testpiece material (see the section "Exposure Factors" in this article for detailed information on radiographic exposure).

Table 5 Approximate radiographic absorption equivalence for various metals

Materials	X-rays, keV					X-rays, MeV			γ -rays			
	50	100	150	220	450	1	2	4 to 25	Ir-192	Cs-137	Co-60	Ra
Magnesium	0.6	0.6	0.05	0.08
Aluminum	1.0	1.0	0.12	0.18	0.35	0.35	0.35	0.40
Aluminum alloy 2024	2.2	1.6	0.16	0.22	0.35	0.35	0.35	...
Titanium	0.45	0.35

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Principles of Shadow Formation

The image formed on a radiograph is similar to the shadow cast on a screen by an opaque object placed in a beam of light. Although the radiation used in radiography penetrates an opaque object whereas light does not, the geometric laws of shadow formation are basically the same. X-rays, γ -rays, and light all travel in straight lines. Straight-line propagation is the chief characteristic of radiation that enables the formation of a sharply discernible shadow. The geometric relationships among source, object, and screen determine the three main characteristics of the shadow--the degrees of enlargement, distortion, and unsharpness (Fig. 23). This theoretical unsharpness is added to the scattering from the atomic attenuation processes (photoelectric effect, Rayleigh and Compton scattering, and pair production, as mentioned in the previous section) to obtain the total unsharpness and blurring of the image.

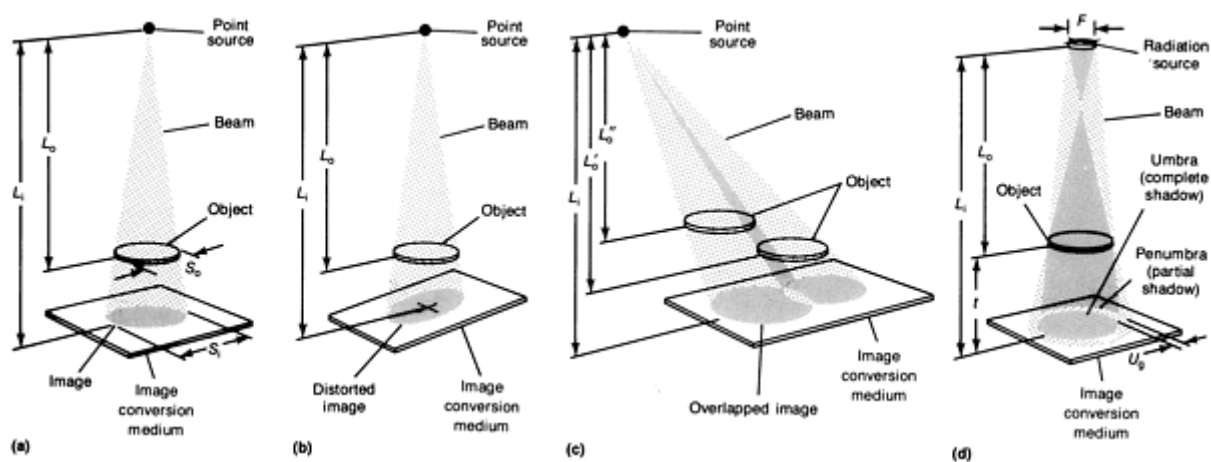

Fig. 23 Schematic of the effect of geometric relationships on image formation with point sources and a radiation source of finite size. (a) Image enlargement, (b) image distortion, and (c) image overlap for point sources of radiation. (d) Degree of image unsharpness from a radiation source of finite size. L_o , source-to-object distance; L_i , source-to-image distance; S_o , size of object; S_i , size of image; U_g , geometric unsharpness; F , size of focal spot; t , object-to-image distance

Enlargement. The shadow of the object (testpiece) is always farther from the source than the object itself. Therefore, as illustrated for a point source in Fig. 23(a), the dimensions of the shadow are always greater than the corresponding dimensions of the object. Mathematically, the size of the image or degree of enlargement can be calculated from the relationship:

$$M = \frac{S_i}{S_o} = \frac{L_i}{L_o} \quad (\text{Eq 9})$$

where M is the degree of enlargement (magnification), S_i is the size of the image, S_o is the size of the object, L_i is the source-to-film or source-to-detector distance, and L_o is the source-to-object distance.

Variations in the position of a given object relative to the source and recording surface affect image size. For example, when the source-to-image distance, L_i , is decreased without changing the distance of the object from the image, the size of the image, S_i , is increased. Alternatively, when the source-to-object distance, L_o , is increased without changing the distance of the recording surface from the source (L_i constant), the size of the image is decreased.

Film Radiography. The effect of enlargement is normally of little consequence in film and paper radiography, mainly because the recording medium is placed close behind the testpiece to minimize geometric unsharpness. Even with this arrangement, however, images of portions of the testpiece farthest from the recording plane will be larger than corresponding portions of the testpiece itself. This effect is greatest for short source-to-image distances.

Microradiography and Real-Time Radiography. There are certain circumstances when enlargement is advantageous. In real-time radiography, for example, the significance of screen unsharpness can be minimized by positioning a testpiece closer to the source. Details that are otherwise invisible in a radiograph can also be enlarged enough to become visible. This technique has been used for microradiography, in which considerable enlargement renders minute details visible. Because of geometric unsharpness, however, only sources with extremely small focal spots can be used to produce enlarged radiographs. For example, focal spots approximately $5 \mu\text{m}$ (0.2 mil) in diameter are used for microradiography (Fig. 24). One shortcoming of this technique may be a low level of radiation intensity, which could limit applications to the inspection of low-density materials. Nevertheless, real-time microradiography has found application in the inspection of high-quality castings and high-integrity weldments.

Fig. 24 Geometric magnification of radiographic images with a microfocus x-ray tube. (a) Greater geometric magnification and unsharpness occur when the testpiece is moved away from the detector and toward the radiation source. With a microfocus x-ray tube, however, the amount of geometric unsharpness (Eq 11) is

minimized, as shown by an integrated circuit magnified at 1.25× (b), 20× (c), and 40× (d). Courtesy of Rockwell International

Reduction of Scattering. Another advantage of placing the testpiece closer to the source is a reduction of secondary (scattered) radiation. When the magnification factor, M , in Eq 9 is greater than 3, the build-up factor, $1 + I_s/I_D$, approaches 1 (Ref 2).

Distortion. As long as the plane of a two-dimensional object and the plane of the imaging surface are parallel to each other, the image will be undistorted regardless of the angle at which the beam of radiation impinges on the object. In addition, the degree of enlargement at different points in a given image is constant because the ratio L_i/L_o is invariant. However, as shown in Fig. 23(b), if the plane of the object and the plane of the recording surface are not parallel, the image will be distorted because the degree of enlargement is different between rays passing through any two points on the surface of the object. This is the main reason radiographic images almost always present a distorted picture of testpiece features; the shape of most testpieces is such that one or more of its features is not parallel to the imaging surface. The degree of distortion is directly related to the degree of nonparallelism; small amounts of nonparallelism produce small degrees of distortion, and large amounts produce large degrees of distortion.

Although there is no distortion of images of features that are parallel to the imaging surface, spatial relationships among testpiece features are distorted, with the amount of distortion being directly related to the cosine of the angle of the beam to the imaging surface. For example, two circular features that are parallel to the imaging surface but at different object-to-detector distances may produce two separate circular images, or one noncircular image because two images overlap, as shown in Fig. 23(c), depending on the direction of the radiation beam. In most actual radiographs, regions where images of different features overlap will appear as regions of greater or lesser contrast than adjacent regions where the images do not overlap, depending on whether the features absorb less radiation or more radiation than portions of the testpiece surrounding the features. For example, overlapping images of voids or cavities will appear darker on film or brighter on fluorescent screens in regions of overlap because less radiation is absorbed along paths intersecting overlapping voids than along paths that intersect only one void.

Geometric Unsharpness. In reality, any radiation source is too large to be approximated by a point. Conventional x-ray tubes have focal spots between 2 by 2 mm (0.08 by 0.08 in.) and 5 by 5 mm (0.2 by 0.2 in.) in size, while microfocus x-ray systems have focal-spot sizes as small as 5 μm (0.2 mil). Even high-energy sources have focal spots of appreciable size, although seldom exceeding 2 mm (0.08 in.) in diameter. Gamma-ray sources vary widely in size, depending on source strength and specific activity, but are seldom less than about 2.5 mm (0.1 in.) in diameter.

Radiographic definition varies according to the geometric relationships among source size, source-to-object distance, and object-to-image distance. When radiation from a source of any finite size produces a shadow, that portion of the image that is in shadow for radiation emanating from all points on the surface of the source is a region of complete shadow known as the umbra. Portions of the image that are in shadow for radiation emanating from any portion of the source, but not in shadow for radiation from some portion, are regions of partial shadow known as the penumbra. The degree of geometric unsharpness is equal to the width of the penumbra. Mathematically, the geometric unsharpness, U_g , is determined from the laws of similar triangles, as illustrated in Fig. 23(d), and can be expressed as:

$$U_g = \frac{F \cdot t}{L_o} \quad (\text{Eq 10})$$

where F is the size of the focal spot γ -ray source, t is the object-to-image distance, and L_o is the source-to-object distance. In most cases, t is considered to be the difference between the source-to-image distance, L_i , and the source-to-object distance, L_o ; therefore, Eq 10 can be alternatively expressed as:

$$U_g = \frac{F(L_i - L_o)}{L_o} = F(M - 1) \quad (\text{Eq 11})$$

The size of the penumbra, or the geometric unsharpness, can be reduced by lengthening the source-to-object distance, by reducing the size of the focal spot, or by reducing the object-to-image distance. In practice, the source size is determined by the characteristics of a given x-ray tube or by the physical dimensions of a radioactive pellet, and the object-to-image

distance is minimized by placing the surface of the imaging medium as close as possible to the testpiece. Therefore, the only variable over which the radiographer has any appreciable amount of control is source-to-object distance. However, as discussed in the following section in this article, this distance is a significant variable affecting the intensity of the penetrating radiation. Consequently, the radiographer often must compromise between maximum definition (minimum unsharpness) and the cost associated with the lower radiation intensity that occurs when the source-to-object distance is increased. Higher costs in film radiography occur with a lower intensity of radiation because exposure time must be increased. In real-time radiography, costs may be less of a factor, but increases in detector efficiency or image-processing time might be required.

Geometric unsharpness is one of several unsharpness factors and is usually the largest contributor to unsharpness in film radiography. When the distance between the actual surface of the imaging medium and the adjacent (facing) surface of the testpiece is neglected (which is an appropriate assumption in film radiography because this distance is usually quite small in relation to testpiece thickness), the geometric unsharpness can be calculated for any source size and can be expressed as a series of straightline plots relating geometric unsharpness, U_g , to testpiece thickness, t , for various values of the source-to-object distance, L_o . A typical series is shown in Fig. 25 for a 5 mm (0.2 in.) diam source. It is often helpful to prepare graphs such as the one in Fig. 25 for each source size used.

Fig. 25 Relation of geometric unsharpness to testpiece thickness for various source-to-object distances when the source is 5 mm (0.2 in.) in diameter

In applications where the maximum unsharpness must be kept below a specific known value to resolve certain types and sizes of flaws, the radiographer can determine the minimum source-to-object distance for a given part from Eq 10. At this value of L_o , the types and sizes of flaws to which the specified value of U_g applies will be resolved if the flaws are in the plane of the testpiece farthest from the imaging surface. Flaws in planes closer to the imaging surface will be even more clearly resolved.

Shadow Intensity and the Inverse-Square Law. The intensity of radiation that penetrates a testpiece and produces a satisfactory image is governed by the energy and spectral quality of the incident radiation, the strength of the radiation, and the source-to-detector distance. In practice, the energy of the incident radiation, which depends mainly on the tube voltage of an x-ray machine or on the radioactive isotope in a γ -ray source, is chosen to be sufficiently penetrating for the type of material and thickness to be inspected. With this factor fixed, the remaining interrelated factors--the source strength (determined by tube current in milliamperes for x-ray sources or by source activity in becquerels, or curies, for γ -ray sources) and the source-to-detector distance--determine the intensity of radiation impinging on the detector.

The intensity of the shadow image determines the amount of exposure time for a given (fast or slow) film or the detector efficiency required in real-time radiography. Similar to visible light, x-rays or γ -rays diverge when emitted from the

radiation source and cover an increasingly larger area, with lessened intensity, as the distance from the source increases. The intensity, or amount of radiation falling on a unit area per unit time, varies inversely with the square of the distance from the source. This can be expressed mathematically as:

$$IL^2 = \text{constant} \quad (\text{Eq 12})$$

where I is the intensity of radiation at a given distance, L , from a source of given strength. More often, the inverse-square law is expressed as a ratio:

$$\frac{I_1}{I_2} = \frac{L_2^2}{L_1^2} \quad (\text{Eq 13})$$

where the subscripts 1 and 2 refer to different points along a line radiating from the source. Because of this inherent characteristic of radiation, if the radiation has a certain intensity at 1 m (3.3 ft) from the source, it will have four times that intensity at 0.5 m (1.65 ft) but only one-fourth that intensity at 2 m (6.6 ft) and only one-ninth that intensity at 3 m (9.9 ft).

Scattered Radiation. When a beam of x-rays or γ -rays strikes a testpiece, secondary radiation is scattered in all directions. This causes a haze over all or part of the image, thus reducing contrast and visibility of detail. Methods for reducing scattered radiation are discussed in the section "Control of Scattered Radiation" in this article.

Internal scatter occurs within the testpiece being radiographed (Fig. 4a). Internal scatter is fairly uniform throughout a testpiece of uniform thickness, but adversely affects definition by diffusing or obscuring the outline of the image.

Side scatter consists of secondary radiation generated by walls, internal holes in the testpiece (as shown in Fig. 4b), or objects near the testpiece. This radiation may pass through the testpiece and may obscure the image of the testpiece.

Back scatter consists of rays that are generated from the floor or table (Fig. 4c) or from any other object that is located on the opposite side of the imaging surface from the testpiece and source. Back scatter increases the background noise and therefore reduces contrast and definition in the recorded image.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Image Conversion Media

After penetrating the testpiece, the x-rays or γ -rays pass through a medium on the imaging surface. This medium may be a recording medium (such as film) or a medium that responds to the intensity of the radiation (such as fluorescent screen or a scintillation crystal in a discrete detector). These two types of media provide the images for subsequent observation.

Radiography can also utilize radiographic screens, which are pressed into intimate contact with the imaging medium. Radiographic screens include:

- Metallic screens placed over film, paper, or the screens used in real-time systems
- Fluorescent screens placed over film or photographic paper

- Fluorometallic screens placed over film

These screens are used to improve radiographic contrast by intensifying the conversion of radiation and by filtering the lower-energy radiation produced by scattering.

Recording Media

By definition, a radiographic recording medium provides a permanent visible image of the shadow produced by the penetrating radiation. Permanent images are recorded on x-ray film, radiographic paper, or electrostatically sensitive paper such as that used in the xeroradiographic process.

X-ray film is constructed of a thin, transparent plastic support called a film base, which is usually coated on both sides (but occasionally on one side only) with an emulsion consisting mainly of grains of silver salts dispersed in gelatin (Fig. 26). These salts are very sensitive to electromagnetic radiation, especially x-rays, γ -rays, and visible light. The film base is usually tinted blue and is about 0.18 mm (0.007 in.) thick. An adhesive undercoat fastens the emulsion to the film base. A very thin but tough coating of gelatin called a protective overcoat covers the emulsion to protect it against minor abrasion. The total thickness of the x-ray film is approximately 0.23 mm (0.009 in.), including film base, two emulsions, two adhesive undercoats, and two protective overcoats.

Fig. 26 Schematic cross section of a typical x-ray film. Dimensions given in inches

The presence of emulsions on both sides of the base effectively increases the speed of the x-ray film because penetrating radiation affects each emulsion almost equally. In addition, thin emulsions allow development, fixing, and washing of the exposed film to be accomplished effectively and in a reasonably short time. Where two emulsions are used, two images are produced--one in the front emulsion and one in the back emulsion. Viewing these images with the unaided eye causes no problems, because the images are separated by only a few hundredths of a millimeter of film base. However, if magnification is used, parallax can cause the two images to be seen slightly separated, which sometimes hampers interpretation. When appropriate, x-ray film with only one emulsion (single-coated x-ray film) can be used to avoid parallax.

When electromagnetic radiation and certain forms of particulate radiation (namely, electrons) react with the sensitive emulsion of x-ray films, they produce a latent image in the emulsion, which cannot be detected visually or by ordinary physical measurements. To produce a visible image, the exposed film must be chemically processed. When the film is treated with a developer, selective chemical reaction converts the exposed silver halide grains in the latent image into black metallic silver. The metallic silver remains suspended in the gelatin and is responsible for blackening or shades of gray in the developed (visible) image. After development, the film is treated with a chemical called a fixer, which converts unexposed silver halide grains into a water-soluble compound. The reaction products of development and fixing

are washed off, and the film is dried. Detailed information on the processing of radiographic film is available in the Appendix to this article.

Although x-ray film is sensitive to light, the characteristics of its emulsion are different from those of emulsions used in photography. Industrial x-ray film is of two general types: that used for direct exposure (called direct-exposure, no-screen, or nonscreen film) and that used with fluorescent screens (often called screen-type film).

Most industrial x-ray film is of the direct-exposure type and is available in various combinations of film speed, gradient, and graininess. The choice of film for a given application depends on the type of radiography to be performed. Film types and selection are discussed in the section "Film Radiography" in this article.

Screen-type films, which are marketed primarily for medical radiography, are only occasionally used for industrial applications--for example, when a low-power x-ray machine is used and exposure time is excessive with direct-exposure x-ray film. Screen-type films are more sensitive to light than to x-radiation and are particularly sensitive to the wavelengths emitted by the fluorescent screen with which they are used. Although blue-sensitive emulsion types are the ones most often used for industrial radiography, other emulsions sensitive to ultraviolet and to green screen light are available.

Radiographic Paper. Ordinary photographic paper can be used to record x-ray images, although its characteristics are not always satisfactory. Photographic paper has a low speed, and the resulting image is low in contrast. However, photographic paper used with fluorescent screens can be effective for some applications.

Specially designed radiographic paper (also known as paper-base film or opaque-base film) is essentially opaque and has only a single emulsion. The emulsion is made of gelatin and silver salts, as in x-ray film, but it also contains developer chemicals. After exposure, the developing action is triggered by an alkaline solution called an activator. Instead of being fixed after development of the radiographic paper, chemicals remaining in the emulsion are made chemically inactive by stabilization processing, which is performed very rapidly in a small automatic processor. The images are similar to those on film radiographs and will not deteriorate for 2 to 3 months. If it is desired to store the radiographs for a longer period, they can be fixed in ordinary x-ray fixer, washed, and dried.

Although paper radiographs can be exposed directly to x-radiation, it is preferred to make the exposure with fluorescent screens that produce ultraviolet light. Fluorescent-screen exposures are preferred because exposure time is short and radiographic contrast is high. With direct exposure, the radiographic contrast is low and the corresponding exposure time is long.

The image is viewed in reflected light like a photograph; however, the greatest amount of detail can be seen when the image is viewed in specular light from a mirrorlike reflector (like a spotlight) directed at about 30° to the surface and to one side of the radiograph. The density (blackening) of paper radiographs, which is known as reflection density, is quite different from the transmission density of film, but the differences do not cause problems in interpretation.

Radiographic paper can exhibit adequate sensitivity, which in many respects matches or exceeds that of fast direct-exposure x-ray films. Radiographic paper does not match the sensitivities of slow x-ray films, but because of their speed, convenience, and low cost, radiographic papers are being used both for the radiography of materials that do not require critical examination and for in-process control.

A new (3M) dry silver film has recently been introduced that is developed with heat in about 12 s. It also is exposed with a fluorescent screen and achieves resolutions up to 7 line pairs per millimeter (or a resolution of 0.0055 in.). Viewing is by reflected or transmitted light.

Xeroradiography (dry radiography) is a form of imaging that uses electrostatic principles for the formation of a radiographic image. In film radiography, a latent image is formed in the emulsion of a film; in xeroradiography, the latent image is formed on a plate coated with selenium. Before use, the plate is given an even charge of static electricity over the entire surface. As soon as the plate is charged, it becomes sensitive to light as well as to x-radiation and must be protected from light by a rigid holder similar to a film cassette. In practice, the holder is used for radiography as though it contained film. X-radiation will differentially discharge the plate according to the amount of radiation received by different areas. This forms an electrostatic latent image of the testpiece on the plate.

The exposed plate is developed by subjecting the plate, in the absence of light, to a cloud of very fine plastic powder, each particle in the cloud being charged opposite to the electrostatic charges remaining on the plate. The charged plastic powder is attracted to the residual charges on the plate. The visible radiographic image at this state is not permanent, because the powder is simply held in place by electrostatic charges. However, the image can be made permanent by placing a piece of specially treated paper over the plate and transferring the powder to the paper, which is then heated to fix the powder in place.

Selenium-coated plates can be easily damaged by fingerprints, dirt, and abrasion. For this reason, automated equipment is used for charging and for development and image transfer to paper.

The image produced by xeroradiography can be either positive or negative, depending on the color of the plastic powder (toner) and the color of the paper upon which the image is deposited. If a negative xeroradiographic image is desired, dark-colored paper with light-colored toner can be used; a positive image would require light-colored paper and dark-colored toner.

Because of an electrostatic edge effect, xeroradiographic images exhibit excellent detail; even small indications in the image are sharply outlined. Optimum results from xeroradiography are more likely when the user develops special techniques rather than employing the radiographic techniques normally used with film.

Lead Screens

It is the combination of filtration and intensification that makes lead screens the most widely used in industrial radiography. Lead absorbs radiation to a greater extent than most other materials, with the amount of absorption depending largely on the penetrating quality of the radiation (photon energy or wavelength). High-energy (short-wavelength) radiation passes through lead much more readily than low-energy radiation; in other words, low-energy radiation is more readily absorbed by a lead screen than high-energy radiation. Because scattered radiation from a testpiece is always of a lower energy than the incident beam passing through a testpiece, a lead screen will absorb a relatively high percentage of unwanted scattered radiation, but will absorb a somewhat lower percentage of the image-forming radiation. This effect is known as filtration, and lead screens are sometimes referred to as lead-filter screens.

Filtration of Secondary Radiation. As discussed in the earlier section "Principles of Shadow Formation" in this article, secondary radiation can arise by internal scatter from within the testpiece and by back scatter from objects behind the film, detector, or screen. Because of the need to filter out both internal scatter and back scatter, two screens are normally used in film radiography. The screen that faces the top of the film is referred to as the front screen, and the screen behind the film toward the table or floor is referred to as the back screen. Both screens absorb scattered radiation.

In practice, the front screen is sometimes the thinner of the two because the image-forming radiation must always pass through this screen. The usual thickness of the front lead screen is 0.13 or 0.25 mm (0.005 to 0.010 in.), but may be greater or less depending on the type of material being inspected and the photon energy of the incident beam. The main function of the beam screen is to absorb unwanted back scatter; back screens can be of any thickness that performs this function adequately, although usually they are of the same thickness as the front screen.

In the radiography of thin-gage or low-density materials, in which low photon energies are used, care must be exercised to ensure that the front screen does not excessively filter the image-forming radiation. Excessive filtration affects subject contrast and tends to reduce radiographic sensitivity. In such cases, lead screens less than 0.13 mm (0.005 in.) thick should be used; lead screens 0.05 or 0.025 mm (0.002 or 0.001 in.) thick or less are available. For thicker testpieces or denser material, where higher photon energies are used, the front screen can be thicker than 0.13 mm (0.005 in.), ranging as high as 1 mm (0.040 in.) when betatrons or high-MeV linear accelerators are used. The back screen can be 0.5 to 10 mm (0.020 to 0.400 in.) thick in these cases.

Intensification. When lead is excited by x-ray or γ -ray radiation, it produces electrons. The number of electrons emitted is directly proportional to the photon energy of the radiation that passes through the testpiece and reaches the screens.

In film radiography, the emitted electrons expose additional silver halide crystals in the film emulsion. After development, film densities are greater than they would have been without the intensifying action of emitted electrons. Intensification not only increases overall photographic density, thus requiring shorter exposure times for producing a given density, but also enhances radiographic contrast, thus improving the ability to resolve small flaws.

In real-time radiography with a fluorescent-screen system, a similar effect occurs. The phosphor material used in fluorescent screens is generally more sensitive to electrons than to primary x-rays. With high-energy x-rays, the electrons generated from a suitable lead screen (or other heavy metal, such as tantalum or tungsten) can be used to enhance the imaging process. These screens are often useful in real-time radiography with MeV radiation.

Because lead screens have properties of both filtration and intensification, there is a combination of thickness of the subject material and photon energy of the incident radiation at which intensification just balances filtration and there is no net advantage. With steel testpieces in film radiography, this null point is generally considered to occur at a combination of 6 mm ($\frac{1}{4}$ in.) testpiece thickness and 140-keV x-rays when a 0.13 mm (0.005 in.) thick front screen and a 0.25 mm (0.010 in.) thick back screen are used. At lower tube voltages or with thinner testpieces, the filtration effect is dominant, resulting in longer exposure times. At high voltages or with thicker testpieces, the intensification factor becomes dominant, and exposure times can be reduced to as much as one-third of the time for direct exposure (no screens), at a tube voltage of 200 to 300 kV. With cobalt-60 radiation and steel testpieces, the exposure time using lead screens is about one-third that for direct exposure.

With light metals such as aluminum, the null point occurs at a greater thickness than for steel. With metals of greater atomic number than steel, it occurs in thinner sections. For both lighter and heavier metals, the null point will occur at a radiation energy different from 140-keV x-rays. Although electrons are produced throughout the volume of lead on both screens when excited by x-rays or γ -rays, electrons produced by radiation having photon energies below 1 MeV are largely low-energy electrons. Such electrons are readily absorbed by the volume of lead in the screen. Only those electrons produced at the surface adjacent to the film escape to intensify the latent image on the film. Therefore, the closer the film emulsion is to the surface of the lead, the more effectively the electrons interact with the emulsion. This is why lead screens should always be in intimate contact with the film.

Low-energy electrons have little penetrating capability. They will affect the emulsion closest to the screen, but will not penetrate the film base to affect the emulsion on the other side. Although electrons have little penetrating capability, they will penetrate interleaving paper, so this should always be removed from the film to avoid a paper-pattern image on the radiograph. Similarly, dust, dirt, lint, and other foreign material between the film and screen must be avoided to prevent extraneous images (artifacts) on the radiograph.

Precautions. Lead sheet of usual screen thicknesses is easily bent. For this reason, lead screens are often backed by cardboard or other material to facilitate handling. Even so, the care and handling of lead screens is important. Deep scratches or dents must be avoided because they can appear as artifacts on the radiographic image. Wrinkles or folds in the screens can also be detected on the radiograph. Chemical spills, dust, and dirt must be carefully removed from the screen before use. Oxidation of the screen, which occurs with age and appears as a gray coating, does not seem to affect the utility of the screen. Some screens are coated with a special material to prevent oxidation. Although coated screens exhibit a reduced capability for intensification, they are easier to keep clean and free of tiny scratches. The use of spray lacquers or acrylics to protect the surface of the screens should be avoided; such coatings often have a highly detrimental effect on the radiographic image.

The composition of the lead used for screens is important. Pure lead is soft and may rub off on the film to produce lead smudge on the radiograph. Lead screens made from 94Pb-6Sb alloy are most commonly used because they are harder and more resistant to scratching. However, care must be taken that there is no segregation of antimony (which appears as shiny or different-colored streaks on the screen), because antimony segregation produces low-density streaks on the radiograph.

Screens must be flat and free of roll marks or chatter. Variations in screen thickness result in areas of poor contact with the film, which can produce fuzzy areas in the radiograph.

Prolonged contact with lead screens can produce an effect called lead-screen fog. Consequently, films should never be left in contact with lead screens longer than is reasonably necessary. This is particularly important under conditions of high temperature and humidity, or within 24 h after cleaning screens with very fine steel wool or other abrasive.

As a general rule, lead screens should be used whenever they can improve the resolution of detail, even though the exposure time may be longer. A single back screen can be used for intensification purposes, but in the absence of a front screen, forward scatter may be present in the radiograph. Sometimes, the single back screen technique is useful in the radiography of very thin materials at low photon energies. If scatter is a problem, other means of control (such as a copper filter located at the tube) are quite effective. Lead screens should always be used in radiography using high photon

energies (above 300-keV x-rays or with most γ -ray sources) to avoid extraneous paper patterns or other effects due to irradiation of the film holder.

Certain types of film packaging incorporate thin lead foil (0.025 or 0.050 mm, or 0.001 or 0.002 in. in thickness) on both sides of the film, with the film-foil composite contained in a lighttight envelope. These prepackaged composites are convenient because the envelopes containing screens and film can be used as a film holder or cassette. In addition, loading in the darkroom is eliminated, and there is less likelihood of foreign particles being present to create artifacts on the radiograph.

Lead Oxide Screens

A variation of lead screens is lead oxide screens, which are made by evenly coating a paper base with lead oxide. The result is an extremely flexible screen, equivalent to about 0.013 mm (0.0005 in.) of lead foil, that is lightweight and free of antimony segregation. Lead oxide screens are available only in lighttight envelopes containing screens on both sides of the film.

The principle of lead oxide screens is essentially the same as for lead screens. The main differences are a lesser degree of filtration than lead screens and a greater intensification below 140 keV as well as slightly lesser intensification at 300 keV than with 0.13 mm (0.005 in.) thick lead screens. Although lead oxide screens are particularly advantageous for the radiography of light alloys or thin material, they can also be used in the radiography of heavier material.

Screens of Metals Other Than Lead

Foils of many of the heavier metals can be as effective as lead for radiographic screens, but usually are not as practical, either because the foils are not as flexible or because of cost.

Gold screens perform as well or better than lead screens, but gold costs considerably more and tends to work harden when bent, which eventually cracks the screen.

Tantalum screens exhibit slightly lower filtration but higher intensification than lead. However, tantalum foil is stiff and springy, which does not allow it to be shaped to fit around a testpiece. Tantalum foil can be used in solid cassettes, can be polished, and is quite resistant to minor abrasion, but is expensive to use.

Depleted-uranium screens exhibit greater filtration than lead screens. However, uranium is brittle, is somewhat difficult to obtain in thin sheets, and is also expensive to use.

Copper screens have been used, especially with cobalt-60 radiography. Copper has a lower degree of filtration than lead and a lower intensification factor, but copper provides greater radiographic sensitivity.

Composite screens of lead, copper, and aluminum (and sometimes other metal foils) to control the radiation reaching the film have occasionally been used with supervoltage x-ray machines for the inspection of thick steel testpieces.

Fluorescent Intensifying Screens

The efficiency of film and paper radiography can be improved by fluorescent intensifying screens, which emit radiation in the ultraviolet, blue, or green portion of the electromagnetic spectrum. These screens are called fluorescent intensifying screens because they fluoresce, or produce light, when excited by x-rays or γ -rays. Certain compounds, such as calcium tungstate or barium lead sulfate, often containing trace elements of some other chemical or phosphor, have the property of emitting light immediately upon excitation by short-wavelength radiation. Crystals of these chemicals are finely powdered, mixed with a binder, and coated on some mildly flexible support such as cardboard or plastic to make a fluorescent screen. A thin, tough, transparent overcoat is applied to the sensitized surface of the screen to prevent damage to the crystals during use.

Screen Speeds. Fluorescent intensifying screens, widely used in medical radiography, are available in a variety of speeds. Perhaps the most common of these are blue-emitting screens, which can be characterized in speed as very slow, slow, medium, medium high, high, and super. In industrial radiography, the screen most often used (with the appropriate blue-sensitive screen-type film) is the medium-speed fluorescent screen.

By the addition of proprietary rare-earth phosphors to the fluorescent crystals, green-emitting screens are produced that, when used with the appropriate green-sensitive film, have relatively fast screen speeds characterized as high speed, superspeed, and beyond superspeed.

With the addition of barium lead sulfate and a proprietary trace element, the crystals can be made to fluoresce in the ultraviolet range. Used with the appropriate ultraviolet-sensitive film or radiographic paper, these screens have speeds that are equivalent to the slow and medium-high-speed blue-emitting screens.

For the greatest radiographic effect, fluorescent screens should be used with a film that is sensitive to the particular wavelengths of light emitted by the screen. In general, though not always true, the slower the screen-film combination, the better the radiographic definition. However, even slow-speed combinations can reduce exposure times by 20 to 98% compared to the fastest direct-exposure film, depending on photon energy, type of screen, type of film, and testpiece material.

Disadvantages. The main reason for using fluorescent intensifying screens in industrial radiography is to reduce exposure times. However, in comparison with lead screens, fluorescent screens have the following disadvantages. First, the screen light reaches the film as cones of light from each fluorescing crystal. Because this tends to blur the image, radiographic definition using lead screens is superior. As in real-time radiography, inherent unsharpness in a fluorescent screen often overshadows any effect of geometric unsharpness.

Second, the purely statistical variations in the number of x-ray quanta (the total amount of x-radiation) absorbed from one small area to another on the screen result in uneven brightness, which in turn is recorded on the film as screen mottle (also known as quantum mottle). Screen mottle is particularly apparent at photon energies in the range 150 to 300 keV. There is essentially no screen mottle associated with lead screens.

Finally, lead screens filter out scattered radiation in addition to intensifying the radiation beam, but fluorescent screens have little or no filtering capability and intensify scattered radiation in the same proportion as transmitted radiation. However, they can be placed between lead screens, using the lead to protect against secondary radiation and back scatter.

Precautions in Use. The combination of a screen and the film that is sensitive to the wavelength of the screen light results in minimum exposures. However, fluorescent screens can be used with the direct-exposure films ordinarily used in industrial radiography. With direct-exposure film, the intensification factor may range from 2 to 25 times, but screen mottle and noticeable light spreading will be less because of the lower speed of the screen-film combination.

Fluorescent intensifying screens are often permanently mounted inside rigid film holders (cassettes). Cassettes of this type are designed to provide even pressure between screen and film to maintain intimate contact during exposure. Lack of contact results in unsharpness in the image and should be carefully avoided. Fluorescent screens may not be permanently mounted and can be used in regular film holders. Under these conditions, however, maintenance of good contact between fluorescent screen and film is more difficult.

The fluorescent crystals on the surface of the screens can be easily damaged by handling, and the screen cannot be repaired. Because fluorescent screens are expensive, great care must be taken to avoid scratches, abrasion, or chemical spills, which can damage the screen and affect the radiographic image. It is even more important to avoid fingerprints, stains, grease, dirt, and dust on the surface of the screens. Because these all absorb screen light, their image will be transmitted to the radiograph. If the screen becomes dirty it may be cleaned, but the manufacturer's cleaning recommendations should be followed to avoid damage to the protective overcoat.

Because of the high radiation intensity used in industrial radiography, great care must be exercised not to expose any portion of a fluorescent screen to the full intensity of the primary beam. When exposed to high-intensity radiation, a screen may continue to fluoresce after being removed from the beam; this semipermanent effect, known as screen lag, will produce false images on subsequent radiographs.

Fluorescent intensifying screens are most often used for the radiography of thick testpieces when the x-ray machine has limited penetrating capability. With medium-speed, blue-sensitive fluorescent intensifying screens (with appropriate screen-type film), it is possible to radiograph 75 mm (3 in.) of steel with 250-keV x-rays in a reasonable exposure time. Fluorescent screens are rarely used with γ -rays or with photon energies exceeding 1 MeV because of screen mottle and low intensification factors. In all cases where fluorescent screens are used, reciprocity law failure is likely to occur;

reciprocity law failure (discussed in the section "X-Ray Tubes" in this article) is not a problem in direct or lead-screen exposures.

Fluorometallic Screens

Fluorometallic screens consist basically of lead screens placed on either side of a fluorescent-screen/film combination. The theory behind combining lead and fluorescent screens is that the lead preferentially absorbs scattered radiation (which fluorescent screens will not do) and that the fluorescent screen next to the film intensifies the radiation beam to shorten the exposure.

Commercial screens incorporating lead and fluorescent materials laminated together require significantly shorter exposure times than lead screens, and the image quality exceeds that of fluorescent screens. When direct-exposure film is used with fluorometallic screens, the exposure time can be reduced to as little as one-seventh of that for lead screens with almost the same radiographic sensitivity. When screen-type film is used, exposure time can be reduced to as little as one-ninth of that for other methods. The speed factor varies with type of film, type of fluorometallic screen, and photon energy of radiation. With high-voltage x-rays, and with cobalt-60 γ -rays, the speed factor is about two to seven.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Real-Time Radiography

Various types of image conversion techniques allow the viewing of radiographic images while the testpiece is being irradiated and moved with respect to the radiation source and the radiation detector. These radiosopic techniques can be classified as real-time radiography (also known as real-time radioscapy) and near real-time radiography (or near real-time radioscapy). The distinction between these two classifications is that the formation of near real-time images occurs after a time delay, and this requires limitation of the test object motion. An example of near real-time radiographic imaging involves the use of discrete detectors (primarily linear arrays) that scan the area being irradiated. The outputs are then processed digitally to form images in near real time. This technique is often referred to as digital radiography.

Background. The predecessor of the modern methods of real-time radiography is fluoroscopy. This technique, which is now largely obsolete, involves the projection of radiographic images on a fluorescent screen (Fig. 27). The screen consists of fluorescent crystals, which emit light in proportion to the intensity of the impinging radiation. The radiographic image can then be viewed, with appropriate measures taken to protect the viewer from radiation.

Fig. 27 Diagram of the components and principles of operation of a fluoroscope

The main problem with fluoroscopes is the low level of light output from the fluorescent screen. This requires the suppression of background light and about 30 min for the viewer's eyes to become acclimated. Moreover, radiation safety dictates viewing through leaded glass or indirectly by mirrors. Because of these limitations, other methods have been developed to improve safety and to amplify the images from fluorescent screens.

One of the early systems (1950s) involved the development of image-intensifier tubes. Image-intensifier tubes (Fig. 28) are glass-enclosed vacuum devices that convert a low-intensity x-ray image or a low-brightness fluorescent-screen image into a high-brightness visible-light image. Image intensification is achieved by a combination of electronic amplification and image minification. The image brightness at the output window of an image-intensifier tube is about $0.3 \times 10^3 \text{ cd/m}^2$ (10^{-1} lambert) as compared to about 0.3 cd/m^2 (10^{-4} lambert) for conventional fluoroscopic screen.

Fig. 28 Schematic of an image-intensifier tube

absorption can be routinely achieved in production inspection applications. The typical dynamic range of an image intensifier before image processing is about 2000:1.

A schematic of a modern x-ray image intensifier is shown in Fig. 29, along with a graph indicating the level of signal strength as the radiation passes through a sample and impinges on the entrance screen of the image-intensifier tube. These screens are usually made of a scintillating material, such as cesium iodide (CsI), and fixed to a photocathode. The energy of the incident radiation quanta generates electrons that produce light in the CsI entrance screen (approximately 150 photons per absorbed gamma quantum). To avoid degradation of the image quality by lateral dispersion of the light in the conversion screen, the CsI scintillating material, with a cubic crystalline structure, is grown under controlled conditions, resulting in small, needle-shaped elements. This structure causes the scintillating screen to act as a fiber-optical faceplate. Light generated in one crystal needle does not spread laterally, but is confined to the needle in a direction parallel to the incident radiation. Therefore, the thickness of the conversion screen does not cause appreciable deterioration in the spatial resolution of the system.

These early image intensifiers were originally developed for medical purposes and were limited to applications with low-energy radiation (because of low detection efficiencies at high energies). Consequently, industrial radiography with these devices was restricted to aluminum, plastics, or thin sections of steel.

By the mid-1970s, other technological developments led to further improvements in real-time radiography. These advances included high-energy x-ray sensitivity for image intensifiers, improved screen materials, digital video processing for image enhancement, and high-definition imaging with microfocus x-ray generators.

Modern Image Intensifiers. Although the early image intensifiers were suitable for medical applications and the inspection of light materials and thin sections of steel, the image quality was not sufficient for general use in radiography. Therefore, image intensifiers had to be redesigned for industrial material testing (Ref 3). The modern image intensifier is a very practical imaging device for radiographic inspection with radiation energies up to 10 MeV. With the image intensifier, a 2% difference in

Fig. 29 Schematic of a typical radiosopic system using an x-ray image intensifier

The light from the scintillating screen then impinges on a photocathode in contact with the entrance screen. The photocathode emits photoelectrons. The electron image produced at the cathode is reduced by a factor of ten and is intensified by means of an accelerating voltage. The final phosphor screen presents a relatively bright image (approximately 5 million photons per second per square millimeter), caused by the impinging electrons. The image then passes through an optical system, which directs the image to a television camera tube, such as a vidicon or plumbicon tube. Vidicons have a dynamic range of 70:1; plumbicons, 200:1.

Contrast Sensitivity. Figure 29 shows the importance of detection efficiency with regard to the contrast sensitivity of the radiosopic system. The example is for a 370 GBq (10 Ci) cobalt-60 source, but a similar analysis can be performed for an x-ray source. A cobalt-60 source with an activity of 3700 GBq (100 Ci) generates 60,000 photons per second per square millimeter at 1 m with energies of 1.1 and 1.3 MeV. After passing through a 100 mm (4 in.) thick steel specimen, the radiation is attenuated in intensity by a factor of 15. Therefore, only 4000 photons per second per square millimeter are available for imaging. The detection efficiency of the CsI entrance screen in a typical modern image-intensifier tube is approximately 2%. This reduces the photon intensity to 80 per second per square millimeter. With this intensity, the laws of statistics (see the section "Quantum Noise (Mottle) and the Detective Quantum Efficiency" in the article "Industrial Computed Tomography" in this Volume) predict a noise-to-signal ratio of approximately 11%, which limits the attainable contrast resolution.

From Fig. 29, it is apparent that the critical factor for determining the contrast resolution is the relatively low detection efficiency of the entrance screen. To overcome this limitation, one must either increase the detection efficiency of the conversion screen or collect the photons over a longer period by summing television frames to improve the photon statistics in each picture element. The detection efficiency of the entrance screen can be improved by reducing the energy of the radiation or by making the entrance screen thicker. The minimum energy of the radiation is generally dictated by the need to have sufficient energy to penetrate the subject and to provide sufficient intensity for imaging at the conversion screen. Therefore, it is generally impossible to reduce the energy to improve conversion efficiency. Although a thicker entrance screen would improve detection efficiency, it would reduce the attainable spatial resolution. In general, improving the detection efficiency and improving the spatial resolution are competitive processes. The most conventional means of enhancing contrast resolution is through the summation of television frames with a digital image-processing system.

The spatial resolution of a real-time system is principally defined by the size and thickness of the detectors (or grain size of fluorescent crystals), the raster scan of the television system, and, for quantum statistical reasons, the intensity of the radiation. The dependencies are plotted in Fig. 30 for a typical image intensifier. Curve A shows a spatial resolution of about four line pairs per millimeter (or a resolution of 0.01 in.) at 10 R/h without television monitoring. Curve C shows the typical resolution of an image intensifier with television monitoring.

Fig. 30 Spatial resolution dependence of an image-intensifier system as a function of radiation intensity at the entrance screen. A, image-converter resolution; B, 625 TV lines limit; C, combined resolution of image converter and TV line

Real-Time Radiography With Fluorescent Screens. Because of the development of low-level television camera tubes and low-noise video circuitry, the dim images on a fluorescent screen can be monitored with video systems. The contrast sensitivity and the spatial resolution of fluorescent-screen systems are comparable to those of image intensifiers, but the use of fluorescent screens is limited to lower radiation energies (below about 320 keV without intensifying screens and about 1 MeV with intensifying screens). Nevertheless, fluorescent screens can provide an unlimited field of view, while image intensifiers have a field of view limited to about 300 mm (12 in.). Example 1 in this article describes an application in which a fluorescent screen (with isocon camera) was preferred over an image intensifier. The dynamic

range of systems with fluorescent screens can vary from 20:1 for raw images to 1000:1 with digital processing and a large number of frames averaged.

Television Cameras. The types of low-level television cameras available include image orthicons, image isocons, and secondary electron-coupled vidicons. Radiographic inspection is also performed with x-ray sensitive television cameras, which require no extra conversion or optics. X-ray sensitive television cameras are limited in image size and sensitivity and are primarily used in the inspection of low-density materials and electronic components.

Image orthicons and image isocons are return beam tubes with internal electron multipliers. The orthicon is useful to light levels of about $1.076 \times 10^{-3} \text{ lm/m}^2$ (10^{-4} ftc), and the isocon is useful to $1.076 \times 10^{-4} \text{ lm/m}^2$ (10^{-5} ftc). The isocon provides the best noise performance and resolution of all tubes for low-light levels and static scenes, but degrades for moving scenes and is highly complex. Both orthicons and isocons exhibit little target overloading damage. Both the image orthicon and isocon camera tubes must be carefully adjusted for optimum performance; the isocon is the most difficult to adjust and demands a skilled technician. Both are temperature sensitive and should be operated under stabilized conditions. The dynamic range for the isocon is about 1000:1.

Secondary electron-coupled vidicons employ an internal initial stage of target amplification, using a secondary target. They are similar in performance to isocons, are less complex, but differ in lag and require special protection circuitry to prevent target destruction from overloading. Their primary use is in low-light level, low-contrast applications down to $1.076 \times 10^{-4} \text{ lm/m}^2$ (10^{-5} ftc).

Fluorescent screens used in real-time radiography are similar in construction and properties to fluorescent intensifying screens for film radiography. The commonly used fluorescent screens consist of a plastic substrate coated with a powdered luminescent material and an epoxy binder. The spatial resolution of the screen depends on the grain size of the luminescent material and the range and distribution of the conversion electrons and light photons. The x-ray absorption properties of the screen depend on the atomic weight and density of the luminescent material. The light conversion efficiency, the color of the emitted light, and the speed of the screen are additional properties that are dependent on the characteristics of the luminescent material.

A wide variety of fluorescent screens are available. Screens using zinc sulfide as the fluorescent material have a high light output and a short afterglow, but the contrast and sharpness of this type of screen are poor. Zinc sulfide screens also use cadmium, which has a higher atomic number and a higher density than zinc. Other phosphor materials used include calcium tungstate and phosphors with rare-earth materials. Until the 1970s, many applications utilized the popular calcium tungstate screens. With the availability of rare-earth materials in high states of purity and at reasonable costs, however, one can design new phosphors with improved x-ray absorptions, greater density, and higher x-ray to light conversion efficiencies. Screens have been made of such materials as gadolinium oxysulfide doped with terbium, LaOBr:Tm , BaFCl:Eu , or $\text{YTbO}_2\text{:Nb}$. These screens are discussed more fully in Ref 4. It should be noted that many rare-earth screens are not as effective as calcium tungstate in absorbing very high energy x-rays.

Because the intensity of the image on a fluorescent screen is rather low, very sensitive TV cameras are required for remote viewing. Different types of low light level cameras are available that have one- or two-stage light amplifiers or extremely sensitive camera tubes. When designing a fluoroscopic system, it is important to recognize that high light amplification from a double-stage amplifier generally yields poor spatial resolution and contributes additional noise to the image. In many cases, depending on the size of the fluorescent screen, the camera can also be the limiting factor in image quality. Therefore, both the entrance screen and the camera must be optimized for the particular inspection application.

Digital Radiography. A third method of radiographic imaging involves the formation of an image by scanning a linear array of discrete detectors along the object being irradiated. This method directly digitizes the radiometric output of the detectors and generates images in near real time. Direct digitization (as opposed to digitizing the output of a TV camera or image intensifier) enhances the signal-to-noise ratio and can result in a dynamic range up to 100,000:1. The large dynamic range of digital radiography allows the inspection of parts having a wide range of thicknesses and densities. Discrete detector arrangements also allow the reduction of secondary radiation from scattering by using a fan-beam detector arrangement like that of computed tomography (CT) systems. In fact, industrial CT systems are used to obtain digital radiographs (see the article "Industrial Computed Tomography" in this Volume).

The detectors used in digital radiography include scintillator photodetectors, phosphor photodetectors, photomultiplier tubes, and gas ionization detectors. Scintillator and phosphor photodetectors are compact and rugged, and they are used in flying-spot and fan-beam detector arrangements. Photomultiplier tubes are fragile and bulky, but do provide the capability

of photon counting when signal levels are low. Gas ionization detectors have low detection efficiencies but better long-term stability than scintillator- and phosphor-photodetector arrays.

A typical phosphor-photodetector array for the radiographic inspection of welds consists of 1024 pixel elements with 25 μm (1 mil) spacing, covering 25 mm (1 in.) in length perpendicular weld seam. The linear photodiode array is covered with a fiber-optic faceplate and can be cooled in order to reduce noise. For the conversion of the x-rays to visible light, fluorescent screens are coupled to the array by means of the fiber optics. A linear collimator parallel to the array is arranged in front of the screen. The resolution perpendicular to the array is defined by the width of this slit and the speed of the manipulator. A second, single-element detector is provided to detect instabilities of the x-ray beam. Using 100-kV radiation, a spatial resolution of 0.1 mm (0.004 in.) can be achieved with a scanning speed of 1 to 10 mm/s (0.04 to 0.4 in./s).

The data from the detector system are digitized and then stored in a fast dual-ported memory. This permits quasi-simultaneous access to the data during acquisition. Before the image is stored in the frame buffer and displayed on the monitor, simple preprocessing can be done, such as intensity correction of the x-ray tube by the data of the second detector and correction of the sensitivity for different array elements. If further image processing or automatic defect evaluation is required, the system can be equipped with fast image-processing hardware. All standard devices for digital storage can be utilized.

Image Processing. Because real-time systems generally do not provide the same level of image quality and contrast as radiographic film, image processing is often used to enhance the images from image intensifiers, fluorescent screens, and detector arrays. With image processing, the video images from real-time systems can compete with the image quality of film radiography. Moreover, image processing also increases the dynamic range of real-time systems beyond that of film (which typically has a dynamic range of about 1000:1).

Images can be processed in two ways: as an analog video signal and as a digitized signal. An example of analog processing is to shade the image after the signal leaves the camera. Shading compensates for irregularities in brightness across the video image due to thickness or density variations in the testpiece. This increases the dynamic range (or latitude) of the system, which allows the inspection of parts having larger variations in thickness and density.

After analog image processing, the images can be digitized for further image enhancement. This digitization of the signal may involve some detector requirements. In all real-time radiological applications, the images have to be obtained at low dose rates (around 20 $\mu\text{R/s}$). In digital x-ray imaging, however, the most often used dose is around 1 mR, in order to reduce the signal fluctuations that would result from a weak x-ray flux. This means that only a short exposure time (of the order of a few milliseconds) and a frequency of several images can be used if kinetic (motion) blurring is to be avoided. The resulting requirements for the x-ray detector are therefore:

- The capability of operating properly in a pulsed mode, which calls for a fast temporal response
- An excellent linearity, to allow the use of the simplest and most efficient form of signal processing
- A wide operating dynamic range in terms of dose output (around 2000:1)

Once the image from the video camera has been digitized in the image processor, a variety of processing techniques can be implemented. The image-processing techniques may range from the relatively simple operation of frame integration to more complex operations such as automatic defect evaluation. The following discussions briefly describe three image-processing operations. More detailed information on image processing is available in the article "Digital Image Enhancement" in this Volume.

Frame integration (or summing) is a simple technique that can improve the signal-to-noise ratio and decrease (or eliminate) the screen mottle associated with low levels of radiation intensity. This technique adds the digital images from a number of frames and displays the result on a video monitor. Frame integration can be done in real time, that is, at standard television frequency of 30 frames per second. The number of television frames that can be integrated depends on the number of frame buffers available for this procedure. Typical summation times range from a few seconds for applications using x-rays with high intensities up to 1 min or more for applications using radiation from low-activity radionuclide sources. However, these times are small compared to the time required for exposing and developing x-ray film.

Image subtraction can be used to improve sensitivity through the subtraction of one integrated image from a second integrated image. The advantage of the subtraction technique is that all areas of the scene having the same brightness cancel each other to produce an extremely flat or uniformly gray image. With such an image available, the contrast and brightness can then be electronically enhanced to reveal details not visible in either a real-time or a simple integrated image. Example 1 in this article describes one method called pairs subtraction.

Automated defect evaluation systems have been developed for the radiographic inspection of welds (Ref 5). The automatic detection of defects with such systems is based on a mathematical algorithm that evaluates a set of parameters for each indication and compares this set to a catalog of known defects. For any particular problem, the inspection parameters must be selected to provide optimum and reproducible results. To compare different radiographs and to extract features such as the depth of a defect, it is necessary to calibrate the gray levels against material thickness and to calibrate the linear dimensions. Once established, the optimized conditions must be consistently used for all inspections.

Figure 31 shows a flow chart of an automatic image evaluation procedure, and Fig. 32 shows the images from different steps in the procedure. The first step is to remove irrelevant details from the digitized image. This can be done by subtracting a background image. This background image is generated by creating an unsharp image with a low-pass filter. Although radiographs usually have a center brightness that differs from that at the edges, this gradient is eliminated by subtracting the background image from the original image. At this state (Fig. 32b), it is possible to set a threshold and to identify as possible defects all pixels whose gray levels exceed this threshold.

Fig. 31 Flow chart of an automatic image evaluation procedure

Fig. 32 Images developed by an image-processing procedure that identifies and evaluates the images of weld defects in real-time radiographs. (a) Original image. (b) Binary image. (c) Binary image after noise reduction. (d) Original image with defects identified. Courtesy of RTS Technology, Inc

In the next step, these potential defects are examined. First, all very small indications are examined, such as single pixels or groups of only a few pixels, which result from image noise. Larger details, which are obviously separated by one or two missing pixels, are connected (Fig. 32c). This algorithm prevents the computer from spending time analyzing noise that exceeds the threshold.

For each potential defect, a number of parameters are evaluated. These parameters include position, orientation, and a set of descriptors for size and shape. The values of these parameters are compared with the mean value and standard deviation for each parameter in the catalog data already stored. Where some consistency is found between measured and stored data, the program identifies the defects (Fig. 32d) and calculates the probability that the indication is a particular type of defect. Where there is insufficient consistency between the measured and stored data, the program calls for the assistance of an interpreter and enters a learn mode. Once the interpreter has evaluated the defect, the program stores the values for each parameter of the defect, along with the evaluation in the catalog. This information is now considered in future automated evaluations. Relevant defects cause the rejection of the workpiece.

Applications. Real-time radiography is often applied to objects on assembly lines for rapid inspection. Digital radiography with discrete detectors, in particular, is being more widely used because it provides an unlimited field of view and the largest dynamic range of all the radiographic methods. Because a larger dynamic range allows the inspection of parts having a wider range of thicknesses, digital radiography has found application in the inspection of castings (see the article "Castings" in this Volume).

Radiography is also an accepted method of detecting internal discontinuities in welds. Image intensifiers are the most widely used system for the real-time radiographic inspection of welds, although digital radiography with discrete detectors is also used. Projective magnification with microfocus x-ray sources is also useful in weld and diffusion bond inspection.

Advantages and Limitations. Real-time radiography provides immediate information without the delay and expense of film development. Real-time systems also allow the manipulation of the testpiece during inspection and the improvement of resolution and dynamic range by digital image enhancement. Real-time radiography with discrete detectors (that is, digital radiography) also provides good scatter rejection.

Nevertheless, film radiography is a simpler technique that represents less of a capital investment. The sensitivity and resolution of real-time systems are usually not as good as those of film, although real-time radiography can approach the

sensitivity and resolution of film radiography when good inspection techniques are used. Good technique is often more important than the details of the imaging system itself.

Example 1: Design of a Rapid, High-Sensitivity Real-Time Radiographic System.

A system was needed for the real-time radiographic inspection of jet-engine turbine blades. These were critical nickel alloy castings that required inspection to at least a 2-1T (1.4%) penetrameter sensitivity level through thicknesses that ranged from about 0.5 to more than 13 mm (0.02 to 0.5 in.). The volume of parts produced necessitated inspection at a rate of 60 parts per hour or more. For consistency, all aspects of the inspection were to be computer controlled. In addition, it was necessary to visually compare the actual parts with their radiographic images to separate castings with excess metal due to mold flaws that might be acceptable from castings with high-density inclusions that might be rejectable.

Image Processing. A preliminary evaluation of the parts indicated that the 2-1T penetrameter sensitivity requirement could be met with suitable image-processing techniques. Both analog and digital processing were used for these complex parts.

The analog processing technique used was an electronic adjustment called shading. Shading is performed in the camera control unit after the signal leaves the camera and before it is sent to the image processor for digitizing and further processing. Shading compensates for variations in brightness across the video image due to thickness variations in the part. In effect, proper shading adjustment increases the latitude (dynamic range) of the image. In the case of the airfoils to be inspected with the real-time radiographic system, shading permitted blade thicknesses ranging from 0.5 to 4 mm (0.02 to 0.16 in.) to be adequately imaged in a single view.

Once the image from the video camera had been digitized in the image processor, a great many processing techniques were implemented. The simplest was to integrate the image. This technique added the digital images from a number of frames and displayed the result on the video monitor. Integration improved the signal-to-noise ratio over that of a single frame from the video camera. For these castings, 128 frames of integration produced good results.

To achieve the required sensitivity, an image subtraction technique was also used. This was an extremely useful processing technique in which one integrated image was subtracted from a second integrated image. There are a number of variations of this technique. It was experimentally determined that the best technique for this application was the one termed "pairs subtraction." To produce a "pairs subtraction," the part was displaced slightly between the two integrated images that were subsequently subtracted from each other.

X-Ray Source. Because of the range of thicknesses to be inspected, two x-ray sources were selected for the system--one rated at 160 kV for the thinner sections and the other at 320 kV for the thicker sections. The use of 0.4 mm (0.015 in.) focal spots for the 160-kV unit and 0.8 mm (0.03 in.) focal spots for the 320-kV unit provided sufficient resolution to detect 0.25 mm (0.01 in.) defects even at the relatively short source-to-screen distances available in the final real-time radiographic system design. Because it was required that the blade be exposed to only one source of radiation at a time and that the x-ray tubes be run continuously, two computer-controlled, high-speed lead shutters were designed to block the unwanted radiation.

Imaging System. The imaging camera, which was housed in its own shielded enclosure, included a 100 × 100 mm (4 × 4 in.) rare-earth fluorescent screen for converting x-rays to visible light. Light from the screen was directed to the objective lens of an image isocon camera by a 45° front surface mirror (Fig. 33). An isocon camera was selected over an image intensifier for two reasons. First, an isocon camera is much less susceptible to blooming due to bypass radiation. This permitted the use of relatively loose masking around the part. Second, computer-selectable shading channels were available with the isocon camera; therefore, shading could be preadjusted for different views. The computer program could then set the required shading channel during an inspection. The camera system was designed to include remote controls to facilitate focusing of the camera and adjustment of the field of view from the full-screen size down to a 25-mm (1-in.) square to increase the optical magnification if necessary.

Fig. 33 Schematic of the equipment described in Example 1

Part Handling. To minimize part-handling time, a very accurate, high-speed, commercially available robot with four axes of movement (X, Y, Z, and rotation) was selected. The robot was equipped with a computer and sophisticated operating programs. After the robot was taught a few fixed points, it determined its own path from one position to another. This was especially convenient because a large number of parts were to be placed into the real-time radiographic system in a tray. The robot only needed to be told the number of rows and columns in the tray and taught three corner pickup locations. From this information, it could calculate the exact pickup points for all other locations in the tray.

The part containers required considerable development before consistent robot pickup was achieved. In the final design, parts were dropped into molded plastic holders with no special care, and they were positioned well enough for the robot to pick them up with a high degree of reliability.

System Layout and Operating Console. To permit installation in a factory, the x-ray sources, imaging camera, and robot were located in an exempt, radiation-shielded enclosure. Trays of parts to be inspected were inserted through a sliding access door from an adjacent environmental enclosure.

An environmental enclosure was included for the operator's station to provide a relatively clean environment in the manufacturing area. The inspection operator's station was designed to include a desktop console with a video monitor on which either real-time or processed images could be viewed. The console also included a computer terminal and keyboard; a joystick control was used for performing various image processor functions and for manual control of the robot. The x-ray controls, the robot controller, the isocon camera controls, and the computer and image processor were located near the console.

A console for reviewing images while examining parts visually was also provided in the environmental enclosure. In addition to the video monitor, image processor, and computer terminal, a voice recognition system was added so that commands and information could be input to the computer without using the keyboard.

System Software. Three separate programs were developed for the real-time radiographic system: Inspect, Review, and Supervisor. The computer selected included a multiuser operating system to allow the Inspect and Review programs to be run concurrently at different terminals. All the programs were menu driven; the operator simply entered information or exercised options when prompted to do so by the menu on the computer terminal.

The Inspect program was designed for day to day inspection operation. In this program, a preestablished scan plan controlled all the parameters required for an inspection. As long as the operator continued accepting views, the program moved through the plan for each part in turn until all parts in the tray had been completed.

In running the scan plan, the computer interfaced with the x-ray machines to control the kilovolt and milliamp settings, the shutters, and x-ray on and off. It also interfaced with the isocon camera control unit to turn the camera beam on and off and to call the required shading channel, and it interfaced with the robot controller to direct the part movements.

The software was designed so that the scan plan could be interrupted at any time. One option in the interrupt mode gave the operator complete manual control of all system functions through the terminal keyboard. The ability to call an image quality indicator (IQI) to check for proper radiographic sensitivity was also designed into the interrupt mode. When the IQI was called for, the part was returned to its tray position, and the IQI was picked up and moved into the x-ray beam. An image of the IQI was generated using the same x-ray parameters and image processing as employed for the part view being inspected at the time.

The Review program was designed to allow stored images to be recalled when the parts were available for visual review. In addition to accessing images, this program allowed various enhancement techniques to be performed on the image. All program functions could be exercised using the voice recognition capability so that the operator's hands were free to handle parts. Once a final disposition for a part was entered, the views for that part were automatically deleted from memory.

The Supervisor program was written to include a number of program functions that were to be protected from normal operator access. These included changing the lists of authorized users and their passwords, access to an operations log, and creation or modification of scan plans.

System Performance. The sensitivity of the system was demonstrated with plaque penetrameters, a wire penetrometer, and an actual part with small holes. The plaque penetrometer sensitivity of the system is shown in Fig. 34. Figure 34(a) shows a pairs-subtracted image of a 0.025 mm (0.001 in.) thick penetrometer through 1.25 mm (0.05 in.) of material, and Fig. 34(b) shows a 0.125 mm (0.005 in.) penetrometer through 6.4 mm (0.25 in.) of material. All three holes can be seen near the centers of the circles as adjacent white and black areas that result from the pairs subtraction technique.

Fig. 34 Examples of plaque penetrameter indications. (a) 0.025 mm (0.001 in.) thick penetrameter on a testpiece with a thickness of 1.3 mm (0.050 in.). (b) 0.125 mm (0.005 in.) penetrameter on a testpiece with a thickness of 6.4 mm (0.25 in.)

Figure 35 shows a pairs-subtracted image of an actual part in which a series of holes was drilled using the electrical discharge machining process. The holes have a nominal diameter of 0.25 mm (0.01 in.) and a depth that is 2% of the material thickness at the location where they were drilled. The material thickness in this airfoil view ranged from 1 to approximately 4 mm (0.04 to 0.16 in.).

Fig. 35 Radiographic image of holes with a nominal diameter of 0.25 mm (0.01 in.) and a depth of 2% of wall thickness. Holes are indicated with arrows. Courtesy of Lockheed Missiles & Space Company, Inc.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Film Radiography

Film selection and exposure time are two major factors in film radiography. The selection of radiographic film for a particular application is generally a compromise between the desired quality of the radiograph and the cost of exposure time. The quality of the radiograph depends mainly on film density, gradient, graininess, and fog, which are functions of film type and development procedure. Exposure time depends mainly on film speed and on radiation intensity at the film surface. The factors affecting film selection and exposure time are discussed in more detail in this section.

Characteristics of X-Ray Film

Three general characteristics of film--speed, gradient, and graininess--are primarily responsible for the performance of the film during exposure and processing and for the quality of the resulting image. Film speed, gradient, and graininess are interrelated; that is, the faster the film, the larger the graininess and the lower the gradient--and vice versa. Film speed and gradient are derived from the characteristic curve for a film emulsion, which is a plot of film density versus the exposure required for producing that density in the processed film. Graininess is an inherent property of the emulsion, but can be influenced somewhat by the conditions of exposure and development.

There are other characteristics of x-ray film that can be used to produce special effects. However, the following discussion is mainly confined to film speed, gradient, graininess, and the factors that affect them.

Density. The quantitative measure of the blackening of a photographic emulsion is called density. Density is usually measured directly with an instrument called a densitometer.

There are two kinds of density:

- Transmission density, which is associated with transparent-base radiographic film
- Reflection density, which is associated with opaque-base imaging material such as radiographic paper

In the following discussion, the unqualified term density will refer to transmission density.

Transmission density is defined by:

$$D = \log \left(\frac{I_0}{I_t} \right) \quad (\text{Eq 14})$$

where D is the density, I_0 is the intensity of light incident on the film, and I_t is the intensity of light transmitted through the film. Reflection density is defined by:

$$D_r = \log \left(\frac{I_0}{I_r} \right) \quad (\text{Eq 15})$$

where D_r is the reflection density, I_0 is the light intensity incident on the radiographic image, and I_r is the light intensity reflected from the image. Although Eq 14 and 15 are similar, the densities are quite different.

The ratio of incident intensity, I_0 , to transmitted intensity, I_t , in Eq 14 is called opacity. The inverse of this ratio, I_t/I_0 , is called transmittance and indicates the fraction of incident light transmitted through the film. The relationship of density to opacity and transmittance is as tabulated below:

Density, $\log(I_0/I_t)$	Opacity, I_0/I_t	Transmittance, I_t/I_0
0	1	1.00
0.3	2	0.50
0.6	4	0.25
1.0	10	0.10
2.0	100	0.01

3.0	1,000	0.001
4.0	10,000	0.0001

If the light transmitted through the film is half of the incident light (transmittance = 0.5), the density is only 0.3, and for a density of 1.0, only one-tenth of the incident light intensity is transmitted. The fact that only $\frac{1}{100}$ of the incident light is transmitted at a density of 2.0 is the reason that it is necessary to use high-intensity illuminators for viewing industrial radiographs at densities exceeding 2.0.

Exposure is the intensity of radiation multiplied by the time during which it acts, that is, the amount of energy that reaches a particular area of the film and that is responsible for producing a particular density on the developed film. Exposure can be specified either in absolute units (such as ergs per square centimeter or roentgens) or in relative units (where one particular exposure is used as a reference and all others are specified in terms of that reference). Unless equipment and time are available for making the precise radiation measurements that are required for defining exposure in absolute units, relative exposure is much more convenient than absolute and is equally as useful.

In discussing film properties, only absolute exposure or relative exposure as defined above is appropriate. Relative exposure is used in the present discussion.

Characteristic Curves. The relation between the exposure applied to a given type of radiographic film and the resulting density is expressed in a curve known as the characteristic curve of that particular type of film. Other names for this curve are the H and D curve, D log E curve, or sensitometric curve. Such curves are determined by applying a series of known exposures to the film and, after processing the film according to a standard procedure, reading the resulting densities. The curve is generated by plotting density against the logarithm of relative exposure. Figure 36(a) shows the characteristic curves of three commercial films exposed to x-radiation between lead screens.

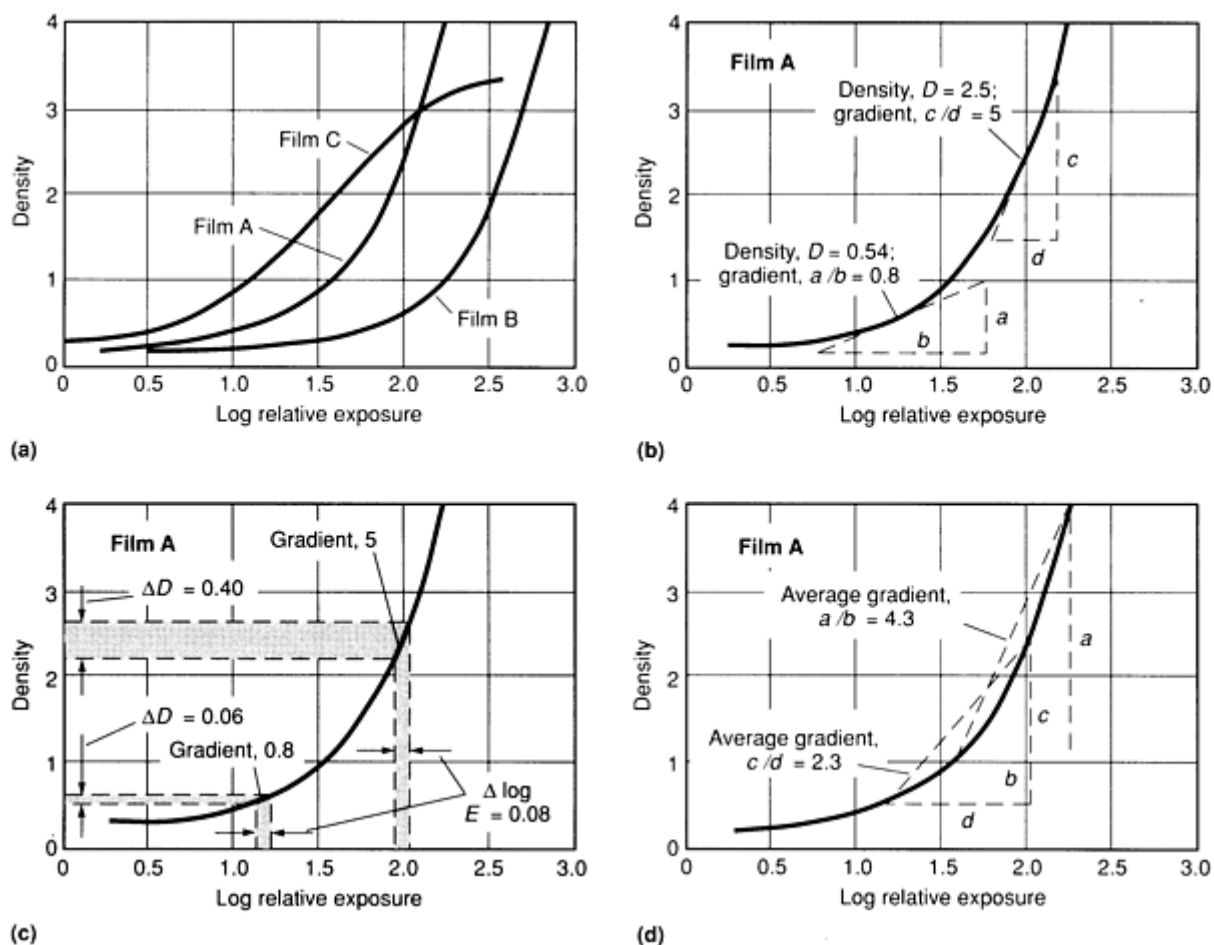

Fig. 36 Characteristic curves for x-ray film that determine type of film and film gradient, speed, and density. (a) Typical curves for three industrial x-ray films exposed to x-radiation between lead screens. (b) Evaluation of gradients at two points on the curve for film A in (a). (c) Density differences (ΔD) corresponding to a 20% difference in relative exposure ($\Delta \log E = 0.08$) determined for the two values of gradients evaluated in (b). (d) Average gradients for film A determined over two density ranges

Relative exposure is used partly because there are no convenient units suitable to all kilovoltages and scattering conditions and partly because it is easy to determine the logarithm of relative exposure. Using the logarithm of relative exposure instead of only relative exposure has several other advantages; for example, the otherwise long scale is compressed, and ratios of intensities or exposures (which are determined by simply subtracting logarithms) are usually more significant in radiography than actual exposures or intensities.

Characteristic curves are very useful in determining the speed and gradient of the film as well as indicating the type of film. For example, in Fig. 36(a), characteristic curves for films A and B are J-shaped, which is typical of industrial x-ray film of types 1, 2, and 3. The curve for film C begins to flatten at a density between 3.0 and 3.5, giving it the S-shape typical of type 4 x-ray films used with fluorescent screens.

Film speed is inversely related to the time required for a given intensity of radiation to produce a particular density on the film; the shorter the exposure, the faster the film. In absolute units, film speed is inversely proportional to the total energy (roentgens) of a particular radiation spectrum (wavelength distribution at a given kilovoltage) that produces a given density on the film. For most practical applications, it is convenient and effective to deal with relative speeds. In using relative speeds, film speeds are expressed in terms of the speed of one particular film whose relative speed is arbitrarily assigned a value, for example, 100. Thus, if film A requires half the exposure of film B, the slower film (film B) is chosen as the standard and assigned an arbitrary speed of 100. Film A, which is twice as fast, would have a relative speed of 200.

To avoid making absolute measurements to determine film speed, it is convenient to refer to a group of film curves such as those in Fig. 36(a). Curves positioned to the left of the chart require less exposure for a given density; those to the right, more exposure. Thus, for a density of 2.0, film C in Fig. 36(a) is faster than film A, and both are faster than film B. Their relative speed is calculated by determining the differences in log relative exposure and converting to the antilog. Film B is the slowest film and requires a log relative exposure of 2.5 for a density of 2.0. Film B is chosen as the standard and is assigned a speed of 100. Film A requires a log relative exposure of 1.9 for the same density. Subtracting 1.9 from 2.5 gives a difference of 0.6, for which the antilog is about 4, so the relative speed of film A is four times that of film B, or has a relative speed of 400. Similarly, at a density of 2.0, film C requires a log relative exposure of 1.6. Subtracting 1.6 from 2.5 gives a log difference of 0.9, for which the antilog is about 8. Thus, film C is eight times faster than film B, or has a relative speed of 800 at a density of 2.0.

Another advantage of using groups of characteristic curves is that the visual assessment of relative speeds can be easily made. For example, although films A and B have similarly shaped curves running almost parallel, the curve for film C is radically different. As calculated above, film C has a relative speed of 800 at a density of 2.0; however, at greater densities, the relative speed of film C is lower than 800, and at lesser densities (down to a density of 1.0), the relative speed of film C is greater than 800. Therefore, whenever relative speeds are used, the density at which they were determined must be given.

Film gradient, also called film contrast, is a measure of the slope of the characteristic curve. If the difference is great, the gradient (contrast) is said to be high. If the difference is slight, the gradient is said to be low. The contrast seen on a radiograph is known as radiographic contrast and is composed of two factors:

- Subject contrast, which is the result of variations in the amount of radiation absorbed by the testpiece and which causes variations in radiation intensity impinging on the film
- Film gradient (or film contrast), which is a measure of the response of the emulsion to the intensity of impinging radiation and is a characteristic of a given film

Film gradient is determined from the characteristic curve by finding the slope of the curve at a given density. The slope of the characteristic curve changes continuously over its entire length, as indicated in Fig. 36(a). The steeper the slope of the curve over a range of relative exposures, the greater the difference in density and therefore the greater the resolution of detail; thus, high gradient is important for good radiography.

In Fig. 36(b) tangents to a characteristic curve for a typical x-ray film have been drawn at two points, and the two corresponding gradients (a/b and c/d) have been evaluated. Note that the gradient varies from 0.8 in the shallow portion of the curve (called the toe) to 5 in the steeper portion of the curve.

Two regions of a testpiece that are slightly different in thicknesses will transmit slightly different intensities of radiation to the film. On the characteristic curve, this would represent a small difference in the log relative exposure. For example, assume that at a given kilovoltage the thinner section transmits 20% more radiation than the thicker section. The difference in log relative exposure is 0.08 and is independent of tube current, exposure time, or source-to-film distance. In the toe of the characteristic curve where, the gradient is only 0.8, the density difference is only 0.06, as indicated in Fig. 36(c). However, in the steeper portion of the curve where the gradient is 5, the density difference is 0.40. This effect of film gradient is the main reason why it is best to use high exposures, obtaining the highest density that can be viewed on a given illuminator for the greatest resolution of minor differences in transmitted radiation.

It is often more convenient to express gradient as an average over a given useful range of densities than for a single density. This is a simple calculation in which the difference between the two densities is divided by the difference between the log relative exposures for these densities; this ratio, known as the average gradient, is shown in Fig. 36(d).

Graininess. The silver halide grains that are contained in the emulsion of x-ray film are minute and can be seen only with a high-power microscope, such as an electron microscope. Even though the emulsion on each side of the film is only about 0.013 mm (0.0005 in.) thick, the grains are piled on top of each other in countless numbers. When the exposed-and-processed radiograph is viewed, these small individual silver grains appear grouped together in relatively large masses. This clumping, which is visible to the unaided eye or at low magnification, produces the visual impression called graininess.

All films exhibit some degree of graininess. In general, slower films have less graininess than faster films. This general relation is reflected in Table 6, which is an old classification scheme specified by the American Society for Testing and Materials (ASTM) in the earlier 1984 edition of ASTM E 94. Although this classification scheme is somewhat arbitrary, it is still sometimes specified in codes and specifications. Type 1 films have the least graininess, type 3 films exhibit the most graininess, and type 2 films are intermediate.

Table 6 General characteristics of the four types of radiographic film specified in the earlier (1984) edition of ASTM E 94

These groupings are given only for qualitative comparisons. For a more detailed discussion on film classification, see the section "Film Types" in this article.

Film type	Film characteristic		
	Speed	Gradient	Graininess
1	Low	Very high	Very fine
2	Medium	High	Fine
3	High	Medium	Coarse
4 ^(a)	Very high ^(b)	Very high ^(b)	^(c)

(a) Normally used with fluorescent screens.

(b) When used with fluorescent screens.

(c) Graininess is mainly a characteristic of the fluorescent screens.

(d) When used for direct exposure or with lead screens

The energy of the radiation also affects the graininess of films. As the penetrating capability of radiation increases (photon energy increases and wavelength decreases), the graininess of all films increases, but the rate of increase may be different for different films. As a result, it is possible that of two film types, one will show more graininess at long wavelengths while the other shows more graininess at short wavelengths. The graininess of the images that are produced at high photon energies makes the inherently fine-grain films such as types 1 and 2 particularly useful at photon energies of 1 MeV or more.

Another source of graininess occurs in radiography using fluorescent intensifying screens. The graininess seen in fluorescent-screen radiographs is primarily caused by the graininess that is inherent in the screen. This effect overshadows the effect of film graininess, especially with films that are particularly sensitive to screen fluorescence. The graininess of fluorescent-screen radiographs increases significantly with increased kilovoltage.

Lead screens have little effect on the graininess of the image; only slight increases in graininess at equal densities have been noted when lead-screen radiographs are compared with direct radiographs made at the same photon energy.

Spectral Sensitivity. The shape of the characteristic curve of a given x-ray film is for all practical purposes unaffected by the wavelength distribution in the x-ray or γ -ray beam used for the exposure. However, the sensitivity of the film in terms of roentgens required to produce a given density is strongly affected by radiation energy (beam spectrum of a given kilovoltage or given γ -ray source).

Figure 37 shows the exposure required for producing a density of 1.0 on radiographic film developed in an x-ray developer for 5 min at 20 °C (68 °F). The exposures were made directly, without screens. The spectral-sensitivity curves for all x-ray films have approximately the same general features as the curves shown in Fig. 37. The details, however, differ from film to film; for example, the ratio of maximum-to-minimum sensitivity of the film to roentgens of exposure varies. The details of the curves also differ with the degree that long wavelengths have been filtered from the beam (Fig. 37).

Fig. 37 Spectral-sensitivity curves for a radiographic film showing exposure required to produce a density of 1.0

The spectral sensitivity of a given film, or the difference of spectral sensitivity between films, is usually considered in the preparation of exposure charts and tables of relative speeds. For example, in tables of relative speeds, the speed of a particular film usually varies with tube voltage. Also, in the preparation of exposure calculators for γ -rays, where roentgens necessary to expose a given film to produce a given density are extensively used, spectral sensitivity is important. As a result, manufacturers of radiographic film often furnish tables of spectral sensitivity for the films they manufacture, indicating the roentgens required to produce several net densities at various x-ray tube voltages and γ -ray photon energies.

Effect of Development on Film Characteristics. Although the shape of the characteristic curve is not affected by variations in photon energy, it is affected by variations in the degree of development. The degree of development depends on the type of developer used (including its degree of activity), temperature, and developing time. These factors are discussed in the Appendix to this article. Within limits, an increased degree of development increases the speed and gradient of a given film. If the limits are exceeded (that is, the film is overdeveloped), film speed based on density (density above fog) no longer increases and may even decrease. Also, the fog (gray cloudiness) resulting from excessive action of developer chemicals on unexposed grains will increase, and the gradient may decrease.

Figure 38 shows the characteristic curve of a radiographic film as affected by various times of manual development at 20 °C (68 °F) in an x-ray developer mixed from powder. As the developing time increases, the characteristic curve progressively becomes steeper (gradient increases) and positioned more to the left on the chart (speed increases). It is from such curves that values of relative speed and average gradient can be determined and developing recommendations can be derived.

Fig. 38 Effect of various developing times on the characteristic curve of a radiographic film developed at 20 °C (68 °F) in a manual process

Figure 39 shows the values of relative speed, average gradient, and fog plotted against developing time for the same film and processing conditions detailed in Fig. 38. These curves indicate that at an 8-min developing time the average gradient has reached its peak and further development would decrease film gradient. The speed, gradient, and fog curves of Fig. 39 are characteristic of this type of film, and similar curves are different for other types of films.

Fig. 39 Effect of developing time on (a) relative speed, (b) average gradient, and (c) fog for a radiographic film. These graphs were derived from the same data as Fig. 38.

The degree of development also affects graininess. For example, if development time is increased to produce higher film speed, the graininess is also increased. On the other hand, a developer or developing technique that gives an appreciable reduction in graininess will also result in an appreciable loss of film speed. Adjustments in developing techniques made to compensate for changes in temperature or in activity of a developer have little effect on graininess.

The variation of film gradient, speed, fog, and graininess with development time and temperature for a given radiographic film and developer solution makes it imperative that standardized procedures for development of radiographic film be meticulously followed. Unless this is done, it is impossible to obtain consistent resolution of variations in radiation intensity. Inconsistency in the resolution of variations in radiation intensity can seriously impair the ability to detect flaws in metals.

Film Types and Selection

The selection of radiographic film for a particular application is generally a compromise between the desired quality of the radiograph and the cost of exposure time. This compromise occurs because slower films generally provide a higher film gradient and a lower level of graininess and fog.

Film Types. The classification of radiographic film is complicated, as evidenced by changes in ASTM standard practice E 94. The 1988 edition of ASTM E 94 references a new document (ASTM E 746-87), which describes a standard test method for determining the relative image-quality response of industrial radiographic film. Careful study of this document is required to arrive at a conclusive classification index suitable for the given radiographic film requirements of a facility.

Earlier editions (1984 and prior) of ASTM E 94 contained a table listing the characteristics of industrial films grouped into four types. The general characteristics of these four types are summarized in Table 6. This relatively simple classification method is referenced by many codes and specifications, which may state only that a type 1 or 2 film can be used for their specification requirements. However, because of this relatively arbitrary method of classification, many film manufacturers may be reluctant to assign type numbers to a given film. Moreover, the characteristics of radiographic films can vary within a type classification of Table 6 because of inherent variations among films produced by different manufacturers under different brand names and because of variations in film processing that affect both film speed and radiographic density. These variations make it essential that film processing be standardized and that characteristic curves for each brand of film be obtained from the film manufacturer for use in developing exposure charts.

Because the variables that govern the classification of film are no longer detailed in ASTM E 94-88, it is largely the responsibility of the film manufacturer to determine the particular type numbers associated with his brand names. Some manufacturers indicate the type number together with the brand name on the film package. If there is doubt regarding the type number of a given brand, it is advisable to consult the manufacturer. Most manufacturers offer a brand of film characterized as very low speed, ultrahigh gradient, and extremely fine grain.

Film selection for radiography is a compromise between the economics of exposure (film speed and latitude) and the quality desired in the radiograph. In general, fine-grain, high-gradient films produce the highest-quality radiographs. However, because of the low speed typically associated with these films, high-intensity radiation or long exposure times are needed. Other factors affecting radiographic quality and film selection are the type and thickness of the testpiece and the photon energy of the incident radiation.

Although the classification of film is more complex than the types given in Table 6, a general guide is that better radiographic quality will be promoted by the lowest type number in Table 6 that economic and technical considerations will allow. In this regard, Table 7 suggests a general comparison of film characteristics for achieving a reasonable level of radiographic quality for various metals and radiation-source energies. It should be noted, however, that the film types are only a qualitative ranking of the general film characteristics given in Table 6. Many radiographic films, particularly those designed for automatic processing, cannot be adequately classified according to the system in Table 6. This compounds the problem of selecting film for a particular application.

Table 7 Guide to the selection of radiographic film for steel, aluminum, bronze, and magnesium in various thicknesses

Thickness		Type of film ^(a) for use with these x-ray tube voltages, or radioactive isotopes:										
mm	(in.)	50-80 kV	80-120 kV	120-150 kV	150-250 kV	Ir-192	250-400 kV	1 MeV	Co-60	2 MeV	Ra	6-31 MeV
Steel

100-200	(4-8)	...	3	2	2	3
>200	(>8)	4

- (a) These recommendations represent a usually acceptable level of radiographic quality and are based on the qualitative classification of films defined in Table 6. Optimum radiographic quality will be promoted by use of the lowest-number film type that economic and technical considerations will allow. The recommendations for type 4 film are based on the use of fluorescent screens.

Film latitude, which is the range of testpiece thickness that can be recorded with a single exposure, also influences film selection (see the following section in this article for a discussion of latitude). High-gradient films generally have narrow latitude, that is, only a narrow range of testpiece thickness can be imaged with optimum density for interpretation. If the

testpiece is of nonuniform thickness, more than one exposure may have to be made (using different x-ray spectra or different exposure times) for complete inspection of the piece. The number of exposures, as well as the exposure times, can often be reduced by using a faster film of lower gradient but wider latitude, although there is usually an accompanying reduction in ability to image small flaws.

Exposure Factors

The exposure time in film radiography depends mainly on film speed, the intensity of radiation at the film surface, the characteristics of any screens used, and the desired level of photographic density. In practice, the energy of the radiation is first chosen to be sufficiently penetrating for the type of material and thickness to be inspected. The film type and the desired photographic density are then selected according to the sensitivity requirements (Eq 2) for recording the expected variations in the intensity of the transmitted radiation. Once these factors are fixed, then the source strength, the source-to-film distance, and the characteristics of any screens used determine the exposure time.

With a given type of film and screen, the exposure time to produce the desired photographic density obeys the reciprocity law for equivalent exposures (Eq 5). The reciprocity law can be modified to include the inverse-square law (Eq 13), which models the relation between radiation intensity at the film and the source-to-film distance. Therefore, because the intensity is inversely proportional to the square of distance from the source according to Eq 13, the reciprocity law for equivalent exposures with an x-ray tube (Eq 5) can be rewritten as:

$$\frac{i_1 t_1}{L_1^2} = \frac{i_2 t_2}{L_2^2} \quad (\text{Eq 16})$$

where i is the tube current, t is the exposure time, L is the source-to-film distance, and the subscripts refer to two different combinations that produce images with the desired photographic density. The parallel expression that applies to exposures made with a γ -ray source is:

$$\frac{a_1 t_1}{L_1^2} = \frac{a_2 t_2}{L_2^2} \quad (\text{Eq 17})$$

where a is the source strength in gigabecquerel (curies).

For practical applications using the same quality of x-rays (same kilovoltage) or the same radioactive source, Eq 16 or 17 is applied in the following manner. If a satisfactory radiograph of a given testpiece can be obtained at a 1 m (3.3 ft) source-to-film distance, 20-mA tube current, and 10-s exposure time, an equivalent radiograph can be obtained in 6.4 s with 20-mA tube current or in 8 s with 16-mA tube current when the distance is reduced to 0.8 m (2.6 ft). However, if the source-to-film distance is increased to 2 m (6.6 ft), it will take 40 s at 20 mA or 32 s at 25 mA or 16 s at 50 mA to produce equivalent film density.

Similarly, if a satisfactory radiograph can be obtained with a 440 GBq (12 Ci) cobalt-60 source at 1 m (3.3 ft) source-to-film distance in 20 min, a radiograph of equivalent density will require a 45-min exposure time with the same 440 GBq (12 Ci) source if the distance is increased to 1.5 m (4.9 ft).

Exposure Charts for X-Ray Radiography. A starting point must be determined for the calculations described in the discussions above. The starting point is ordinarily derived from exposure charts of the type shown in Fig. 40. Equipment manufacturers usually publish exposure charts for each type of x-ray generator that they manufacture. These published charts, however, are only approximations; each particular unit and each installation is unique. Radiographic density is affected by such factors as radiation spectrum, film processing, setup technique, amount and type of filtration, screens, and scattered radiation.

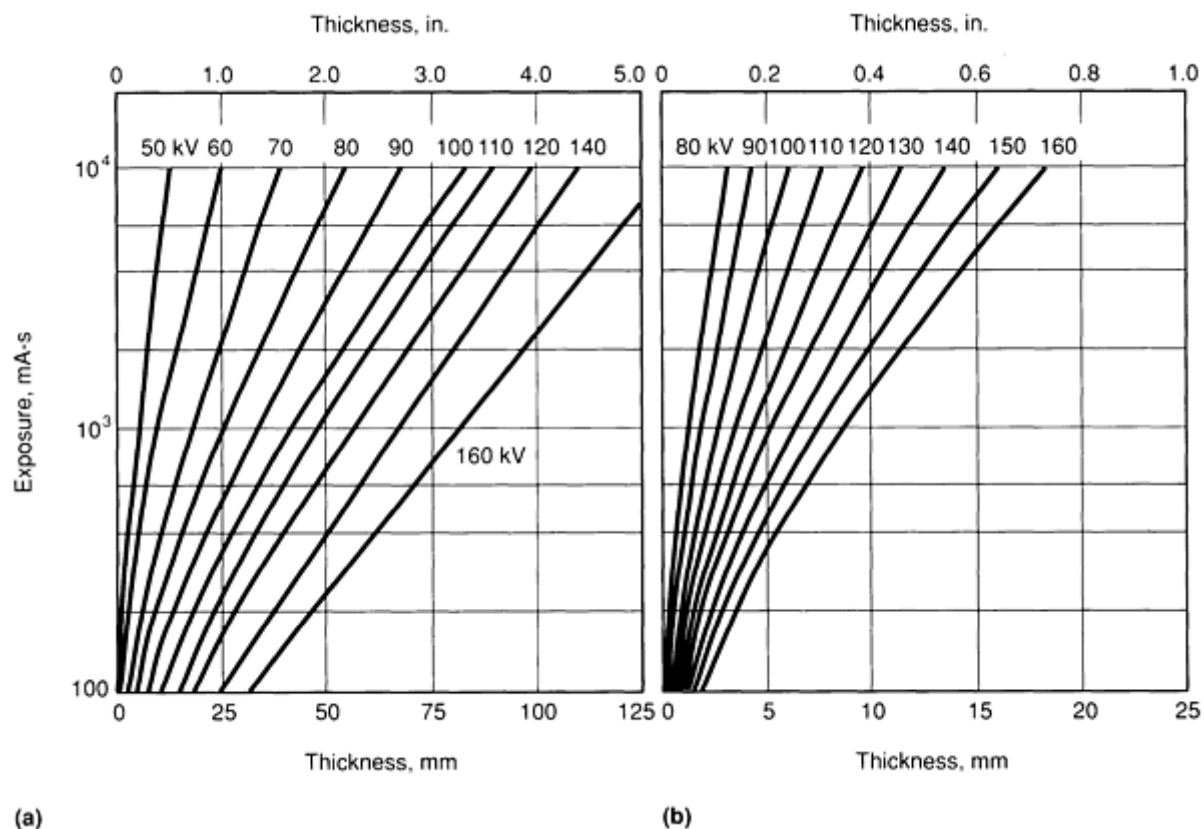

Fig. 40 Typical radiographic exposure charts for (a) aluminum and (b) steel for a film density of 2.0 without screens that relate exposure to thickness of testpieces for several values of tube voltage. Charts for aluminum and steel were prepared specifically for an Andrex 160-kV directional x-ray machine, using a source-to-film distance of 910 mm (36 in.) and Industrex AA film (Eastman Kodak) developed in a manual process for 7 min in PIX developer (Picker).

Although published exposure charts are acceptable guides for equipment selection, more accurate charts that are prepared under normal operating conditions are recommended for each x-ray machine. A simple method for preparing accurate exposure charts is as follows:

1. Make a series of radiographs of a calibrated multiple-thickness step wedge, using several different values of exposure at each of several different tube voltage settings
2. Process the exposed films together under conditions identical to those that will be used for routine application
3. From the several densities corresponding to different thicknesses, determine which density (and thickness) corresponds exactly with the density desired for routine application. This step must be done with a densitometer because no other method is accurate. If the desired density does not appear on the radiograph, the thickness corresponding to the desired density can be found by interpolation
4. Using the thickness determined in step 3 and the tube voltage (kilovoltage) and exposure (milliamp-second or milliampmin) corresponding to that piece of film, plot the relation of thickness to exposure on semilogarithmic paper with exposure on the logarithmic scale
5. Draw lines of constant tube voltage through the corresponding points on the graph

The resulting chart will be similar to those in Fig. 40, but will be accurate for the x-ray machine, type of film, and film development technique that were used. Different charts should be prepared for different film types, both with and without screens.

Charts prepared as described above will be strictly accurate only for testpieces of uniform thickness. Some adjustment in exposure or source-to-film distance will have to be made for the more usual circumstances involving testpieces of nonuniform thickness.

Latitude charts can sometimes be used to help determine the correct exposure when the thickness of a testpiece varies within the area of coverage. Latitude is a range of metal thickness that produces a specific range of density in the processed film for a given combination of radiation spectrum, source-to-film distance, and exposure. The bands in Fig. 41 are latitude curves for the inspection of steel testpieces using x-rays from a 250-kV x-ray machine. As shown in Fig. 41(a), increasing the tube voltage not only decreases the exposure needed to radiograph a section of given nominal thickness but also increases the range of testpiece thickness that is satisfactorily recorded on the radiograph. For example, at a nominal steel thickness of 15 mm ($\frac{5}{8}$ in.), about 2200 mA-s exposure is needed to produce a satisfactory image on type 2 film with 150-kV x-rays; the image will have satisfactory density for a range of thickness from about 14 to 18 mm (0.57 to 0.70 in.). On the other hand, when 250-kV x-rays are used, an equivalent image can be produced on type 2 film with only about 220 mA-s exposure, and thicknesses from about 13 to 20 mm (0.50 to 0.78 in.) can be recorded with satisfactory density.

(a)

(b)

Fig. 41 Latitude curves for the radiographic inspection of steel at film densities ranging from 1.5 to 3.0. (a) Effect of tube voltage on latitude of a type 2 radiographic film. (b) Effect of film type on latitude for radiography using 250-kV x-rays. Curves were prepared from data obtained using a 250-kV x-ray machine, 910-mm (36-

in.) source-to-film distance, and 0.25 mm (0.010 in.) thick lead screens. Films were processed using a standardized technique.

Alternatively, latitude charts for different types of film can be used to determine the ranges of thickness covered by each type at a given exposure (Fig. 41b). The difference in latitude for different types of film is one basis for the use of multiple-film techniques. For example, if a steel testpiece is radiographed using 250-kV x-rays and a film holder loaded with one sheet each of types 1, 2, and 3 film, then a range of testpiece thickness of 13 to 40 mm (0.5 to 1.6 in.) can be recorded with a single exposure of 600 mA-s. Each of the films is viewed and interpreted separately for the range of thickness corresponding to its optimum density range. For thicknesses corresponding to gaps between optimum density ranges for the different films, enough contrast and detail usually exist in one or both of the films on either side of the gap to yield a satisfactory image.

When filters are used or when other variations in technique are introduced, further adjustments in exposure or source-to-film distance will have to be made. In fact, if large numbers of a given part are to be inspected, it is usually worthwhile to make a series of radiographs of a representative testpiece using different tube voltages and different exposures. From the results of these experiments a standard setup and exposure can be established.

When there is only one opportunity to inspect a part for which there is no established standard technique or when circumstances will not permit experimentation, one of several alternative techniques can be used. For example, replicate radiographs can be made using different values of one or more of the following: tube voltage, tube current, exposure time, source-to-film distance, or film speed. Alternatively, film holders can be loaded with two or more sheets of film, either of the same type or of different types; the resulting radiographs can be viewed both as double-film and single-film images to obtain wider latitude. The latter technique, using two or more sheets of film, is especially useful when there are large variations in testpiece thickness. Sometimes, it can be advantageous to adopt the technique for routine applications. Another method involves making duplicate radiographs with and without a filter or with and without lead screens. In such cases, exposure time and tube current will have to be varied to compensate for either beam attenuation with a filter or the combined effects of filtration and intensification with lead screens.

Exposure charts apply only to the material of which the step wedge was composed. Most often, this is a standard material such as aluminum or steel. However, exposure charts for a standard material can be used to determine exposure factors for other materials by applying radiographic equivalence factors such as those listed in Table 5. First, the exposure is derived from the exposure chart as if the part were actually made out of the standard material. The exposure so derived is then multiplied by the radiographic equivalence factor from Table 5. For example, if a 13 mm ($\frac{1}{2}$ in.) thick part made of titanium is to be radiographed using 150-kV x-rays without screens, the exposure for a 13 mm ($\frac{1}{2}$ in.) thick part made of steel can be determined from the exposure chart in Fig. 40(b). That exposure would be 4000 mA-s for a source-to-film distance of 910 mm (36 in.). From Table 5, the radiographic equivalence of titanium for 150-kV x-rays is 0.45. Thus, for 150-kV x-rays and a source-to-film distance of 910 mm (36 in.), the exposure for the titanium part would be 0.45 times 4000 mA-s, or 1800 mA-s. A reasonable exposure for this part would be 2 min (120 s) at 15-mA tube current.

In addition to exposure charts, nomograms or specially constructed slide rules are often used for calculating radiographic exposures. These devices can be constructed using the same type of information as that used in constructing exposure charts. The main advantage of these devices is speed in making a calculation, which can reduce setup time and produce economic benefits.

Gamma-ray exposure charts are constructed in a manner similar to the exposure charts used in determining x-ray exposures. Instead of expressing the exposure in milliamperere-seconds, γ -ray exposures are expressed in curie-hours or curie-minutes. To use a γ -ray exposure chart, the source strength must be known. Source strength decreases exponentially with time, and each radioactive isotope has a characteristic half-life. This behavior can be used to determine the strength of a radioactive source at any one time, provided its strength at one time is known. (Normally, source manufacturers provide the source strength as of a given date along with each new source). A graph of source strength versus time is constructed as described in the following paragraph.

On the logarithmic scale of semilogarithmic graph paper, plot the known source strength. (For convenience, the date when the determination of source strength was made should be noted.) Divide the linear scale into convenient units of time (with the known source strength corresponding to zero time), extending the scale at least one half-life. At the time corresponding to one half-life, plot a point corresponding to half of the known source strength that was plotted at zero

time. Draw a straight line between the two points, extending the line as far beyond the second point as desired. This line represents the source strength at any time; if desired, the linear scale may now be renumbered using dates, so that at any time the source strength corresponding to a given date can be seen at a glance.

Figure 42 shows two types of γ -ray exposure charts for cobalt-60 radiation and testpieces of steel, gray iron, or ductile iron. In Fig. 42(a), exposure in curie-minutes to produce an average photographic density of 2.0 is read directly for each combination of testpiece thickness and source-to-film distance. Exposure time is determined by dividing exposure determined from the chart by the source strength determined as outlined in the preceding paragraph. In Fig. 42(b), an exposure factor is read directly for each combination of testpiece thickness and desired photographic density. The exposure time is calculated from:

$$t = E \times \frac{L_i^2}{S} \quad (\text{Eq 18})$$

where t is the exposure time in minutes, E is the exposure factor, L_i is the source-to-film distance (in inches), and S is the source strength (in curies). For example, if it is desired to radiograph a 3 in. thick steel testpiece on Industrex AA film with a photographic density of 3.0 and if a 15-Ci cobalt-60 source is to be used at a source-to-film distance of 12 in., then the corresponding exposure factor is 0.58 (dashed line, Fig. 42), and from Eq 18, the exposure time is $t = 0.58 \times 12^2/15 = 5.6$ min.

Fig. 42 Two types of exposure chart for computing γ -ray exposures that apply to Co-60 radioisotopes and steel, gray iron, or ductile iron testpieces. (a) Exposure in curie-minutes to produce a photographic density of

2.0 on NDT 75 film (DuPont) as a function of testpiece thickness for various source-to-film distances. (b) Exposure factor, E , for Industrex AA film (Eastman Kodak) as a function of testpiece thickness; four lines of constant photographic density are shown.

As with x-ray exposures, latitude charts such as the one shown in Fig. 43 can be used to determine the range of thickness that can be recorded with a given exposure. By comparing Fig. 43 with Fig. 41, it can be seen that the latitude of type 2 film with cobalt-60 radiation is almost four times the latitude of type 2 film with 250-kV x-rays. Also, as with x-ray exposures, nomograms or slide rules can be constructed to simplify calculation of γ -ray exposures.

Fig. 43 Latitude curve for radiographic inspection of steel using Co-60 γ -rays to produce a film density range of 1.5 to 3.0. Curve is for type 2 film exposed at a source-to-film distance of 810 mm (32 in.) and with 0.25 mm (0.010 in.) thick lead screens both front and back.

Selection of View

The view selected for the radiography of a testpiece is a major factor that controls the ability to detect certain types of flaws. In some circumstances, although flaws are detected, the selected view presents an unsatisfactory or distorted picture of the relationship of the flaws to testpiece shape. For example, a crack in the fillet of a T-shape section of a casting or in a weld in a T-shape weldment is most likely to be revealed when the radiation is directed along the bisector of the angle between the legs of the section, because most cracks in such a location run perpendicular to the surface midway between the legs of the T. When the radiation is directed at an equal angle to both legs, it is most likely to be parallel to any crack that is present, which is the most favorable orientation for revealing cracks. With this orientation, however, there is no distinct line of demarcation between the sections of different thickness, and the portions of the testpiece that have the greatest object-to-detector distance will be recorded with a considerable degree of unsharpness and distortion.

Radiographic Shadows. As discussed in the section on "Principles of Shadow Formation" in this article, radiographic images can be compared to the shadows formed when a beam of light is interrupted by an opaque object. The difference between shadows and radiographic images is that in the umbra of a shadow there is a complete absence of radiation from the light source, while in the umbral region of a radiograph the amount of radiation that falls on the image conversion medium depends mainly on the absorption characteristics of the testpiece. Ordinarily, only the umbral region of a radiograph is of interest because it is only in this region that internal features of the testpiece are revealed.

When a section of the testpiece contains a discontinuity that is essentially planar, such as a crack or cold shut, the planar discontinuity will be revealed only when the radiation is parallel or nearly parallel to that discontinuity (Fig. 44a). Such a discontinuity can be revealed as a difference in absorption compared to the surrounding material only when the radiation impinges on the edge of the discontinuity, as shown at left in the actual setup in Fig. 44(a). In all other orientations, such

as that shown at right in the actual setup in Fig. 44(a), the effective thickness of the testpiece is the same, whether in the region of the planar discontinuity or not, and there is no difference in absorption.

Fig. 44 Effect of direction of radiation beam on the appearance of (a) planar discontinuities (such as cracks or cold shuts) and (b) globular voids. See text for discussion.

When a section of the testpiece contains a flaw that is spherical in shape, such as a globular void or inclusion, the flaw will be revealed regardless of viewing direction. However, as shown in Fig. 44(b), the shape of a void will be undistorted only when it is aligned with the portion of the radiation beam that is perpendicular to the plane of the recording medium. Distortion is less of a problem for long source-to-detector distances and small testpieces than for short source-to-detector distances or large testpieces.

The size of almost all spherical flaws is difficult to assess. The thickness of a spherical flaw is greatest along a line through the center of the flaw and decreases to nil at the outer edge. Correspondingly, the thickness of the surrounding material is at least at the center of the spherical flaw. Thus, for example, the amount of radiation passing through the testpiece is greatest in the shadow of the center of a void. Progressively outward from the center, the image of the void will grow gradually less dense as the effective thickness of the void grows smaller, and finally the image of the void will fade into the image of the surrounding material. Images of spherical flaws are more distinct and true in size when the flaws account for a substantial portion of the thickness of the section or when the features have absorption characteristics that are markedly different from those of the matrix. Also, the image will be larger than the flaw itself, less distinct, and more likely to be distorted the farther the flaw is above the plane of the image conversion medium.

Figure 45 shows the effect of viewing direction on the image of a solid block of material. When the center of the block is aligned with the central beam and one side of the block rests on the image conversion medium (in this case, film as shown in setup 1 in Fig. 45), the central region of the image presents an undistorted view of the lower surface of the block. Surrounding the undistorted region is a region representing an enlarged view of the upper portion of the block, and surrounding this region is the penumbra. When the block is tilted onto one edge but still aligned with the central beam (setup 2, in Fig. 45), the entire image is distorted and is surrounded by a distorted penumbra. When the block rests on the film but the radiation beam is inclined to both the block and the film (setup 3, Fig. 45), only the image of the lower surface of the block remains undistorted. The remainder of the image is enlarged or otherwise distorted; the greater the object-to-detector distance, the greater the enlargement or distortion. The penumbra is enlarged or distorted similarly to the way the image is affected.

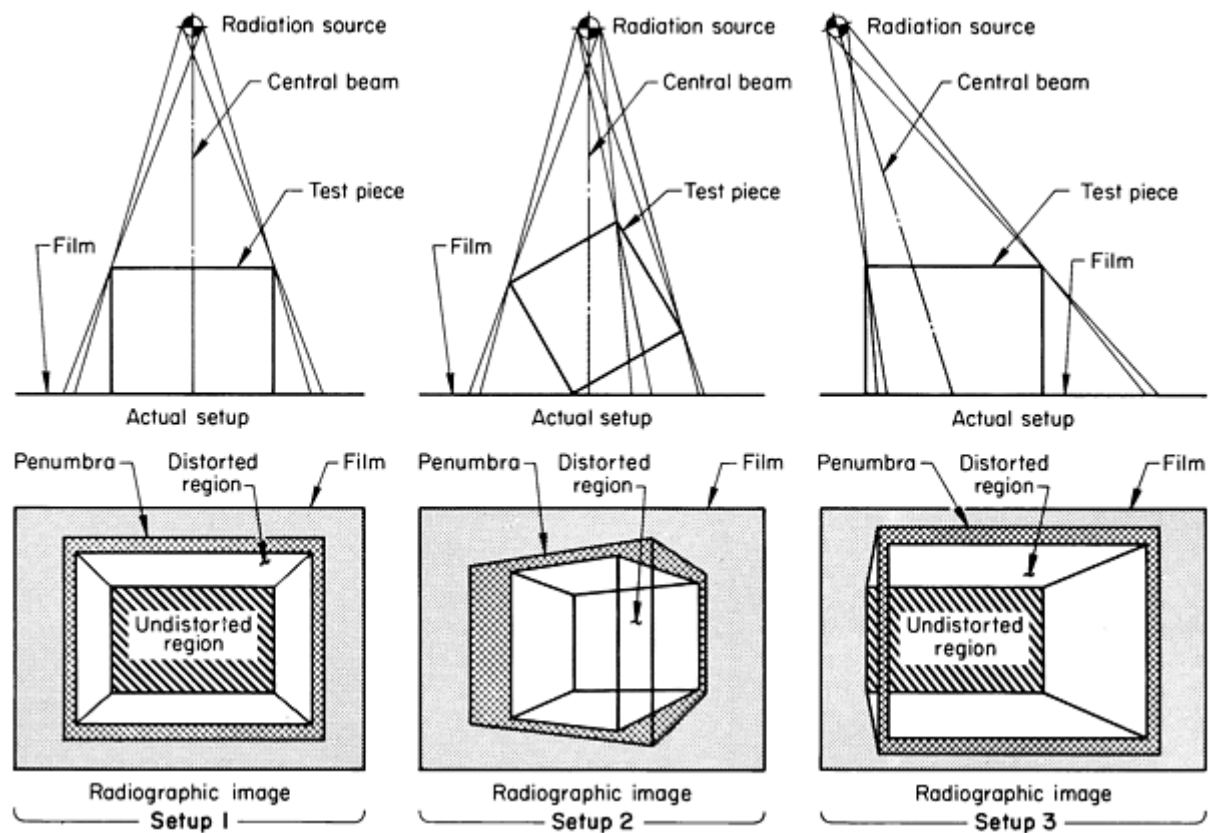

Fig. 45 Effect of viewing direction on the radiographic image of a solid block of material. See text for discussion.

It is important to understand that almost all radiographic images are somewhat distorted in size or shape or both, as compared to the actual features they represent. When viewing or interpreting radiographs, the individual features in the image should be recognized as projected shadows of the actual features in the testpiece.

Inspection of Simple Shapes

It is usually best to direct the radiation at right angles to a surface, along a path that presents minimum thickness to the radiation. This not only increases the radiation intensity reaching the detector but, more important, also ensures that any internal feature (except for a planar feature that is not parallel to the radiation beam) will generate the greatest subject contrast. Obviously, for a flaw of a given size, the difference between the amount of radiation transmitted through the material in the area of the flaw and the amount transmitted through an adjacent area will be greater if the flaw occupies a greater portion of the testpiece thickness.

When the presence of planar discontinuities (cracks) is suspected, radiation must be directed essentially parallel to the expected crack plane, regardless of testpiece thickness in that direction. In film radiography, any increased inspection cost resulting from increased exposure time is well justified because only a view parallel to the crack plane will reveal a crack.

Flat plates have the simplest shape and are usually inspected by radiography as an integral part of a more complex assembly or component. The most favorable direction for viewing a flat plate is one in which the radiation impinges perpendicular to the surface of the plate and penetrates the shortest dimension. The image is produced with minimum distortion and with maximum sensitivity and resolution of internal features.

When inspecting a difficult-to-reach region of a complex-shape part, it may be necessary to avoid superimposing the image of one section on another, by selecting a viewing direction other than 90° for a flat-plate section, as shown in Fig. 46 with film as the conversion medium. Nevertheless, except when there is a good reason to do otherwise, it is always desirable to use a viewing direction as close to 90° as possible. Except in the most unusual circumstances, views parallel

or nearly parallel to the plate surface should be avoided. These views give severely reduced resolution of detail, a high degree of image distortion, and an excessively low level of radiation intensity transmitted through the testpiece.

Fig. 46 Use of offset radiation beam to avoid superimposing image of one section of a complex-shape part on another when inspecting difficult-to-reach regions

When large areas are being radiographed, they should be inspected as a series of radiographs, each one overlapping the area of coverage of all adjacent radiographs. Use of a relatively short source-to-detector distance and multiple, overlapping radiographs is frequently more satisfactory than a single large radiograph. The long source-to-detector distance necessary to avoid the type of distortion illustrated in Fig. 44 and 45 reduces the intensity of transmitted radiation and may require frame summing in real-time radiography or longer exposures in film radiography. In film radiography, the longer exposures of the single-exposure technique may make the single-exposure technique uneconomical as compared to a multiple-exposure technique.

Curved plates are most satisfactorily inspected using views similar to those for flat plates. For optimum resolution of detail, the image conversion plane should be shaped to conform with that of the back surface of the curved plate. If the curved plate has its convex side toward the incident radiation, it is usually advantageous to minimize distortion by making multiple radiographs with reduced individual areas of coverage. If the curved plate has its concave side toward the incident radiation, a distortion-free image can be achieved by placing the source at the center of the radius of curvature. In this latter case, there is no angular limit to the area that can be inspected in a single radiograph, except for any limitations imposed by the directionality of the radiation field. Frequently, this technique is used for the on-site radiography of large-diameter pipes. The source is placed on the centerline of the pipe, and simultaneous exposures are made on one or more films wrapped around the outside of the pipe. The entire circumference is inspected with one shot because the source emits equal amounts of radiation in all directions.

This panoramic technique can also be used for the simultaneous inspection or exposure of several small parts. In a panoramic exposure, testpieces are placed in a circle around a source that emits equal radiation intensity in all directions. Separate films are placed behind each testpiece, and all are exposed at one time.

Solid cylinders can be inspected either by a longitudinal view, which is generally satisfactory only for short large-diameter cylinders, or by a transverse view, which is most satisfactory for relatively small-diameter cylinders. If the cylinder is neither short nor small in diameter, either view poses problems to the radiographer. However, in such cases, the transverse view is usually satisfactory.

The thickness of a cylindrical testpiece varies across a diametral plane in a similar manner as for a sphere, being thickest in the center and progressively thinning out to nil thickness at the edges. Edge definition is relatively good for light-metal cylinders less than about 50 mm (2 in.) in diameter and for heavy-metal cylinders less than about 25 mm (1 in.) in diameter. When the diameter of the cylinder exceeds these values, multiple radiographs using different tube voltages are usually needed to increase the latitude (or dynamic range) of the inspection. In real-time radiography, image processing can also increase the latitude for inspecting the inner and outer portions of the cylinder. In film radiography, double-film

techniques can also correct for the inevitable overexposure of the outer portions of the image. An alternative technique is to make a radiograph at the proper exposure for all but the outer portions of the image, then rotate the cylinder 90° and make a second radiograph at the same exposure.

Sometimes, section-equalizing techniques are helpful in film (or paper) radiography. In a section-equalizing technique, the outer edges of the cylinder, where the section is thinnest, are built up to present a greater radiographic density to the x-rays. Close-fitting solid cradles, liquid absorbers, or many layers of shim stock--all having radiographic absorption characteristics equivalent to those of the cylinder--are alternative means of equalizing radiographic density (Fig. 47). Regardless of the form of the absorber, it is placed in contact with the cylinder around one-half of the circumference, as shown in Fig. 47. The effect of a section-equalizing technique is to reduce the subject contrast by about one-half. This is usually sufficient to ensure that the entire image of the cylinder will have a photographic density within the range that can be interpreted correctly.

Fig. 47 Three alternative methods of equalizing radiographic density to avoid overexposure of the image of thinner portions of a solid cylinder. The solid cradle (a), liquid absorber (b), and shim stock (c) have radiographic absorption characteristics equivalent to those of the cylinder.

Because the probable orientation of planar discontinuities is difficult to define for cylinders, it is good practice to make more than one radiograph, rotating the cylinder equal amounts between them. Two radiographs, 90° apart, would be considered a minimum number.

In general, hollow cylinders (or tubular sections) present fewer problems to the radiographer than solid cylinders. For example, in hollow cylinders or tubular sections, there is much less subject contrast because of the nonabsorbing cavity in the center. The inspection of hollow cylinders is discussed in the section "Inspection of Tubular Sections" in this article.

Inspection of Complex Shapes

The inspection of complex shapes most often requires multiple exposures, usually with different viewing directions. The selection of view for each exposure depends primarily on the shape of the section of the testpiece to be inspected with that exposure and the probable orientation of suspected flaws. In principle, the view should be chosen with the objectives of minimizing geometric unsharpness and of reducing the image to a simple shape for easy interpretation. A small variation in testpiece thickness is desirable because this will highlight subject contrast due to flaws. However, the use of high-energy sources, multiple radiographs with different radiation energy levels, or double-film techniques with a single view can circumvent most problems arising from excessive material-thickness variations over a given area of coverage. The following example illustrates the use of three different views to obtain complete coverage of a cast stainless steel impeller.

Example 2: Three-View, Nine-Shot Inspection of a Large Cast CF-8M Stainless Steel Impeller.

A large impeller cast from CF-8M stainless steel (Fig. 48) was specified to be radiographically inspected in accordance with ASTM E 94, E 1030, and E 142, using the standard radiographs of ASTM E 186 and E 446 as a reference for

acceptance. The impeller was to be inspected in the as-cast, center-bored condition; specified image quality with plaque penetrameters was 2-2T.

Fig. 48 Cast CF-8M stainless steel impeller that required three different viewing directions and nine separate shots to provide complete coverage in radiographic inspection. Dimensions given in inches

Three different views were chosen to provide complete coverage of the impeller. These are shown in Fig. 48 as view A, selected to inspect the hub (a hollow cylinder) with a single shot; view B, using two shots with each providing coverage of half of the 18 volutes in the impeller; and view C, using six shots with each providing coverage of the thicker section of three volutes in a direction that is perpendicular to view B.

View A presented certain problems, namely, the high absorption of the 115 mm ($4\frac{1}{2}$ in.) thick hub, which required high-intensity radiation of relatively high energy for adequate penetration, and the bore area along the central axis, which allowed incident radiation to impinge directly on the film and favored undercut because of side scattering along the cylindrical wall of the bore. The hub could not be radiographed in a radial plane because of excessive interference by the surrounding volutes, so the bore was filled with lead shot to absorb the direct radiation in this region and to eliminate undercut.

All radiographs were made with a source-to-film distance of 1.5 in (5 ft), and 1-MV x-rays were used from a source having an 8 mm (0.3 in.) focal-spot size. Shot 1 (view A) was made with 3.0 mA tube current and 4.7-min exposure time on a 180 × 430 mm (7 × 17 in.) double film of NDT 75 (DuPont). Shots 2 and 3 (view B) were made with 1.0-mA tube current and 2.2-min exposure time on three 350 × 430 mm (14 × 17 in.) films of different types--one sheet each of NDT 45 (DuPont), Industrex M, and Industrex AA (Eastman Kodak). Shots 4 to 9 (view C) were made with 1.0-mA tube current and 2.5-min exposure time on 125 × 175 mm (5 × 7 in.) double films of Industrex M (Eastman Kodak). Lead screens, 0.13 mm (0.005 in.) thick, were used both front and back.

For control of image quality, standard ASTM penetrameters were used. The penetrameter for view A was 2 mm (0.08 in.) thick and was placed on a 110 mm ($4\frac{1}{4}$ in.) thick block adjacent to the impeller. Four penetrameters were used for view B: a 0.25 mm (0.010 in.) thick penetrameter on a 13 mm ($\frac{1}{2}$ in.) thick block, a 0.38 mm (0.015 in.) thick penetrameter on a 20 mm ($\frac{3}{4}$ in.) thick block, a 0.5 mm (0.020 in.) thick penetrameter on a 25 mm (1 in.) thick block, and a 1.15 mm (0.045 in.) thick penetrameter on a 57 mm ($2\frac{1}{4}$ in.) thick block. For view C, a 0.38 mm (0.015 in.) thick penetrameter was placed directly on the part. All penetrameters and blocks were made of austenitic stainless steel.

This procedure gave both the required complete coverage and the specified 2-2T image quality. Castings were routinely inspected to a minimum quality level corresponding to severity level 1 (in ASTM E 186) in the hub area and to severity level 2 to 3 (in ASTM E 446) in the shroud area.

Inspection of Weldments

The radiographic inspection of weldments is usually intended to cover only welds and heat-affected zones. The quality of the base metal beyond the heat-affected zones is seldom of interest at this stage of inspection. Therefore, the viewing direction is usually selected to reveal clearly the features of welds and heat-affected zones, regardless of the overall shape of the weldment. See the article "Weldments, Brazed Assemblies, and Soldered Joints" in this Volume for further information on the NDE of welds.

Arc Welds. Generally, arc-welded joints are radiographed using a viewing direction normal to the surface of the weld. For butt joints, this view directs the central beam perpendicular to the surfaces of the adjacent plates, but for other types of joints such as T-joints and lap joints, the central beam is usually inclined to both adjacent legs. The maximum area of coverage for a single radiograph is normally recommended to be no more than would result in a 6 to 10% difference in penetrated thickness between the center of the area and the extremities. Mathematically, this can be expressed for flat plates of uniform thickness as:

$$\frac{x}{2L} \leq 0.35 \text{ to } 0.46 \quad (\text{Eq 19})$$

where x is the field size, L is the source-to detector distance, and the values 0.35 and 0.46 are derived from the laws of similar triangles for 6 and 10% increase in penetrated thickness, respectively. The numerical range in Eq 19 is equivalent to a radiation-beam cone angle of about 39 to 49°. This range is not intended to limit the thickness range inspected in a single radiograph but rather to ensure the detection of transverse cracklike discontinuities by keeping the image relatively sharp and undistorted.

Views normal to the surface of the weld are not always satisfactory. Flaws in a weld such as dense inclusions due to the deposition of metal from a tungsten electrode, excessive segregation in light alloys, porosity, and shrinkage can be revealed regardless of view. However, cracks or nonfusion along the edge of the fusion zone can be best revealed when the viewing direction is parallel to the face of the joint. The detection of centerline cracks or incomplete penetration requires a normal view. Only square-groove butt joints, U-groove joints, and J-groove joints can be satisfactorily inspected with a normal view; other types of joints, including V-groove joints, bevel joints, flare joints, and fillets, require two views, one parallel to each original prepared edge, for correct inspection for cracks or regions of incomplete fusion. Certain flaws cannot be detected at all because they lie along planes that are more or less parallel to the weld surface. The shape of most weldments prohibits selection of a viewing direction parallel to the weld surface, which is the most favorable view for detecting underbead cracking or delamination. (Ultrasonic inspection is a much more suitable method for detecting either underbead cracking or delamination.)

The most favorable view for fillet welds is a direction that roughly bisects the angle between the legs of the section. Preferred arrangements for several types of fillet welds are shown in Fig. 49. Single-fillet T-joints can be inspected with the simple arrangement shown in Fig. 49(a) or with an arrangement incorporating an equalizing wedge (Fig. 49b) to reduce the inherent subject contrast caused by variations in penetrated thickness across the weld zone. The arrangement in Fig. 49(b) is more relevant for film radiography than for real-time radiography because image processing can be used in real-time radiography. In film radiography, the high subject contrast can result in overexposure of the thin section on one side of the weld or in underexposure of both the weld and thick sections. Either underexposure or overexposure reduces

sensitivity and may not resolve images of flaws having low subject contrast. An equalizing wedge is most effective when the size of the fillet weld exceeds the thickness of the thin section. The technique is mainly used on straight seams; special-shape wedges would be required for other seam shapes.

Fig. 49 Preferred viewing directions for the radiographic inspection of several types of fillet-welded joints. (a) Single-fillet T-joint. (b) Single-fillet T-joint with equalizing wedge. (c) Two adjacent single-fillet joints radiographed simultaneously. (d) Double-fillet T-joint. (e) Corner joint with film positioned at the inside surface. (f) Corner joint with film positioned at the outside surface. (g) and (h) Alternative views for double-welded lap joint

Occasionally, the shape of the weldment is such that two or more seams can be inspected with a single exposure in film radiography (Fig. 49c). The savings in time and material often justify selection of a single view whose area of coverage encompasses two or more seams. However, if the shape of the seam is such that a single view would give severely reduced sensitivity, multiple views should be specified on the radiographic standard shooting sketch.

T-joints that are welded on both sides usually cannot be inspected satisfactorily with a single radiographic view or exposure. Two radiographs, one for each fillet (Fig. 49d), are needed. Corner welds can be inspected from either side, depending on which side provides access (Fig. 49e and f). Lap joints can be inspected using multiple views or by a single view, as shown in Fig. 49(g) and 49(h). The main factor that determines which technique is most appropriate is the amount of separation between welds in a double-welded joint. When multiple views are used, the central beam of radiation should be aligned with the weld for each view, as in Fig. 49(g). When a single view is used, the central beam should be aligned with a spot midway between the welds, as in Fig. 49(h). Only a single radiograph is needed for each weld segment in a single-welded lap joint.

The techniques discussed above, particularly those for the inspection of fillet welds, are also appropriate for the inspection of junction areas of castings, forgings, and formed parts. Circumferential welds, which are one of the more usual types of arc welds inspected by radiography, can be inspected with techniques discussed in the section "Inspection of Tubular Sections" in this article.

Resistance welds, mainly spot welds and seam welds, are used to join relatively thin sheets. Most often, a resistance-welded joint can be considered a type of lap joint, with the weld positioned inboard of the overlapping edge. Usually, the only outward sign of weld position is a slight depression on the surface of the workpiece resulting from electrode pressure applied during welding.

In the radiography of spot welds and seam welds, the central beam is ordinarily directed normal to the surface of one of the sheets and is centered on the depression that indicates the location of the weld. Radiography can detect discontinuities in both weld metal and base metal, including cracks, inclusions and porosity in the weld, cracking and deformation in the

base metal, segregation in the fusion zone of resistance welds in light alloys, and expulsion of molten metal between the faying surfaces. Normally, deficiencies such as underbead cracking and incomplete fusion are not revealed by radiography, although incomplete fusion can sometimes be inferred from the presence of other discontinuities. The area of coverage should be limited in a manner similar to that suggested for arc welds so that maximum sensitivity to cracklike discontinuities can be maintained.

A view other than the normal view is sometimes dictated by the shape of the weldment, especially when portions of the weldment may cast shadows that would detract from the clarity of the weld-zone image. Even in such cases, it is best to select a view as near to normal as possible so as to minimize distortion. In contrast to arc welds, in which an oblique view adversely affects both the intensity of the transmitted radiation and the sensitivity, only sensitivity is affected to any great degree by using an oblique view for the inspection of resistance welds. Most resistance-welded assemblies are thin enough that the section can be penetrated by relatively low-energy radiation even with oblique views. The sensitivity, expressed as minimum detectable discontinuity size, varies with the cosecant of the angle between the viewing direction and the sheet surface. This relationship indicates that the smallest value of minimum detectable discontinuity size occurs with a 90° viewing direction, and viewing directions between 90° and 65° give no more than about a 10% increase in this value. The main disadvantage of oblique views is their inability to resolve the images of transverse cracks (through-thickness cracks) in either the weld or adjacent heat-affected zones.

Inspection of Tubular Sections

Although film radiography is not well suited to the inspection of continuously produced tubular products such as tubing and pipe, the method is suited to the inspection of tubular sections in a wide variety of products and assemblies. Real-time radiography, on the other hand, is more suited to the inspection of continuously produced tubular products, but not tubular sections in large, complex assemblies.

Radiography is the method most often specified for the inspection of welded joints between tubes or pipes or between a tube and a pressure vessel when the weldment is manufactured to ASME Boiler and Pressure Vessel Code specifications. Other hollow sections such as cylindrical bosses on castings and forgings, brazed tube-and-socket joints, large-diameter transmission pipe (line pipe), and longitudinally welded square or circular structural tubing, are frequently inspected by radiography. There are three major inspection techniques for tubular sections:

- The double-wall, double-image technique
- The double-wall, single-image technique
- The single-wall, single-image technique

The double-wall, double-image technique is mainly applicable to sections with an outside diameter of no more than 90 mm ($3\frac{1}{2}$ in.). This technique produces a radiograph in which the images of both walls of a tubular section are superimposed on one another. The beam of radiation is directed toward one side of the section, and the radiation conversion medium surface is placed on the opposite side, usually tangent to the section.

As shown in Fig. 50(a), two radiographs 90° apart are required to provide complete coverage when the ratio of outside diameter to inside diameter is 1.4 or less. In exposure 1 in Fig. 50(a), the area between the phantom lines is recorded as a through-thickness image, and the area outside the lines is recorded essentially as an image in the plane of the tube wall that exhibits too much subject contrast for meaningful interpretation. In exposure 2, the area outside the lines in exposure 1 is recorded as a through-thickness image, and there is a certain amount of overlap between the through-thickness images of exposures 1 and 2, which is shown as darker shading in exposure 2 in Fig. 50(a).

Fig. 50 Diagrams illustrating the relation of radiation beam, testpiece, and film for the double-wall, double-image technique of inspecting hollow cylinders or welds in tubular sections. Dimensions given in inches

When the ratio of outside diameter to inside diameter is greater than 1.4--that is, when radiographing a thick-wall tube--the number of views required to provide complete coverage can be determined by multiplying that ratio by 1.7 and rounding off to the next higher integer. For example, to examine a 50 mm (2 in.) OD cylinder with a 25 mm (1 in.) diam axial hole, a total of $1.7 \times 2 = 3.4$, or 4 views, will provide complete coverage. The circumferential displacement between each view is found by dividing 180° by the number of shots. In this case, $180^\circ/4$, or 45° , rotation of the cylinder with respect to the viewing direction is required between exposures, as shown in Fig. 50(b). The area within the phantom lines for each exposure in Fig. 50(b) indicates the region of a 50 mm (2 in.) OD cylinder with a 25 mm (1 in.) diam axial hole that is recorded as a through-thickness image; heavy shading indicates regions recorded as a through-thickness image on preceding views. If only three shots are used for a cylinder with a 2:1 ratio of outside to inside diameters, there is only a minimal amount of overlap between shots, inadequate to ensure that all detectable discontinuities in the regions of overlap will be recorded.

When an odd number of views are required for complete coverage, the angular spacing between shots can be determined by dividing 360° by the number of views as an alternative to dividing 180° by the number. This alternative cannot be used when the number of views is even, because half of the resulting radiographs would be mirror images of the remaining radiographs and sections of the outside circumference would not receive adequate coverage.

The double-wall, double-image technique can be applied to the inspection of diagonally opposite corner welds in a section of rectangular structural tubing constructed by welding four pieces of metal strip together to form a box section. Only two views are required for the inspection of all four longitudinal welds, as shown in Fig. 50(c). As with circular sections, hollow box sections can be inspected by the double-wall, double-image technique only when they are small; that is, when section height in direction or selected view is 100 mm (4 in.) or less.

A variation of the double-wall, double-image technique, sometimes called the corona or offset technique, is often used for the inspection of circumferential butt welds in small-diameter tubing and pipe. In the corona technique, the central beam is directed at an acute angle to the run of the tube (Fig. 50d) so that the weld is projected on the film as an ellipse rather than a straight band. The offset angle of the radiation beam shown in Fig. 50(d) must be large enough that the image of the upper section of the weld zone does not overlap the image of the lower portion, but not so large as to introduce an unnecessary degree of distortion. Also, the larger the offset angle, the greater the probability that the technique will fail to detect incomplete fusion at the root of the plain butt weld. Incomplete fusion at the root can have the radiographic appearance of a root void, but if it exists in a tightly butted joint or if the root gap is filled by capillary action of the

molten weld metal, incomplete fusion has the appearance of a cracklike discontinuity lying in the plane of the joint. The incident radiation must be parallel to the plane of the joint so as to detect incomplete root fusion in a tight joint.

The correct number of views and the circumferential location of corresponding views can be determined for the corona technique in the same manner as for the basic double-wall, double-image technique. Sometimes, as when a weld must be inspected for both radial cracks and internal voids, it is beneficial to use both the basic technique and the corona technique--the former to detect cracks and the latter to locate voids.

In all variations of the double-wall, double-image technique, the image of the section of the cylinder wall that is closest to the radiation source will exhibit the greatest amount of enlargement, the greatest degree of shape distortion, and the greatest degree of unsharpness. Selection of proper source-to-detector distance should be based on obtaining the specified image quality for that section of the cylinder. Also, penetrameters should be located where they will evaluate the image of the section closest to the source.

The double-wall, single-image technique is mainly applicable to hollow cylinders and tubular sections exceeding 90 mm ($3\frac{1}{2}$ in.) in outside diameter. This technique produces a radiographic image of only the section of the wall that is closest to the imaging plane, although the radiation penetrates both walls. The source is positioned relatively close to the section, so that blurring caused by geometric unsharpness in the image of the cylinder wall closest to the source makes the image completely indistinguishable. Only the image of the wall section closest to the detector is sharply defined.

In film (or paper) radiography, exposures are calculated on the basis of double the wall thickness of the hollow section, as they are for the double-wall, double-image technique. The area of coverage is limited by geometric unsharpness and distortion at the extremities of the resolved image for hollow cylinders that are less than about 380 mm (15 in.) in outside diameter. For larger cylinders, film size is the usual limiting factor. Usually, at least five separate exposures equally spaced around the circumference are required for complete coverage. There must be enough overlap between adjacent exposures to ensure that all of the outside circumference is clearly recorded.

The radiation is usually directed normal to the surface of the cylinder. However, in some cases, it may be advantageous to use viewing direction similar to that of a corona exposure. For example, if a circumferential weld has a high and irregular crown, it may be desirable to have the radiation that impinges on the area of the weld being inspected pass through the tube wall adjacent to the weld so that the incident radiation is attenuated by a more uniform and thinner section, as shown in Fig. 51.

Fig. 51 Schematic of the double-wall, single-image inspection technique applied to a circumferential butt weld in a large-diameter pipe showing relation of radiation beam, weld, and film

The **single-wall, single-image technique** is an alternative to either of the double-wall techniques and can be used only when the interior of a section is accessible. With this technique, the radiation source can be placed outside the cylinder and the radiation detector inside the cavity (Fig. 52a), or the detector can be placed outside the cylinder and the radiation source inside (Fig. 52b). In both setups, only a single wall is radiographed. A significant advantage of the single-wall technique is that it is more sensitive than double-wall techniques because any flaw that may be present occupies a greater percentage of the penetrated thickness.

Fig. 52 Schematic of techniques employing different arrangements of radiation source, cylinder, and film for the single-wall, single-image radiography of cylindrical sections using external and internal radiation sources. See text for discussion.

When using the technique shown in Fig. 52(a), the cylinder is rotated to generate a series of radiographs. In film radiography, the amount of rotation must be controlled so that successive radiographs contain regions of overlap. The correct amount of overlap can be proved by placing lead view markers on the surface that is remote from the film; if the image of a view marker appears in both adjacent radiographs, complete coverage is ensured.

In the technique shown in Fig. 52(b), the radiation source is placed inside the cylinder, and one continuous piece of film is wrapped around the outside of the cylinder. Alternatively, several overlapping pieces can be used, as shown in Fig. 52(c). The radiation source, which is usually either a rod-anode type of x-ray tube having 360° radiation emission or a γ -ray source, is placed on the central axis of the hollow cylinder. The entire circumference is inspected with one exposure, regardless of whether a single strip of film or several overlapping pieces are used.

Special adaptations of these techniques can be used. For example, when maximum sensitivity is required for the technique in Fig. 52(b), the radiation source can be moved to a position close to the inside surface of the cylinder diametrically opposite a single piece of film, as illustrated in Fig. 52(d). This adaptation can almost double the source-to-film distance, thus reducing geometric unsharpness by almost 50%. Although there is a gain in sensitivity, there is a loss in efficiency because the entire circumference can no longer be inspected by a single exposure. Several exposures must be made, with the radiation source and film repositioned to several points equally spaced around the circumference to obtain complete coverage.

Another special adaptation is shown in Fig. 52(e). In this arrangement, a continuous piece of film is placed in contact with the inside surface of the cylinder. The film is held in place by a close-fitting, lead-covered mandrel. Incident radiation is directed through a slit in a lead diaphragm to impinge on a narrow section of the circumference of the cylinder. The cylinder, film, and mandrel are rotated slowly past the slit one or more times, so that the total time that a given point on the cylinder is in front of the slit equals the required exposure time. Radiographs produced in this manner are remarkably clear and distinct compared to other single-wall or double-wall techniques. Because the radiation beam impinges on only a narrow region of the cylinder and because the film is in contact with the inner surface, both geometric unsharpness and variations in transmitted intensity caused by variations in penetrated thickness are minimized. As a result, the subject contrast and definition of internal flaws are maximum. The technique shown in Fig. 52(e) is a form of in-motion radiography.

In-Motion Radiography

In-motion radiography is useful when large areas must be inspected. Generally, real-time radiography is more suitable for in-motion radiography because a detector can be used to scan the test area during motion. Nevertheless, in-motion film radiography can be used to inspect longitudinal welds in very large pipe, such as line pipe. In one method, a portable x-ray unit is attached to a traveling carriage inside the pipe and is positioned so that a narrowly collimated x-ray beam impinges on the weld, as shown in Fig. 53(a). The carriage moves slowly along the pipe, successively exposing a series of films placed along the outside surface over the weld. The correct rate of travel is equal to the width of the beam in the direction of relative motion divided by the required exposure time.

(a)

(b)

Fig. 53 Arrangements for the in-motion single-wall, single-image film radiography of longitudinal welds in line pipe, using (a) a conventional portable x-ray unit and (b) a rod-anode x-ray tube

An alternative setup for in-motion film radiography, in which a rod-anode x-ray tube is substituted for the portable x-ray unit, is shown in Fig. 53(b). The principle of operation is the same; only the x-ray equipment and method of travel are different. This setup is particularly advantageous when two or more welded joints are to be radiographed because the joints can be radiographed simultaneously. With a rod-anode tube, radiation is emitted 360° around the axis of the tube. As long as the center of the target is maintained on the axis of the pipe, the disk of radiation that emerges between the two lead disks that act as a collimator will produce equal nominal film densities on all radiographs. Even with the portable x-ray unit illustrated in Fig. 53(a), the source-to-film distance must be kept constant because if the distance is permitted to vary there will be a gradual change in nominal film density from radiograph to radiograph as the radiation source moves along the pipe.

The principal advantage of in-motion radiography is that less time is needed for setup and operation. The inspection of long welds by conventional methods requires frequent repositioning of the testpiece with respect to the source and film; consequently, there is a considerable amount of time spent in setting up for successive exposures. With in-motion radiography, a much smaller proportion of total inspection time is required for setup. Therefore, in-motion radiography is seldom, if ever, accomplished with a radioactive source.

Techniques similar to those described above for radiographing longitudinal welds in large-diameter pipe can also be adapted for other product forms when radiographic inspection is to be applied to long testpieces. Also, it may be desirable to adapt in-motion radiography for the inspection of relatively small parts, especially when the diverging beam used in normal radiography would cause unacceptable distortion at the edges of the radiograph.

In general, a real-time radiographic technique is preferred for in-motion radiography. However, if only film techniques are available, then in-motion radiography would be considered whenever more than four to six shots are required for complete coverage of a long straight or circumferential weld in a relatively thin section. It is essential that the source move at constant speed in film radiography because any variations in speed will produce parallel bands of overexposure and underexposure in the radiograph, oriented at right angles to the direction of relative motion.

Motion Unsharpness. The real-time and film techniques used for in-motion radiography cause a specific type of unsharpness called motion unsharpness. Any amount of relative motion of source or testpiece with respect to the image conversion plane results in blurring of the image; the greater the amount of motion, the greater the blurring. In conventional still radiography, it is considered good practice to eliminate all sources of motion, even vibrations, so that motion unsharpness does not detract from radiographic quality. The amount of unsharpness caused by relative motion of the source with respect to the testpiece and detector in in-motion radiography can be evaluated from characteristics of the setup, much as geometric unsharpness is evaluated for conventional techniques. Motion unsharpness, U_m , is described by:

$$U_m = \frac{wt}{L_o} \quad (\text{Eq 20})$$

where w is the width of the radiation beam in the direction of motion, t is the penetrated thickness, and L_o is the source-to-object distance.

Motion unsharpness is generally greater for in-motion radiography than geometric unsharpness for an equivalent conventional technique. This limits the use of in-motion techniques to thin testpieces or to situations in which a long source-to-detector distance can be used. It is essential that there be no relative movement between testpiece and detector, so that only the movement of the source contributes to motion unsharpness.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Identification Markers and Penetrameters (Image-Quality Indicators)

It is important to relate a particular radiographic image to the direction of the radiation beam used to generate that image. Furthermore, it is important that any permanent record of inspection be traceable to the particular testpiece that was inspected or to the production lot represented by that testpiece. Identification markers are used for these purposes.

In addition to identification, the image should contain some means of evaluating the radiographic procedure in terms of its sensitivity to test conditions. This sensitivity, known as image quality, bears directly on the ability of the radiographic process to record images of small flaws and is usually determined by the use of penetrameters, which are also called image-quality indicators.

Identification Markers

Identification markers are made of lead or lead alloy and are usually in the form of a coded series of letters and numbers. The markers are placed on the testpiece or on the film adjacent to the testpiece during setup. When the testpiece is radiographed, a distinct, clear image of the radiographically dense identification markers is produced at the same time. Identification markers must be located so that their projected shadows do not coincide with the shadows of any regions being inspected in the testpiece. Because markers are radiographically dense, their images will obscure any coinciding image of the testpiece.

Both view identification and testpiece identification almost always appear in coded form. View identification is usually a simple code (such as A, B, C, or 1, 2, 3) that relates some inherent feature of the testpiece or some specific location on the testpiece to the view used; the term sequence numbering, which is used in some specifications, refers to view identification. Often, the location of view markers is handwritten in chalk or crayon directly on the testpiece so that the radiographic image can be correlated with the testpiece itself during interpretation and evaluation of the radiograph. Sometimes, the locations of markers are steel-stamped on the surface of the part being radiographed and become a permanent reference. It is advisable always to mark the location of view markers because it may be necessary to recheck the setup procedure against specifications. Although the specific location of view markers is largely a matter of personal preference, several suggested arrangements are discussed in this section. It is required only that the markers be placed so that their images on the radiograph are legible and do not obscure any area being inspected.

View markers need not be different if identical viewing directions are used for radiographing a series of testpieces of the same type and size. Actually, it is much simpler to begin at the letter "A" or the number "1" for view identification on each individual testpiece. Most radiographers adopt standard methods of identifying views and indicate the type of view markers to be used on the specification sheet for the radiographic procedure, which is commonly called a radiographic standard shooting sketch.

The code for identification of the testpiece is usually more complex than the code used for identification of viewing direction. Each radiographic laboratory must adopt a system of identification that is suited to its specific requirements. As a minimum requirement, the identification code must enable each radiograph to be traced to a particular testpiece or section of a testpiece. Identification codes can be based on part number, lot number, inspection date, customer code, or manufacturing code; or they can be merely a series of consecutive multiple-digit numbers, with the pertinent data concerning testpiece identification recorded in a logbook opposite the corresponding testpiece number.

Penetrameters

Penetrameters, or image-quality indicators, are of known size and shape and have the same attenuation characteristics as the material in the testpiece. They are placed on the testpiece or on a block of identical material during setup and are radiographed at the same time as the testpiece. Penetrameters are preferably located in regions of maximum testpiece thickness and greatest testpiece-to-detector distance and near the outer edge of the central beam of radiation. Because of this location, the degree to which features of the penetrometer are visible in the developed image is a measure of the quality of that image. The image of the penetrometer that appears on the finished radiograph is evaluated during interpretation to ensure that the desired sensitivity, definition, and contrast have been achieved in the developed image.

Penetrameters of different designs have been developed by various standards-making organizations; several of the standard designs most widely used are shown in Fig. 54. Regardless of the design, all penetrameters have the following in common:

- Material used for penetrameters is the same as that of the testpiece or has the same absorption characteristics. Suitable penetrometer materials for various metallic testpieces are grouped in ASTM E 1025 and E 142 as shown in Table 8
- In use, the penetrometer is normally placed directly on the surface of the testpiece that faces the source. Alternatively, when the testpiece is small or when its shape is unfavorable, the penetrometer is placed on

a block or shim of the same nominal composition and thickness as the testpiece, with the upper surface of the block at the same distance from the recording plane as the upper surface of the testpiece. In pipe radiography, when permitted by specification, the penetrameter can be placed on the surface of the pipe that faces the film. This film-side placement of the penetrameter is usually read to a tighter sensitivity requirement (for example, 2-1T instead of 2-2T)

- The location of the penetrameter should be such that its projected image does not coincide with any area of interest in the image of the testpiece
- The image of the penetrameter is viewed at the same time as the image of the testpiece; the two images appear simultaneously on the recording medium. The image of the penetrameter is evaluated separately from the image of the testpiece and is used solely as a direct check on the quality of the recorded image
- Image-quality levels are usually expressed as the size of the smallest penetrameter feature (such as hole size or wire size) that is clearly visible in the processed image
- A penetrameter is never used as a size standard against which flaw sizes are compared

Table 8 ASTM penetrameter material grades for the material groups in ASTM E 1025 and E 142

Material groups of testpieces	Suitable penetrameter grade and material
Group Mg: magnesium	Penetrameter grade 000: made of all magnesium, or magnesium being the predominant constituent
Group Al: aluminum	Penetrameter grade 00: made of all aluminum, or aluminum being the predominant constituent
Group Ti: titanium	Penetrameter grade 0: made of all titanium, or titanium being the predominant constituent
Group 1: all carbon steels, all low-alloy steels, all stainless steels, manganese-nickel-aluminum bronze	Penetrameter grade 1: carbon steel or type 304 stainless steel
Group 2: all aluminum bronzes, all nickel-aluminum bronzes, Haynes alloy IN-100	Penetrameter grade 2: may be aluminum bronze (Alloy No. 623 of ASTM Specification B 150) or equivalent, or nickel-aluminum bronze (Alloy No. 630 of Specification B 150) or equivalent
Group 3: nickel-chromium-iron alloys and 18% Ni maraging steel. Some specific alloys include: Haynes alloy No. 713C, Hastelloy alloy D, G.E. alloy SEL, Haynes Stellite alloy No. 21, GMR-235 alloy, Haynes alloy No. 93, Inconel X, Inconel 718, Haynes Stellite alloy No. 6 S 816	Penetrameter grade 3: nickel-chromium-iron alloy UNS N06600 or equivalent
Group 4: nickel, copper, all the nickel-copper series or copper-nickel series of alloys, all the brasses (copper-zinc alloys) exclusive of leaded brasses. There is no restriction on using grade 4 penetrameters for the leaded brasses, because they are more attenuating of radiation, the degree depending on the lead content. This would be equivalent to using a lower grade penetrameter, which is permissible.	Penetrameter grade 4: may be 70Ni-30Cu alloy (Monel) (Class A or B of ASTM Specification B 164) or equivalent, or 70Cu-30Ni alloy (Alloy G of ASTM Specification B 161) or equivalent
Group 5: tin bronzes including gun metal and valve bronze, but excluding any leaded tin bronzes of higher lead content than valve bronze. There is no restriction on using grade 5 penetrameters for bronzes of higher lead content,	Penetrameter grade 5: tin bronze (Alloy D of ASTM Specification B 139) or equivalent

because they become more attenuating of radiation with increasing lead content. This would be equivalent to using a lower grade penetrameter, which is permissible.

Fig. 54 Designs of several widely used penetrameters (image-quality indicators). (a) Rectangular plaque-type penetrameter (ASTM-ASME standard) for plaque thicknesses of 0.13 to 1.3 mm (0.005 to 0.050 in.). (b) Circular plaque-type penetrameter (ASTM-ASME standard) for plaque thicknesses of 4.6 mm (0.180 in.) or more. (c) Typical wire-type penetrameter (Deutsche Industrie Norm standard DIN 54109). (d) Square-step wedge penetrameter used by British Welding Research Association (BWRA standard). (e) Hexagonal and (f) linear triangular-step wedge penetrameters used by the French Navy (AFNOR standard). Dimensions given in inches, except where otherwise indicated

Applicable codes, specifications, or purchase agreements usually determine the type of penetrameter to be used. Even when the specification does not require the use of a penetrameter, it is advisable to use a penetrameter to ensure that appropriate image quality has been achieved. Some of the standard penetrameters, including those illustrated in Fig. 54, are described below.

Plaque-type penetrameters consist of strips of materials of uniform thickness with holes drilled through them. There are two general types of plaque penetrameters specified by ASTM and the American Society of Mechanical Engineers (ASME): rectangular plaque penetrameters (Fig. 54a) and circular plaque penetrameters (Fig. 54b).

The rectangular plaque design shown in Fig. 54(a) is specified by ASTM and ASME for plaque thicknesses of 0.13 to 1.3 mm (0.005 to 0.050 in.). The holes in rectangular plaque penetrameters are T, 2T, and 4T in diameter, where T is the thickness of the plaque. A notch system (Fig. 55) is also used to identify the ASTM grade of the penetrameter. For example, the penetrameter shown in Fig. 54(a) would be a grade 1 penetrameter for testpiece materials in group 1 of Table 8.

The circular plaque design is larger than the rectangular plaque design and is specified for plaque thicknesses of 1.5 to 4 mm (0.060 to 0.160 in.). Figure 54(b) shows the circular design specified by ASTM and ASME for plaque-type penetrameters with thicknesses of 4.6 mm (0.180 in.) or more.

Various degrees of image quality can be measured by using plaque-type penetrameters of different thicknesses. Sensitivity is usually expressed in terms of penetrameter thickness (as a percentage of testpiece), and resolution is determined by the smallest hole size visible in the radiograph. For example, an image-quality level of 2-2T indicates that the thickness of the penetrameter equals 2% of section thickness and the 2T hole is visible. If image quality of 1-1T were required, a radiograph would be acceptable if the outline of a 1% penetrameter were distinguishable. Alternatively, image quality can be expressed as a percentage only. In the ASTM or ASME systems, the equivalent sensitivity in percent is based on visibility of the 2T hole. Table 9 lists equivalent sensitivities for various standard image-quality levels.

Table 9 Equivalent sensitivities of various standard ASTM or ASME sensitivity levels

Equivalent sensitivity is a percentage equivalent for penetrameter thickness in which 2T is the smallest distinguishable hole size. For example, 1-1T is equivalent to 0.7-2T.

Image-quality level	Penetrameter thickness, % of testpiece thickness	Smallest visible hole size	Equivalent sensitivity, %
1-1T	1	1T	0.7
1-2T	1	2T	1.0
2-1T	2	1T	1.4
2-2T	2	2T	2.0
2-4T	2	4T	2.8
4-2T	4	2T	4.0

Wire-type penetrameters are widely used in Europe, and a standard design is used in the United Kingdom, Germany, the Netherlands, and Scandinavia and by the International Organization for Standardization (ISO) and the International Institute of Welding (IIW). In the United States, the penetrameter design specified in ASTM E 747 is widely used. The ISO design of wire-type penetrameters has a group (typically seven) of straight 30 mm (1.2 in.) wires made of the same material as the testpiece. The diameters of the seven wires are sized in a geometric progression from a range of 21 wire sizes with a numbered geometric progression of diameters ranging from wire number 1 (0.032 mm, or 0.00126 in., in diameter) to wire number 21 (3.200 mm, or 0.126 in., in diameter). This ISO standard is similar to the standard of Deutsche Industrie Norm (DIN 54109), which consists of sixteen wire sizes of three metals--steel, aluminum, and copper. However, the wire numbers in the DIN standard are the reverse of the ISO standard; in the DIN standard, wire diameters decrease in geometric progression from wire number 1 (which has a 3.20 mm, or 0.126 in., diameter) to wire number 16 (which has a 0.10 mm, or 0.004 in., diameter).

The wire sizes on a wire penetrameter consist of different groupings. In the DIN system, for example, a wire penetrameter may have one of three groupings of seven wire sizes:

- One group contains wire numbers 1 through 7, which correspond to wire diameters of 3.20 through 0.80 mm (0.126 through 0.031 in.)
- The second group (Fig. 54c) contains wire numbers 6 through 12, which correspond to wire diameters of 1.00 through 0.25 mm (0.039 through 0.010 in.)
- The third group contains wire numbers 10 through 16, which correspond to wire diameters of 0.40 through 0.10 mm (0.016 through 0.004 in.)

Regardless of whether the wire type is designed to ISO, DIN, or ASTM specifications, image quality is denoted by the wire number of the thinnest wire distinguishable on the radiograph. In contrast to the plaque system, however, the wire system does not provide constant sensitivity, because the sensitivity varies with testpiece thickness. Therefore, the equivalent sensitivities of wire penetrameter indications are defined for a range of testpiece thickness (as indicated in Table 10 for the DIN system). Table 11 lists the wire sizes equivalent to a 2-2T sensitivity for a variety of testpiece thicknesses.

Table 10 DIN specification for minimum image quality and equivalent-sensitivity range for each range of testpiece thickness

Minimum image quality is expressed as wire number (BZ) of thinnest wire distinguishable in radiograph.

Testpiece thickness		High-sensitivity level (category 1)		Normal-sensitivity level (category 2)	
mm	in.	Wire No., BZ	Equivalent sensitivity, %	Wire No., BZ	Equivalent sensitivity, %
0-6	>0-0.25	16	1.7 min	14	2.7 min
6-8	0.25-0.30	15	2.0-1.6	13	3.3-2.5
8-10	0.30-0.40	14	2.0-1.6	12	3.1-2.5
10-16	0.40-0.60	13	2.0-1.3	11	3.2-2.0
16-25	0.60-1.00	12	1.6-1.0	10	2.5-1.6

- (a) Wire diameters for use with specimens less than 13 mm ($\frac{1}{2}$ in.) in thickness do not represent the true 2-2T level. They follow the same relationship as the hole type.

Step wedge penetrameters usually have either an arithmetic or a geometric progression of step thicknesses. A plain step wedge penetrometer is useful only for determining the ability of a radiograph to resolve variations in testpiece thickness; it cannot be used to evaluate the effect of imaging unsharpness, which is often the chief factor that determines image quality. However, if a plain step wedge is modified by drilling holes in each step, it becomes sensitive to imaging unsharpness. This type of design is used by the British Welding Research Association (BWRA) and the French Navy (AFNOR). In the BWRA design (Fig. 54d), the holes in a given step wedge are all of the same size--0.635 mm (0.025 in.) diameter for the step wedge ranging from 0.13 to 1.0 mm (0.005 to 0.040 in.) in step thickness and 1.3 mm (0.050 in.) diameter for the step wedge ranging from 1.0 to 2.0 mm (0.040 to 0.080 in.) in step thickness. AFNOR step wedges (Fig. 54e and f) have holes that are the same in diameter as the step thickness. The BWRA standard specifies a uniform increment between step thicknesses; the AFNOR standard specifies a constant ratio between successive thicknesses (similar to that of successive wire diameters in the DIN standard). The BWRA standard incorporates only two penetrameters, both of which are shown in Fig. 54(d). The AFNOR standard specifies penetrameters having four different series of step thicknesses, as follows:

Series	Step thicknesses, mm
1	0.125, 0.16, 0.20, 0.25, 0.32, 0.40
2	0.32, 0.40, 0.50, 0.63, 0.80, 1.00
3	0.80, 1.00, 1.25, 1.60, 2.00, 2.50
4	2.00, 2.50, 3.20, 4.00, 5.00, 6.30

The four series cover the entire range of testpiece thicknesses from about 4 to 300 mm (1.6 to 12 in.). Series 3 is illustrated as a hexagonal penetrometer in Fig. 54(e), and series 2 is illustrated as a linear penetrometer in Fig. 54(f).

Both the BWRA and AFNOR penetrameters are sensitive to image definition and to contrast. Definition is judged on the visibility of holes in the specified step. Sometimes, the image quality defined by a step wedge penetrometer is somewhat ambiguous because the image can be evaluated both on the visibility of steps and on the visibility of holes. When contrast is good and definition is poor, more steps than holes can be seen on the radiograph. However, when the image quality is judged as intended--that is, on the visibility of individual holes for AFNOR penetrameters and on the visibility of the symbol (not necessarily the visibility of individual holes) for BWRA penetrameters--the step wedge penetrameters are quite sensitive to variations in radiographic technique. One minor limitation of AFNOR penetrameters is that the hole size in the thinnest steps are comparable to the size of graininess visible in the radiograph. Sometimes it is not easy to be certain that a hole is visible, but the use of two holes in the thinnest steps partly overcomes this limitation.

Penetrameters for electronic components use spherical particles and wire sizes, typical of the wire used in such devices, for determinations of resolution or sensitivity. The wires are arranged in a three-dimensional grid with close-toleranced spacing for the purpose of providing a measure of distortion. The image of the grid is measured on the radiograph, and the distortion is calculated by:

$$D = \frac{(S_m - S_A) 100}{S_A} \quad (\text{Eq 21})$$

where D is the percent distortion, S_m is the wire spacing as measured on the radiograph, and S_A is the actual wire spacing.

The ASTM standard E 801 describes a set of eight penetrameters having different cover thicknesses and wire sizes. The cover densities and wire sizes are typical of the case materials and internal connecting wires of electronic components. Two of these penetrameters are typically used for each exposure--usually the number having the density closest to that of the component being radiographed and the next-higher-number penetrameter. Because electronic components are typically exposed in groups, the penetrameters are placed at opposing corners of the group edges. This ensures that the worst-case parameter values will be indicated.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Placement of Identification Markers and Penetrameters

The location of identification markers with respect to the testpiece is important only to the extent that shadows cast by the identification markers should not obscure shadows cast by the testpiece itself. This is accomplished most easily by attaching the lead letters or numbers to the film holder in a region outside the area being inspected, usually along the edges of the holder. When it is important to ensure that identification markers do not obscure the image of some well-defined region of the testpiece, such as a weld, it may be desirable to attach the identification markers to the testpiece adjacent to that region.

When several views of the same testpiece are to be shot, it is good practice to attach an identification (view) marker to the testpiece at each end of the area to be inspected in each view. These markers should be left in place until after the adjacent exposures have been shot. Each view marker should be visible in two adjacent radiographs; if it is not, incomplete coverage has been obtained. In some codes and specifications, this practice (known as sequence numbering) is required.

It is desirable to mark the testpiece with chalk, crayon, or a metal stamp to indicate the exact location of identification markers. This can avoid possible difficulties either in identifying defective testpieces or in correlating radiographs with testpieces.

The placement of penetrameters is important because incorrect placement with respect to the testpiece can result in an incorrect assessment of image quality. On simple shapes, especially flat plates and similar shapes of uniform thickness, it is seldom necessary to be concerned about factors other than placing the penetrameter where it will properly represent maximum unsharpness, will not obscure any region being inspected, and will be located in the outer cone of the radiation beam.

When the shape of a testpiece is complex or when there is a large variation in the thickness of the testpiece, placement of penetrameters can be critical. Several suggested means of achieving proper placement of penetrameters are shown in Fig. 56 for welds between plates of different thickness and for circumferential welds in pipe. When no level testpiece surface is available for placement of the penetrameter, penetrameter blocks placed beside the testpiece are the only reasonable alternative. It is sometimes advantageous to use a stepped wedge as a penetrameter block, with the penetrameter on each step. For example, in the technique used for three-view inspection of the large cast stainless steel impeller discussed in Example 2 in this article, four penetrameters ranging in thickness from 0.25 to 1.15 mm (0.010 to 0.045 in.) were used for six of the exposures. The four penetrameters, each placed on a different block between 13 and 57 mm ($\frac{1}{2}$ and $2\frac{1}{4}$ in.)

thick, were needed for assurance that the specified level of image quality was achieved over the entire range of impeller thicknesses.

Fig. 56 Correct placement of view markers, location markers, and penetrameters for radiographic inspection. Dimensions given in inches

Even though the following discussion and Fig. 56 illustrate the placement of markers and penetrameters on weldments, similar locations for markers and penetrameters can be used on testpieces that do not contain welds. In all arrangements, penetrameters should be placed in the outer cone of the radiation beam.

Radiography of Plates. Figure 56(a) illustrates three alternative arrangements of penetrameters and identification markers for the radiography of a weld joining one plate to another plate of different thickness. In all three arrangements, the identification markers and penetrameters are placed parallel to the weld. View markers and penetrameters are usually placed 3 to 20 mm ($\frac{1}{8}$ to $\frac{3}{4}$ in.) from the edge of the weld zone, but no more than 40 mm ($1\frac{1}{2}$ in.). Testpiece identification markers, however, can be placed farther away if necessary to ensure that their image is outside the image of the weld zone in the processed radiograph. Identification markers are usually placed on the film but view markers should be placed on the surface of the testpiece closest to the radiation source so that correct overlap between adjacent exposures can be verified. (If the view markers were located on the film side, a portion of the testpiece directly above the view markers could be missed even though the images of the markers appeared in adjacent radiographs.)

In Fig. 56(a), the preferred setup (setup 1) has two penetrameters located on the thinner plate. In the alternative setups (setups 2 and 3), two penetrameters are located on the thicker plate (setup 2) or one penetrameter on each plate (setup 3). Shims made of an alloy that has the same absorption characteristics as the weld metal are used under the penetrameters in each instance to compensate for any difference between the thickness of the weld zone, including reinforcement, and the thickness of the plate on which the penetrameter is located. Any shim used should be larger than the penetrameter placed on it, so that the image of the penetrameter can be clearly seen within the umbral image of the shim. Also, the direction of radiation with respect to shim and penetrameter location should be considered, especially with thick shims or penetrameter blocks, to ensure that the shim properly represents the effective penetrated thickness of the testpiece.

Some codes and specifications require that the image of a penetrameter be used to evaluate the quality of only that portion of the radiographic image of the testpiece that has similar photographic density. Strict limits can be placed on the allowable density difference between penetrameter image and testpiece image. For this reason, it may be necessary to use two or more penetrameters to evaluate image quality in different regions on the radiograph. When plaque-type penetrameters are used, plaques of different thickness are used for different regions, depending on testpiece thickness in each region.

Radiography of Cylinders. Figures 56(b), 56(c), and 56(d) illustrate alternative locations for markers and penetrameters for the double-wall, double-image radiography of hollow cylinders or welded pipe. These alternatives can be used for either normal or offset (corona) views. When the penetrameter is placed on the cylinder itself, as shown in Fig. 56(b), or on a short section of pipe having the same diameter and wall thickness as the pipe being inspected, as shown in Fig. 56(c), any shim that is used under the penetrameter should be only thick enough to compensate for weld reinforcement; that is, twice the nominal reinforcement for a normal view, but equal to the nominal reinforcement for an offset (corona) view. If the testpiece is a plain cylinder or if a circumferential butt weld is flush with the surface, no shim is needed. When a penetrameter block is used to provide equivalent penetrated thickness under the penetrameter, the block thickness should equal twice the nominal wall thickness of the cylinder plus twice the nominal weld reinforcement. Also, the penetrameter block should be set on a block of Styrofoam or similar nonabsorbing material so that the upper surface of the penetrameter block is aligned with the upper surface of the pipe, as shown in Fig. 56(d). When a short section of pipe is used under the penetrameter (Fig. 56c), the radiation source should be centered between the pipe being inspected and the short pipe section; otherwise, the radiation source should be centered above the pipe being inspected. To ensure that the penetrameter image is within the umbral region of the image of a shim or penetrameter block, the penetrameter should be aligned with the edge of the shim or block closest to the central beam of radiation.

Figures 56(e), 56(f), and 56(g) illustrate alternative setups for the double-wall, single-image radiography of hollow cylinders or welded pipe. These alternatives are suitable for both normal and offset (corona) views. As for a double-wall, double-image technique, the penetrameter can be placed on the pipe itself--on a short section of pipe being inspected or on a penetrameter block. The setup illustrated in Fig. 56(e) can be used when there is access to the inside of the pipe for placement of the penetrameter. When a shim is used under the penetrameter (Fig. 56e and f), it should be equal to the height of nominal weld reinforcement, regardless of the view that is used. When there is no reinforcement, no shim is needed. If the penetrameter is placed on a penetrameter block, as in Fig. 56(g), the block should be equal to twice the

nominal wall thickness plus the nominal height of weld reinforcement, not plus twice the nominal reinforcement as with the double-wall, double-image technique. Radiation-source location with respect to the testpiece and the location of the penetrameter on the block or shim are the same as for a double-wall, double-image technique.

In any setup for single-wall, single-image radiography, the penetrameters can be placed only on the testpiece because the film is always on one side of the wall and the source on the other side. Figures 56(h), 56(j), and 56(k) illustrate alternative arrangements for single-wall, single-image radiography. Shims, when used, need only compensate for any weld reinforcement. When the radiation source is external, as in Fig. 56(h), location markers should be placed on the outside surface for assurance that the correct overlap between adjacent exposures has been achieved. There should be a minimum of one penetrameter and one set of view and location markers per film, except that there should be three or more penetrameters and sets of markers (spaced equally around the circumference of the pipe) when a 360° simultaneous exposure is made on a single strip of film, as shown in Fig. 56(k). A minimum of three penetrameters is needed for assurance that the radiation source was actually located on the central axis of the cylinder and that equal intensity of radiation was incident on the entire circumference. When a 360° simultaneous exposure is made on overlapping pieces of film, not only should penetrameters be placed so that one appears on each piece of film, but also view markers and location markers should be placed so that they coincide with the regions of overlap between adjacent pieces of film.

Radiography of Flanges. Although single-image techniques (especially the single-wall, single-image technique) are ordinarily used with a normal (vertical) viewing direction, there are applications in which an offset view is advantageous. Three setups for the single-image radiography of flanged pipe using offset views are illustrated in Fig. 56(m), 56(n), and 56(p). The principles of location-marker and penetrameter placement are similar to those previously discussed for normal views; the only difference is that extra precautions must be taken to ensure that the projected images of markers or penetrameters do not fall on the image of any region being inspected.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Control of Scattered Radiation

Although secondary radiation can never be completely eliminated, numerous means are available to reduce its effect. The various methods, which are discussed below in terms of x-rays, include:

- Use of lead screens
- Protection against back scatter and scatter from external objects
- Use of masks, diaphragms, collimators, and filtration

Most of the same principles for reducing the effect of secondary x-rays apply also to γ -ray radiography. However, differences in application arise because of the highly penetrating characteristics of gamma radiation. For example, a mask for use with 200-kV x-rays could be light enough in weight for convenient handling, yet a mask for use with cobalt-60 radiation would be much thicker, heavier, and more cumbersome. In any event, with either x-rays or γ -rays, the means for reducing the effects of secondary radiation must be selected with consideration of cost and convenience as well as the effectiveness.

Lead screens placed in contact with the front and back emulsions of the film diminish the effect of scattered radiation from all sources by absorbing the long-wavelength rays. They are the least expensive, most convenient, and most universally applicable means of combating the effects of secondary radiation. Lead screens lessen the amount of secondary radiation reaching the film or detector, regardless of whether the screens increase or decrease the intensity of detected radiation. (The intensifying effect of lead screens is discussed in the section "Image Conversion Media" in this article.)

Sometimes, the use of lead screens requires increased exposure time (or image processing in the case of real-time monitoring). If high radiographic quality is desired, lead screens should not be abandoned merely because the photon energy is so low that they exhibit no intensifying action. However, at a sufficiently low photon energy, depending on the

testpiece, the absorption of transmitted image-forming radiation by the front screen will degrade image quality. Under these conditions, a front screen should not be used, but a back screen will reduce back-scattered radiation without affecting the image-forming radiation and should be used. In general, lead screens should be used whenever they improve the quality of the radiographic image.

Protection Against Back Scatter. Severe back scatter can produce an image of the back of the cassette or film holder on the film, superimposed on the image of the testpiece. To prevent back scatter from reaching the film, it is customary to place a sheet of lead in back of the cassette or film holder. The thickness needed depends on radiation quality; for example, 3 mm ($\frac{1}{8}$ in.) of lead for 250-kV x-rays and 6 mm ($\frac{1}{4}$ in.) of lead for 1-MeV x-rays or for Ir-192 or Co-60 γ -rays. At 100 kV and lower, the lead that is frequently incorporated into the back of the cassette or film holder usually provides sufficient protection from back scatter. Radiographic tables or stands can also be covered with lead to reduce back scatter. Because providing protection against back scatter can usually be done simply and conveniently, it is better to overprotect than to underprotect.

For assurance of adequate protection from back-scattered radiation, a characteristic lead symbol (such as a 3 mm, or $\frac{1}{8}$ in., thick letter "B") can be attached to the back of the cassette or film holder and a radiograph made in the normal manner. If a low-density image of the symbol appears on the radiograph, it is an indication that protection against back-scattered radiation is insufficient, and additional precautions must be taken. In the event that the image of the symbol is darker than the surrounding image, the intensification effect of lead is the probable cause of the dark image of the symbol. This effect is very rarely observed, and then only when there is little or no filtration, such as in direct or fluorescent-screen exposures or when very thin lead screens are used.

Masks and Diaphragms. Secondary radiation originating in sources outside the testpiece is most serious for testpieces that have high absorption for x-rays (most metals) because secondary radiation from external sources may be large compared with the image-forming radiation that reaches the film through the testpiece. Often, the most satisfactory method of reducing this secondary radiation is by the use of cutout lead masks or some other form of lead-sheet mask mounted over or around the testpiece (Fig. 57).

Fig. 57 Use of lead-sheet masks on a testpiece for reducing secondary radiation

Copper or steel shot having a diameter of 0.25 mm (0.01 in.) or less is an effective and convenient mask. Metallic shot is also very effective for filling cavities in irregular-shape testpieces such as castings, where the normal exposure for thick areas would result in overexposure for thinner areas. Masking can also be accomplished by using barium clay, lead putty, or liquid absorbers such as a saturated solution of lead acetate plus lead nitrate. This solution is made by dissolving approximately 1.6 kg ($3\frac{1}{2}$ lb) of lead acetate in 4 L (1 gal.) of hot water and adding approximately 1.4 kg (3 lb) of lead nitrate. *Caution: Care should be exercised at all times when using liquid absorbers, because of their highly poisonous or lethal nature.*

When metallic shot or a liquid absorber is used as a mask, the testpiece is placed in a container made of aluminum or thin sheet steel, and the metallic shot or liquid absorber is poured in around the testpiece (Fig. 58). A form of masking called blocking, which consists of placing lead blocks at the edges of the testpiece or placing lead plugs in internal holes, also prevents side scatter from reaching the film.

Fig. 58 Setup for radiography using either metallic shot or a liquid absorber as a mask to control secondary radiation

Lead diaphragms limit the area covered by the x-ray beam. Diaphragms are particularly useful when the desired cross section of the beam is a circle, square, or rectangle. Figure 59 shows the combined use of metallic shot, a lead mask, and a lead diaphragm to control scattered radiation.

Fig. 59 Use of a combination of metallic shot, a lead mask, and a lead diaphragm to control scattered radiation

Collimators. Side scatter from walls, equipment, and other structures in the x-ray room can be greatly reduced by improving the directionality of the x-ray beam. Directionality can be improved by the use of a collimator, which is often a thick lead diaphragm with a small hole through the middle. A collimator absorbs most of the diverging radiation that surrounds the central beam, thus eliminating most of the rays that could be scattered from nearby surfaces. Although considered good practice, removing all unnecessary equipment and other material from the x-ray room is sometimes impossible or impractical. In such cases, a collimator placed at the exit port of the radiation source can substantially reduce, if not eliminate, unwanted side scatter.

Filtration. In addition to the filtering effect of lead screens, secondary x-rays can be filtered by using thin copper or lead sheets between the testpiece and the cassette or film holder. Filtration is never used in gamma radiography, because of the essentially monochromatic nature of the beam.

When the testpiece has very thin sections adjacent to thick sections or when the direct beam can strike the detector after passing around the testpiece, undercutting may be encountered. If undercutting occurs, additional filtration (that is, more than can be achieved with conventional lead screens) is necessary. Additional filtration is accomplished by placing a filter at or near the x-ray tube, as shown in Fig. 60. This may adequately eliminate overexposure in thin regions of the testpiece and also along the perimeter of the testpiece. Such a filter is particularly useful for reducing undercutting when a lead mask around the testpiece is impractical or when the testpiece may be damaged by masking with liquid absorbers or metallic shot. Filtration of the incident radiation beam reduces undercut by selectively attenuating the long-wavelength portion of the x-ray spectrum. Long wavelengths do not contribute significantly to the detection of flaws but only produce secondary radiation that reduces radiographic contrast and definition.

Fig. 60 Use of a lead diaphragm to limit the included angle of the x-ray beam, and use of a filter to reduce subject contrast and to eliminate much of the secondary radiation that causes undercutting

The choice of a filter material should be made on the basis of availability and ease of handling. For the same filtering effect, the thickness of filter required is less for those materials that have lower absorption coefficients. Often, copper or brass is the most useful because filters of these materials will be lightweight enough to handle but not so thin that they are easily bent or broken.

Definite rules for filter thicknesses are difficult to formulate because the amount of filtration required depends not only on the materials and thickness range of the testpiece but also on the homogeneity of the testpiece and on the amount of

undercutting that is to be eliminated. In the radiography of aluminum, a filter of copper about 4% as thick as the thickest area of the testpiece is usually satisfactory. With a steel testpiece, a copper filter ordinarily should be about 20%, or a lead filter about 3%, as thick as the thickest area of the testpiece for optimum filtration. These values are maximum values, and depending on circumstances, useful radiographs can often be made with far less filtration.

Radiation Diffraction. A special form of scattering due to x-ray diffraction is occasionally encountered in radiographic inspection. Diffraction of radiation is observed most often in the radiography of thin testpieces having a grain size large enough to be an appreciable fraction of the part thickness. Castings made of austenitic corrosion-resistant and heat-resistant stainless steel or of Inconel and other nickel-base alloys are the products most likely to exhibit diffraction in radiographs.

The radiographic appearance of this type of scattering can be confused with the mottled appearance sometimes produced by porosity, segregation, or spongy shrinkage. Diffraction patterns can be distinguished from these conditions in the testpiece by making successive radiographs with the testpiece rotated between exposures 1 to 5° about an axis perpendicular to the beam. A mottled pattern due to porosity or segregation will be only slightly changed, but a pattern due to diffraction effects will show a marked change. The radiographs of some testpieces will show mottling from both diffraction and porosity, and careful interpretation of the radiographs is needed to differentiate between them.

Mottling due to diffraction can be reduced, and sometimes eliminated, by raising x-ray tube voltage and by using lead screens. Filters will usually aid in the control of diffraction. Raising the tube voltage and filtration are often of positive value even though radiographic contrast and sensitivity are reduced.

Sometimes, diffraction cannot be reduced. In such cases, two radiographs made as described above can be used to identify diffraction.

Scattering at High Photon Energies. Lead screens should always be used when the radiation energy exceeds 1 MeV. Use of the usual 0.13 mm (0.005 in.) thick front screen and 0.25 mm (0.010 in.) thick back screen is both satisfactory and convenient. Some users find 0.13 mm (0.005 in.) thick front and back screens adequate when filters are used both front and back of the cassette or film holder. Other users consider 0.25 mm (0.010 in.) thick front and back screens of value because of greater selective absorption of scattered radiation from the testpiece.

Filtration of the incident x-ray beam offers no improvement in radiographic quality. However, filters at the film improve radiographs for the inspection of uniform sections.

Lead filters are most convenient for energies above 1 MeV. Care should be taken to minimize mechanical damage to the filter because filter defects could be confused with characteristics of the material being inspected.

It is important to block off all radiation except the effective beam with heavy shielding at the anode. This is usually recognized by manufacturers of high-voltage x-ray equipment. For example, in some linear accelerators, depleted-uranium collimators confine the beams to a 22° included angle. Unless a high-energy x-ray beam is well collimated, radiation striking the walls of the x-ray room will generate secondary radiation and thus seriously degrade the quality of the radiograph. This will be especially noticeable if the testpiece is thick or has projecting parts that are not immediately adjacent to the filter.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Interpretation of Radiographs

Proper identification of both the radiograph and the testpiece, clarity of the penetrameter, suitability of radiographic techniques, adequacy of coverage, and the techniques of image processing in real-time systems or the precision and uniformity of film processing in film radiography all offset the image that is being interpreted. Film radiographs and real-time radiographs are interpreted similarly with respect to the recognition of flaws and testpiece features. The primary difference is that film radiographs are negative images, while real-time radiographs are generally positive images (which may also be enhanced with image processing).

A qualified interpreter must:

- Define the quality of the radiographic image, which includes a critical analysis of the radiographic procedure and the image-developing procedure
- Analyze the image to determine the nature and extent of any abnormal condition in the testpiece
- Evaluate the testpiece by comparing interpreted information with standards or specifications
- Report inspection results accurately, clearly, and within proper administration channels

Proper identification of both the radiograph and testpiece is an absolute necessity for correlation of the radiograph with the corresponding testpiece. Identification includes both identification of the testpiece and identification of the view or area of coverage.

Poor-quality film radiographs are usually reshot. However, reshooting radiographs increases inspection costs, not only because the original setup must be duplicated and a new exposure made but also because the testpiece must be retrieved and taken to the radiographic laboratory. With on-site radiography, which involves transporting radiographic equipment to the site and returning the exposed films to the laboratory for processing, especially high costs may be involved when poor-quality radiographs must be reshot. Table 12 lists some of the usual causes of poor quality in a radiographic image and indicates the usual corrective action required to eliminate each cause.

Table 12 Probable causes and corrective action for various types of deficient image quality or artifacts on processed radiographic film

Quality or artifact	Probable cause	Corrective action
Density too high	Overexposure	View with higher-intensity light. Check exposure (time and radiation intensity); if as specified, reduce exposure 30% or more.
	Overdevelopment	Reduce development time or developer temperature.
	Fog	See "Fog" below.
Density too low	Underexposure	Check exposure (time and radiation intensity); if as specified, increase exposure 40% or more.
	Underdevelopment	Increase development time or developer temperature. Replace weak (depleted) developer.
	Material between screen and film	Remove material.
Contrast too high	High subject contrast	Increase tube voltage.
	High film contrast	Use a film with lower contrast characteristics.
Contrast too low	Low subject contrast	Reduce tube voltage.
	Low film contrast	Use a film with higher contrast characteristics.

	Underdevelopment	Increase development time or developer temperature. Replace weak (depleted) developer.
Poor definition	Testpiece-to-film distance too long	If possible, decrease testpiece-to-film distance; if not, increase source-to-film distance.
	Source-to-film distance too short	Increase source-to-film distance.
	Focal spot (or γ -ray source) too large	Use smaller source or increase source-to-film distance.
	Screens and film not in close contact	Ensure intimate contact between screens and film.
	Film graininess too coarse	Use finer-grain film.
Fog	Light leaks in darkroom	With darkroom unlighted, turn on all lights in adjoining rooms; seal any light leaks.
	Exposure to safelight	Reduce safelight wattage. Use proper safelight filters.
	Stored film inadequately protected from radiation	Attach strip of lead to loaded film holder and place in film-storage area. Develop test film after 2 to 3 weeks; if image of strip is evident, improve radiation shielding in storage area.
	Film exposed to heat, humidity, or gases	Store film in a cool, dry place not subject to gases or vapors.
	Overdevelopment	Reduce development time or developer temperature.
	Developer contaminated	Replace developer.
	Exposure during processing	Do not inspect film during processing until fixing is completed.
Finely mottled fog	Stale film	Use fresh film.
Fog on edge or corner	Defective cassette	Discard cassette.
Yellow stain	Depleted developer	Replace developer solution.
	Failure to use stop bath or to rinse	Use stop bath, or rinse thoroughly between developing and fixing.
	Depleted fixer	Replace fixer solution.

Dark circular marks	Film splashed with developer prior to immersion	Immerse film in developer with care.
Dark spots or marblelike areas	Insufficient fixing	Use fresh fixer solution and proper fixing time.
Dark branched lines and spots	Static discharge	Unwrap film carefully. Do not rub films together. Avoid clothing productive of static electricity.
Dark fingerprints	Touching undeveloped film with chemically contaminated fingers	Wash hands thoroughly and dry, or use clean, dry rubber gloves.
Light fingerprints	Touching undeveloped film with oily or greasy fingers	Wash hands thoroughly and dry, or use clean, dry rubber gloves.
Dark spots or streaks	Developer contaminated with metallic salts	Replace developer solution.
Crescent-shaped light areas	Faulty film handling	Keep film flat during handling. Use only clean, dry film hangers.
Light circular patches	Air bubbles on film during development	Agitate immediately upon immersion of film in developer.
Circular or dropshaped light patches	Water or fixer splashed on film before development	Avoid splashing film with water or fixer solution.
Light spots or areas	Dust or lint between screens and film	Keep screens clean.
Sharply outlined light or dark areas	Nonuniform development	Agitate film during development.
Reticulation (leather-grain appearance)	Temperature gradients in processing solutions	Maintain all solutions at uniform, constant temperature.
Frilling (loosening of emulsion from film base)	Fixer solution too warm	Maintain correct temperature of the fixing solution.
	Fixer solution depleted	Replace fixer solution.

Personnel engaged in the interpretation of radiographs should possess certain qualifications. Some qualification recommendations are included in personnel standards published by the American Society for Nondestructive Testing (Ref 6), several governmental agencies, and many private manufacturers. Usually, a minimum level of visual acuity, minimum standards of education and training, and demonstrated proficiency are required of all interpreters of radiographs.

Viewing of radiographs should be carried out in an area with subdued lighting to minimize distracting reflections from the viewing surface. Audible distractions, which interfere with concentration, can best be avoided by locating the work area away from the main production floor or other high-noise area.

Radiographic film images are viewed on an illuminated screen. The viewing apparatus should have an opal-glass or plastic screen large enough to accommodate the largest film to be interpreted. The screen should be illuminated from behind with light of sufficient intensity to reveal variations in photographic density up to a nominal film density of at least 3.0. There may be a need for a smaller, more intensely illuminated viewer for evaluating small areas of film having densities up to 4.5 or more. Viewing screens of high-intensity illuminators should be cooled by blowers or other suitable apparatus to prevent excessive heat from damaging films and to extend lamp life.

When interpreting paper radiographs or xeroradiographs, specular light as from a spotlight or high-intensity lamp should be directed onto the radiograph from the side at an angle of about 30°. Background lighting should be heavily subdued.

A densitometer can be provided for accurate evaluation of small variations in photographic density or for quantitative evaluation of radiographic and processing techniques. A transmission densitometer is used with films, and a reflection densitometer is used with paper radiographs.

Radiographic Acceptance Standards. Usually, a series of radiographs that exhibit various types and sizes of flaws should be selected for acceptance standards. Parts that contain similar flaws should be performance tested to determine the least acceptable condition. The radiograph of the least acceptable part then becomes the minimum acceptance standard for similar parts. Often, the acceptance standard is defined as a length or area of the image that may contain no more than a specified number of flaws of a given size and type. Certain types of flaws, such as cracks or incomplete fusion, may be prohibited regardless of size. The interpreter must determine the degree of imperfection, as related to the minimum acceptance standard, and then decide whether minimum soundness requirements have been met.

Obviously, no single standard can be applied universally to radiographic inspection. However, flaws that are frequently encountered have been reproduced in sets of reference radiographs such as those published by ASTM (Table 13). Reference radiographs depict various types of flaws that may occur in castings or weldments and are graded according to flaw size and severity.

Table 13 Reference radiographs in ASTM standards

ASTM standard	Subject of radiographs in standard
E 155	Aluminum and magnesium castings
E 186	Heavy-wall (50-115 mm, or $2-4\frac{1}{2}$ in.) steel castings
E 192	Investment steel castings for aerospace applications
E 242	Appearance of radiographic images as certain parameters are changed
E 272	High-strength copper-base and nickel-copper alloy castings
E 280	Heavy-wall (115-300 mm, or $4\frac{1}{2}$ -12 in.) steel castings
E 310	Tin bronze castings
E 390	Steel fusion welds
E 431	Semiconductors and related devices

E 446	Steel castings up to 50 mm (2 in.) in thickness
E 505	Aluminum and magnesium die castings
E 689	Ductile cast irons
E 802	Gray iron castings up to 115 mm ($4\frac{1}{2}$ in.) in thickness

Codes or specifications for radiographic inspection, particularly those that have been standardized by an industry through a trade association or a professional society or those that have been adopted by a governmental agency or a prime contractor, may refer to published reference radiographs. In such cases, the code or specification should designate one or more reference radiographs in a specific set as the minimum standard for acceptance. Although it is considered most desirable to have an acceptance standard that is based on actual service data, standardized codes or specifications usually define rigid acceptance criteria that do not allow for variations in specific design features of similar products.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Interpretation of Radiographs

Proper identification of both the radiograph and the testpiece, clarity of the penetrameter, suitability of radiographic techniques, adequacy of coverage, and the techniques of image processing in real-time systems or the precision and uniformity of film processing in film radiography all offset the image that is being interpreted. Film radiographs and real-time radiographs are interpreted similarly with respect to the recognition of flaws and testpiece features. The primary difference is that film radiographs are negative images, while real-time radiographs are generally positive images (which may also be enhanced with image processing).

A qualified interpreter must:

- Define the quality of the radiographic image, which includes a critical analysis of the radiographic procedure and the image-developing procedure
- Analyze the image to determine the nature and extent of any abnormal condition in the testpiece
- Evaluate the testpiece by comparing interpreted information with standards or specifications
- Report inspection results accurately, clearly, and within proper administration channels

Proper identification of both the radiograph and testpiece is an absolute necessity for correlation of the radiograph with the corresponding testpiece. Identification includes both identification of the testpiece and identification of the view or area of coverage.

Poor-quality film radiographs are usually reshot. However, reshooting radiographs increases inspection costs, not only because the original setup must be duplicated and a new exposure made but also because the testpiece must be retrieved

and taken to the radiographic laboratory. With on-site radiography, which involves transporting radiographic equipment to the site and returning the exposed films to the laboratory for processing, especially high costs may be involved when poor-quality radiographs must be reshot. Table 12 lists some of the usual causes of poor quality in a radiographic image and indicates the usual corrective action required to eliminate each cause.

Table 12 Probable causes and corrective action for various types of deficient image quality or artifacts on processed radiographic film

Quality or artifact	Probable cause	Corrective action
Density too high	Overexposure	View with higher-intensity light. Check exposure (time and radiation intensity); if as specified, reduce exposure 30% or more.
	Overdevelopment	Reduce development time or developer temperature.
	Fog	See "Fog" below.
Density too low	Underexposure	Check exposure (time and radiation intensity); if as specified, increase exposure 40% or more.
	Underdevelopment	Increase development time or developer temperature. Replace weak (depleted) developer.
	Material between screen and film	Remove material.
Contrast too high	High subject contrast	Increase tube voltage.
	High film contrast	Use a film with lower contrast characteristics.
Contrast too low	Low subject contrast	Reduce tube voltage.
	Low film contrast	Use a film with higher contrast characteristics.
	Underdevelopment	Increase development time or developer temperature. Replace weak (depleted) developer.
Poor definition	Testpiece-to-film distance too long	If possible, decrease testpiece-to-film distance; if not, increase source-to-film distance.
	Source-to-film distance too short	Increase source-to-film distance.
	Focal spot (or γ -ray source) too large	Use smaller source or increase source-to-film distance.
	Screens and film not in close contact	Ensure intimate contact between screens and film.

	Film graininess too coarse	Use finer-grain film.
Fog	Light leaks in darkroom	With darkroom unlighted, turn on all lights in adjoining rooms; seal any light leaks.
	Exposure to safelight	Reduce safelight wattage. Use proper safelight filters.
	Stored film inadequately protected from radiation	Attach strip of lead to loaded film holder and place in film-storage area. Develop test film after 2 to 3 weeks; if image of strip is evident, improve radiation shielding in storage area.
	Film exposed to heat, humidity, or gases	Store film in a cool, dry place not subject to gases or vapors.
	Overdevelopment	Reduce development time or developer temperature.
	Developer contaminated	Replace developer.
	Exposure during processing	Do not inspect film during processing until fixing is completed.
Finely mottled fog	Stale film	Use fresh film.
Fog on edge or corner	Defective cassette	Discard cassette.
Yellow stain	Depleted developer	Replace developer solution.
	Failure to use stop bath or to rinse	Use stop bath, or rinse thoroughly between developing and fixing.
	Depleted fixer	Replace fixer solution.
Dark circular marks	Film splashed with developer prior to immersion	Immerse film in developer with care.
Dark spots or marblelike areas	Insufficient fixing	Use fresh fixer solution and proper fixing time.
Dark branched lines and spots	Static discharge	Unwrap film carefully. Do not rub films together. Avoid clothing productive of static electricity.
Dark fingerprints	Touching undeveloped film with chemically contaminated fingers	Wash hands thoroughly and dry, or use clean, dry rubber gloves.
Light fingerprints	Touching undeveloped film with oily or greasy fingers	Wash hands thoroughly and dry, or use clean, dry rubber gloves.

Dark spots or streaks	Developer contaminated with metallic salts	Replace developer solution.
Crescent-shaped light areas	Faulty film handling	Keep film flat during handling. Use only clean, dry film hangers.
Light circular patches	Air bubbles on film during development	Agitate immediately upon immersion of film in developer.
Circular or dropshaped light patches	Water or fixer splashed on film before development	Avoid splashing film with water or fixer solution.
Light spots or areas	Dust or lint between screens and film	Keep screens clean.
Sharply outlined light or dark areas	Nonuniform development	Agitate film during development.
Reticulation (leather-grain appearance)	Temperature gradients in processing solutions	Maintain all solutions at uniform, constant temperature.
Frilling (loosening of emulsion from film base)	Fixer solution too warm	Maintain correct temperature of the fixing solution.
	Fixer solution depleted	Replace fixer solution.

Personnel engaged in the interpretation of radiographs should possess certain qualifications. Some qualification recommendations are included in personnel standards published by the American Society for Nondestructive Testing (Ref 6), several governmental agencies, and many private manufacturers. Usually, a minimum level of visual acuity, minimum standards of education and training, and demonstrated proficiency are required of all interpreters of radiographs.

Viewing of radiographs should be carried out in an area with subdued lighting to minimize distracting reflections from the viewing surface. Audible distractions, which interfere with concentration, can best be avoided by locating the work area away from the main production floor or other high-noise area.

Radiographic film images are viewed on an illuminated screen. The viewing apparatus should have an opal-glass or plastic screen large enough to accommodate the largest film to be interpreted. The screen should be illuminated from behind with light of sufficient intensity to reveal variations in photographic density up to a nominal film density of at least 3.0. There may be a need for a smaller, more intensely illuminated viewer for evaluating small areas of film having densities up to 4.5 or more. Viewing screens of high-intensity illuminators should be cooled by blowers or other suitable apparatus to prevent excessive heat from damaging films and to extend lamp life.

When interpreting paper radiographs or xeroradiographs, specular light as from a spotlight or high-intensity lamp should be directed onto the radiograph from the side at an angle of about 30°. Background lighting should be heavily subdued.

A densitometer can be provided for accurate evaluation of small variations in photographic density or for quantitative evaluation of radiographic and processing techniques. A transmission densitometer is used with films, and a reflection densitometer is used with paper radiographs.

Radiographic Acceptance Standards. Usually, a series of radiographs that exhibit various types and sizes of flaws should be selected for acceptance standards. Parts that contain similar flaws should be performance tested to determine the least acceptable condition. The radiograph of the least acceptable part then becomes the minimum acceptance standard

for similar parts. Often, the acceptance standard is defined as a length or area of the image that may contain no more than a specified number of flaws of a given size and type. Certain types of flaws, such as cracks or incomplete fusion, may be prohibited regardless of size. The interpreter must determine the degree of imperfection, as related to the minimum acceptance standard, and then decide whether minimum soundness requirements have been met.

Obviously, no single standard can be applied universally to radiographic inspection. However, flaws that are frequently encountered have been reproduced in sets of reference radiographs such as those published by ASTM (Table 13). Reference radiographs depict various types of flaws that may occur in castings or weldments and are graded according to flaw size and severity.

Table 13 Reference radiographs in ASTM standards

ASTM standard	Subject of radiographs in standard
E 155	Aluminum and magnesium castings
E 186	Heavy-wall (50-115 mm, or 2-4 $\frac{1}{2}$ in.) steel castings
E 192	Investment steel castings for aerospace applications
E 242	Appearance of radiographic images as certain parameters are changed
E 272	High-strength copper-base and nickel-copper alloy castings
E 280	Heavy-wall (115-300 mm, or 4 $\frac{1}{2}$ -12 in.) steel castings
E 310	Tin bronze castings
E 390	Steel fusion welds
E 431	Semiconductors and related devices
E 446	Steel castings up to 50 mm (2 in.) in thickness
E 505	Aluminum and magnesium die castings
E 689	Ductile cast irons
E 802	Gray iron castings up to 115 mm (4 $\frac{1}{2}$ in.) in thickness

Codes or specifications for radiographic inspection, particularly those that have been standardized by an industry through a trade association or a professional society or those that have been adopted by a governmental agency or a prime contractor, may refer to published reference radiographs. In such cases, the code or specification should designate one or more reference radiographs in a specific set as the minimum standard for acceptance. Although it is considered most

desirable to have an acceptance standard that is based on actual service data, standardized codes or specifications usually define rigid acceptance criteria that do not allow for variations in specific design features of similar products.

Radiographic Inspection

Revised by the ASM Committee on Radiographic Inspection*

Radiographic Appearance of Specific Types of Flaws

The radiographic appearance of many of the more usual types of flaws found in castings and weldments is described in this section. The descriptions apply specifically to images on film radiographs, although paper radiographs and xeroradiographs will exhibit similar images. Real-time images of the same types of flaws will be reversed in tone (dark tones in a radiograph will be light in a fluoroscopic image and vice versa) but otherwise will be similar to the images described here.

Some of these types of flaws are not unique to castings and weldments. For example, cracks can be found in any product form. Surface inspection methods such as liquid penetrant or magnetic particle inspection are more appropriate than radiography for detecting most surface cracks, yet some forms of metal separation (forging bursts, for example) are entirely internal and cannot be found by surface methods.

Flaws in Castings

It is possible in most cases to identify radiographic images of the usual types of flaws in castings. The main types of foundry flaws that can be identified radiographically are described in the paragraphs that follow. Specific examples can be found in reference radiographs, such as those published by ASTM (Table 13).

Microshrinkage appears as dark feathery streaks or dark irregular patches, corresponding to grain-boundary shrinkage. This condition is most often found in magnesium alloy castings.

Shrinkage porosity (spongy shrinkage) appears as a localized honeycomb or mottled pattern (Fig. 61). Spongy shrinkage may be the result of improper pouring temperature or alloy composition.

Fig. 61 Radiographic appearance of gross shrinkage porosity (arrow) in an aluminum alloy 319 manifold casting. Radiograph was made at 85 kV with 1-min exposure.

Gas porosity appears as round or elongated smooth, dark spots. It occurs individually or in clusters or may be distributed randomly throughout the casting. This condition is caused by gas released during solidification or by the evaporation of moisture of volatile material from the mold surface.

Dispersed Discontinuities. Although the flaws usually encountered in light-alloy castings are similar to those in ferrous castings, a group of irregularities called dispersed discontinuities may be present in the former. These dispersed discontinuities, prevalent in aluminum and magnesium alloy castings, consist of tiny voids scattered throughout part or all of the casting. Gas porosity and shrinkage porosity in aluminum alloys are examples of dispersed discontinuities. On radiographs of sections more than 13 mm ($\frac{1}{2}$ in.) thick, it is difficult to distinguish images corresponding to the individual voids. Instead, dispersed discontinuities may appear on film deceptively as mottling, dark streaks, or irregular patches that are only slightly darker than the surrounding regions.

Tears appear as ragged dark lines of variable width having no definite line of continuity. Tears may exist in groups, starting at a surface, or they may be internal. Tears usually result from normal contraction of the casting during or immediately after solidification.

Cold cracks generally appear as single, straight, sharp dark lines and are usually continuous throughout their lengths. Cold cracks are produced by internal stresses caused by thermal gradients and may occur upon cooling from elevated temperatures during flame cutting, grinding, or quenching operations.

Cold shuts appear as distinct dark lines of variable length and smooth outline. Cold shuts are formed when two bodies of molten metal flowing from different directions contact each other but fail to unite. Cold shuts may be produced by interrupted pouring, slow pouring, or pouring the metal at too low a temperature.

Misruns appear as prominent dark areas of variable dimensions with a definite smooth outline. Misruns are produced by failure of the molten metal to completely fill a section of casting mold, leaving the region void.

Inclusions of foreign material in the molten metal may be poured into the mold. They appear as small lighter or darker areas in a radiograph, depending on the absorption properties of the included material as compared to those of the alloy. Sand inclusions appear as gray or light spots of uneven granular texture and have indistinct outlines. Inclusions lighter than the parent metal appear as isolated irregular or elongated variations of film blackening. Occasionally, an inclusion will have absorption characteristics equivalent to those of the matrix and will go undetected, although normally an inclusion that exhibits a radiographic contrast of about 1.4 to 2.3% can be seen. A contrast of 1.4 to 2.3% corresponds to about 0.005 to 0.01 density difference between adjacent areas on the film. Dross inclusions in the outer flange of a casting are shown in Fig. 62.

Fig. 62 Radiographic appearance of dross inclusions (arrows) in the outer flange of a cast aluminum alloy 355

housing body. Radiograph made at 75 kV, 1-min exposure.

Unfused chaplets usually appear in outline conforming to the shape of the chaplet. The outline is caused by a lack of bond between the chaplet and the cast metal.

Core shift can be detected when the view makes it impossible to measure deviation from a specified wall thickness (Fig. 63). Core shift may be caused by jarring the mold, insecure anchorage of cores, or omission of chaplets.

Fig. 63 Uneven wall thickness in an internal passage of a casting caused by core shift (top right). This radiograph, of an aluminum alloy casting about 3 to 6 mm ($\frac{1}{8}$ to $\frac{1}{4}$ in.) thick, was made at 65 kV with an exposure time of 1 min.

Centerline shrinkage is localized along the central plane of a wall section, irrespective of the position occupied by the section in the mold. Such shrinkage is composed of a network of numerous filamentary veinlets leading in the direction of the nearest riser and can sometimes be mistaken for tears.

Shrinkage cavities occur when insufficient feeding of a section results in a continuous cavity within the section. Shrinkage cavities appear on the radiograph as dark areas that are indistinctly outlined and have irregular dimensions.

Segregation is the separation of constituents in an alloy into regions of different chemical compositions. This condition, seen mostly in aluminum alloys, appears as lighter areas on the film that produce a somewhat mottled appearance.

Surface irregularities may produce an image corresponding to any deviation from normal surface profile. It is possible to confuse these with internal flaws unless the casting is visually inspected at the time of interpretation.

Flaws in Weldments

In welding, heat must be carefully controlled to produce fusion and adequate penetration. Too much heat can cause porosity, cracks, and undercutting; too little heat can cause inadequate joint penetration and incomplete fusion.

Most weld flaws consist of abrupt changes in homogeneity and can be readily detected by radiographic inspection. Stresses that are induced in the metal by welding but that are not accompanied by a physical separation of material will not be detected by radiography. Also, cracks not aligned with the x-ray beam may be missed. Conditions that can be detected in welds by radiography are described below. Several reference radiographs of flaws in weldments are provided in the article "Weldments, Brazed Assemblies, and Soldered Joints" in this Volume.

Undercutting appears as a dark line of varying width along the edge of the fusion zone. A fine dark line in this darker area could indicate a crack and should be further investigated.
