Tungsten Carbide-Cobalt Alloys. The first commercially available cemented carbides consisted of tungsten carbide particles bonded with cobalt. These are commonly referred to as straight grades. These alloys exhibit excellent resistance to simple abrasive wear and thus have many applications in metal cutting. Table 5 lists the representative properties of several straight WC-Co alloys.

Table 5 Properties of representative cobalt-bonded cemented carbides

Nominal composition	Grain size	Hardness, HRA	Density g/cm ³	oz/in. ³	Transverse strength		Compressive strength		Modulus of elasticity		Relative abrasion resistance ^(a)	Coefficient of thermal expansion, $\mu\text{m/m} \cdot \text{K}$		Thermal conductivity, W/m · K

(a) Based on a value of 100 for the most abrasion-resistant material

The commercially significant alloys contain cobalt in the range of 3 to 25 wt%. For machining purposes, alloys with 3 to 12% Co and carbide grain sizes from 0.5 to more than 5 μm are commonly used.

The ideal microstructure of WC-Co alloys should exhibit only two phases: angular WC grains and cobalt binder phase. Representative microstructures of several straight WC-Co alloys are shown in Fig. 12. The carbon content must be controlled within narrow limits. Too high a carbon content results in the presence of free and finely divided graphite (Fig. 13), which in small amounts has no adverse effects in machining applications. Deficiency in carbon, however, results in the formation of a series of double carbides (for example, $\text{Co}_3\text{W}_3\text{C}$ or $\text{Co}_6\text{W}_6\text{C}$), commonly known as η phase, which causes severe embrittlement. Because the formation of η phase involves the dissolution of the original carbides into the cobalt binder, η phase appears as an irregularly shaped phase in the microstructure (Fig. 14).

Fig. 14 η phase microstructure. Micrograph shows a $(\text{Co}_3\text{W}_3)\text{C}-\eta$ phase in detail. η phase appears as various shades of gray with clearly defined grain boundaries. Light gray WC particles surrounded by η phase are rounded because of the solubility of tungsten carbide in the binder. 85WC-8(Ta,Ti,Nb)C-7Co alloy etched with Murakami's reagent for 3 s. 900 \times

Submicron Tungsten Carbide-Cobalt Alloys. In recent years, WC-Co alloys with submicron carbide grain sizes have been developed for applications requiring more toughness or edge strength. Typical applications include indexable inserts and a wide variety of solid carbide drilling and milling tools. Grain refinement in these alloys is obtained by small additions (0.25 to 3.0 wt%) of tantalum carbide, niobium carbide, vanadium carbide, or chromium carbide. Additions can be made before carburization of the tungsten or later in the powder blend. Vanadium carbide is the most effective grain growth inhibitor. Chromium carbide, in addition to being an efficient grain growth inhibitor, imparts excellent mechanical properties. Tantalum carbide is not as effective as vanadium carbide or chromium carbide in grain refinement.

Alloys Containing Tungsten Carbide, Titanium Carbide, and Cobalt. The tungsten carbide-cobalt alloys, developed in the early 1920s, were successful in the machining of cast iron and nonferrous alloys at much higher speeds than were possible with high-speed steel tools, but were subject to chemical attack or diffusion wear when cutting steel. As a result, the tools failed rapidly at speeds not much higher than those used with high-speed steel. This led to the development of WC-TiC-Co alloys.

Tungsten carbide diffuses readily into the steel chip surface, but the solid solution of tungsten carbide and titanium carbide resists this type of chemical attack. Unfortunately, titanium carbide and WC-TiC solid solutions are more brittle and less abrasion resistant than tungsten carbide. The amount of titanium carbide added to tungsten carbide-cobalt alloys is therefore kept to a minimum, typically no greater than 15 wt%. The carbon content is less critical in WC-TiC-Co alloys than in WC-Co alloys, and the η phase does not appear in the microstructure unless carbon is grossly inadequate. In addition, free graphite rarely occurs in these alloys.

Steel-Cutting Grades of Cemented Carbide Alloys. The WC-TiC-Co alloys have given way to alloys of tungsten carbide, cobalt, titanium carbide, tantalum carbide, and niobium carbide. The tungsten carbide-cobalt alloys containing TiC, TaC, and NbC are called complex grades, multigrades, or steel-cutting grades. Adding TaC to WC-TiC-Co alloys partially overcomes the deleterious effects of TiC on the strength of WC-Co alloys. Tantalum carbide also resists cratering and improves thermal shock resistance. The latter property is particularly useful in applications involving interrupted cuts. Tantalum carbide is often added as (Ta, Nb)C because the chemical similarity between TaC and NbC makes their separation expensive. Fortunately, NbC has an effect similar to TaC in most cases. The relative concentrations of tantalum carbide and niobium carbide in these alloys are dependent on the raw material used, the desired composition, the properties, and the microstructure.

Unlike the WC-Co alloys, the microstructure of WC-TiC-(Ta,Nb)C-Co alloys shows three phases: angular WC grains, rounded WC-TiC-(Ta,Nb)C solid-solution grains, and cobalt binder. The solid-solution carbide phase often exhibits a cored structure, indicating incomplete diffusion during the sintering process. Representative microstructures of several WC-TiC-(Ta,Nb)C alloys are shown in Fig. 15. The size and distribution of the phases vary widely, depending on the amounts and

grain sizes of the raw materials employed and on the method of manufacture. Similarly, the properties of these complex alloys also vary widely, as indicated in Table 5 for a few representative steel-cutting grades.

Fig. 15 Representative microstructures of steel-cutting grades of cemented tungsten carbide. (a) 85WC-9(Ta,Ti,Nb)C-6Co alloy, medium grain size. (b) 78WC-15(Ta,Ti,Nb)C-7Co alloy, medium grain. (c) 73WC-19(Ta,Ti,Nb)C-8Co alloy, medium grain. The gray, angular particles are WC, and the dark gray, rounded particles are solid-solution carbides. The white areas are cobalt binder. All etched with Murakami's reagent for 2 min. 1500×

Classification

There is no universally accepted system for classifying cemented carbides. The systems most often employed by producers and users are discussed below. Each system has inherent strengths and weaknesses in describing specific materials, and for this reason close cooperation between user and producer is the best means of selecting the proper grade for a given application.

C-Grade System. The U.S carbide industry uses an application-oriented system of classification to assist in the selection of proper grades of cemented carbides. This C-grade system does not require the use of trade names for identifying specific carbide grades (Table 6). Although this classification simplifies tool application, it does not reflect the material properties that significantly influence selection of the proper carbide grade. Additionally, the definitions of work materials involved in this classification scheme are imprecise. There is also no universal agreement on the meanings of the terms used to describe the various application categories. Despite these limitations, the C-grade classification has been successfully used by the manufacturing industry since 1942.

Table 6 C-grade classification of cemented carbides

C-grade	Application category
Machining of cast iron, nonferrous, and nonmetallic materials	
C-1	Roughing
C-2	General-purpose machining
C-3	Finishing
C-4	Precision finishing
Machining of carbon and alloy steels	
C-5	Roughing
C-6	General-purpose machining
C-7	Finishing
C-8	Precision finishing
Nonmachining applications	
C-9	Wear surface, no shock
C-10	Wear surface, light shock
C-11	Wear surface, heavy shock

C-12	Impact, light
C-13	Impact, medium
C-14	Impact, heavy

ISO Classification. In 1964, the International Organization of Standardization (ISO) issued ISO Recommendation R513 "Application of Carbides for Machining by Chip Removal." The basis for the ISO classification of carbides is summarized in Table 7.

Table 7 ISO R513 classification of carbides according to use for machining

Designation ^(a)	Groups of application	
	Material to be machined	Use and working conditions
P 01	Steel, steel castings	Finish turning and boring; high cutting speeds, small chip section, accuracy of dimensions and fine finish, vibration-free operation
P 10	Steel, steel castings	Turning, copying, threading, and milling; high cutting speeds, small or medium chip sections
P 20	Steel, steel castings, malleable cast iron with long chips	Turning, copying, milling, medium cutting speeds and chip sections; planing with small chip sections
P 30	Steel, steel castings, malleable cast iron with long chips	Turning, milling, planing, medium or low cutting speeds, medium or large chip sections, and machining in unfavorable conditions ^(b)
P 40	Steel, steel castings with sand inclusion and cavities	Turning, planing, slotting, low cutting speeds, large chip sections with the possibility of large cutting angles for machining in unfavorable conditions ^(b)
P 50	Steel, steel castings of medium or low tensile strength, with sand inclusion and cavities	For operations demanding very tough carbide: turning, planing, slotting, low cutting speeds, large chip sections, with the possibility of large cutting angles for machining in unfavorable conditions ^(b) and work on automatic machines
M 10	Steel, steel castings, manganese steel, gray cast iron, alloy cast iron	Turning, medium or high cutting speeds; small or medium chip sections
M 20	Steel, steel castings, austenitic or manganese steel, gray cast iron	Turning, milling; medium cutting speeds and chip sections
M 30	Steel, steel castings, austenitic steel, gray cast iron, high-temperature resistant alloys	Turning, milling, planing; medium cutting speeds, medium or large chip sections
M 40	Mild free-cutting steel, low-tensile steel, nonferrous metals, and light alloys	Turning, parting off, particularly on automatic machines
K 01	Very hard gray cast iron, chilled castings of over 85 scleroscope hardness, high-silicon aluminum alloys, hardened steel, highly abrasive plastics, hard cardboard, ceramics	Turning, finish turning, boring, milling, scraping
K 10	Gray cast iron over 220 HB, malleable cast iron with short chips, hardened steel, silicon aluminum alloys, copper alloys, plastics, glass, hard rubber, hard cardboard, porcelain, stone	Turning, milling, drilling, boring, broaching, scraping
K 20	Gray cast iron up to 220 HB, nonferrous metals: copper, brass, aluminum	Turning, milling, planing, boring, broaching, demanding very tough carbide
K 30	Low-hardness gray cast iron, low-tensile steel, compressed wood	Turning, milling, planing, slotting, for machining in unfavorable conditions ^(b) and with the possibility of large cutting angles
K 40	Softwood or hardwood, nonferrous metals	Turning, milling, planing, slotting, for machining in unfavorable conditions ^(b) and with the possibility of large cutting angles

(a) In each letter category, low designation numbers are for high speeds and light feeds; higher numbers are for slower speeds and/or heavier feeds. Also, increasing designation numbers imply increasing toughness and decreasing wear resistance of the cemented carbide materials.

(b) Unfavorable conditions include shapes that are awkward to machine; material having a casting or forging skin; material having variable hardness; and machining that involves variable depth of cut, interrupted cut, or moderate to severe vibrations.

In the ISO system, all machining grades are divided into three color-coded groups:

- Highly alloyed tungsten carbide grades (letter P, blue color) for machining steel
- Alloyed tungsten carbide grades (letter M, yellow color, generally with less TiC than the corresponding P series) for multipurpose use, such as steels, nickel-base superalloys, and ductile cast irons
- Straight tungsten carbide grades (letter K, red color) for cutting gray cast iron, nonferrous metals, and nonmetallic materials

Each grade within a group is assigned a number to represent its position from maximum hardness to maximum toughness. P-grades are rated from 01 to 50, M-grades from 10 to 40, and K-grades from 01 to 40. Typical applications are described for grades at more or less regular numerical intervals. Although the coated grades had not been developed at the time the ISO classification system was prepared, one should be able to classify them as easily as the uncoated grades.

Selection

As cutting tool materials, tungsten carbide materials may be separated into two types. First and most common is the simple two-phase type consisting of tungsten carbide with a cobalt binder (C-1 through C-4). If metal removal involves generation of a short, weak, discontinuous chip, as in the machining of cast iron, this type of material is most effective. These carbides exhibit extreme hardness and excellent resistance to abrasive wear. However, if the workpiece material yields a strong, continuously curling chip, such as with steel, the alloyed grades C-5 through C-8 must be used.

Tungsten carbide and cobalt usually are alloyed with additional carbide(s), usually titanium carbide and/or tantalum carbide. These alloying additions delay crater development and increase tool life.

Straight tungsten carbide grades are most resistant to abrasive wear and have the greatest strength for a given hardness value. Two possible variables affect mechanical properties: grain size of the tungsten carbide particles and the percentage of cobalt. The following factors should be considered in grade selection:

- Finer grain size results in higher hardness.
- Lower cobalt content results in higher hardness.
- Higher hardness results in greater abrasive wear resistance.
- Lower cobalt content results in lower strength.
- Finer grain size results in lower strength.

Straight tungsten carbide grades are classified in the C-1 through C-4 range. They are used to machine most cast irons, 200 and 300 series stainless steels, most high-temperature alloys, nonferrous alloys, and nonmetals.

Alloyed tungsten carbide grades are used where the predominant wear factors are adhesion and diffusion due to high cutting forces and high heat. The following factors should be considered in grade selection.

Higher titanium carbide content results in:

- Greater resistance to cratering
- Higher hot hardness
- Higher wear resistance
- Lower strength

Higher tantalum carbide content results in:

- Greater resistance to thermal deformation and cratering

- Higher hot hardness
- Lower wear resistance
- Lower strength

Alloyed tungsten carbide grades are classified in the C-5 through C-8 range. These grades are used to machine most carbon and alloy steels, 400 and 500 series stainless steels, and malleable and ductile irons.

Wear Applications

Many applications exist for cemented carbides in noncutting areas. These may be generally categorized as wear parts. Properties that are paramount for wear part applications include abrasion resistance, impact strength, and corrosion resistance. Due to the physical property requirements, suitable materials for wear part applications include tungsten carbide and cobalt.

Tantalum carbide may be added in some applications for antigalling and corrosion resistance. Nickel may be substituted for cobalt in corrosion-resistant applications. Titanium carbide, widely used in metal cutting grades, is never used in wear applications, because it lowers strength and abrasion resistance.

Cemented carbides used for wear applications may be divided into the following categories:

Light impact, high abrasion resistance applications:

- Blast nozzles
- Spray nozzles
- Reamers
- Gun drills
- Wear pads
- Powder compaction dies
- Glass cutters
- Plastic extrusion dies
- Guide rings
- Circuit board drills
- Paper slitters

Medium impact, medium abrasion resistance applications:

- Tape slitters
- Metal draw dies
- Aluminum extrusion dies
- Shear knives
- Guide rolls
- Snowplow blades

High impact, low abrasion resistance applications:

- Cold header dies
- Stamping dies
- Bar mill rolls

Corrosion resistance applications:

- Seal rings
- Nozzles
- Ball valves
- Metering chokes
- Aluminum can tooling

Specialty applications:

- Nuclear components
- Nonmagnetic guidance gyros
- Nonmagnetic dies for magnets

Light Impact, High Abrasion Resistance Applications. A large number of applications capitalize on the abrasion resistance of cemented carbides. These include sliding friction, light uninterrupted cutting, or particle abrasion applications, which involve minimal mechanical shock. Generally only straight tungsten carbide/cobalt grades are used. High abrasion resistance grades typically have low cobalt contents (4 to 6%) and fine tungsten carbide particle sizes (1 to 2 μm). High abrasion resistance grades, which are classified in the C-9 through C-12 range, have the lowest impact strengths.

Submicron grades with 6 to 10% cobalt also are used for these applications. Abrasion-resistant grades have the lowest thermal shock resistance. As such, care should be taken when brazing cemented carbides to other materials such as steel, which have significant differences in thermal expansion. The difference in thermal expansion rates can result in fracture during brazing.

Medium impact, medium abrasion resistance applications require a combination of abrasion resistance and impact strength. Generally only straight tungsten carbide/cobalt grades (C-13 classification) are used for these applications. Grade composition ranges from 9 to 13% Co, and tungsten carbide particle size ranges from 2 to 3.5 μm . Submicron grades with from 10 to 15% Co also are suitable for this usage. Tantalum carbide may be added to prevent galling or to improve elevated-temperature properties (Fig. 16). Due to the higher cobalt content and coarser tungsten carbide particle size, these grades have improved thermal shock properties.

Fig. 16 Effect of tantalum carbide additions on hot hardness of tungsten carbide/cobalt cemented carbides

High Impact, Low Abrasion Resistance Applications. In many high-impact applications, cemented carbides compete with tool steel. Suitable cemented carbide grades (C-14 classification) have cobalt contents ranging from 15%, with 3 to 4 μm tungsten carbide particle sizes for lamination dies, to 25% with 4 to 5 μm tungsten carbide particle sizes for cold header dies. Generally, submicron grades are not used in impact applications.

The 25% Co binder content is the highest available because of the difficulty maintaining shape during liquid-phase sintering. Tantalum carbide is used in some applications for galling resistance. High cobalt grades (18% and above) may be machined with aluminum oxide and silicon carbide wheels and cemented carbide tooling. Below 17 to 18% Co, diamond tools are required.

Corrosion Resistance Applications. Cemented carbides frequently are used for their combined corrosion and abrasion resistance. Typically, the binder metal corrodes. Finer tungsten carbide particle size and lower cobalt content improve corrosion resistance. Grades with binder metal contents as low as 1.5% are used.

Nickel binder grades with fine tungsten carbide grain sizes are finding increasing usage. Important corrosion resistance applications include the use of cemented carbides for valve stems and seats, chemical seal rings, and for aluminum can tooling for use with synthetic lubricants. Grades with small chromium additions are used for sour gas applications (natural gas with high hydrogen sulfide). Ultimately, the optimum cemented carbide composition for a corrosion application depends on the intended service environment.

Specialty Applications. Many wear part applications require the special properties of cemented carbide in addition to abrasion resistance and impact strength. These include nuclear and nonmagnetic applications. In parts for the nuclear industry (seal rings, wear pads, and hardfacing), nickel binder grades are suitable, because nickel has a much shorter radioactive half-life than cobalt.

For nonmagnetic applications (guidance gyros, dies for ceramic magnets, and tape player heads), nickel binder grades with high dissolved tungsten or chromium contents are used. Cobalt binder grades are ferromagnetic. Another prominent application for cemented carbides is gage blocks. A chromium carbide/nickel grade typically is used. This material has a low coefficient of thermal expansion, is corrosion resistant, nonmagnetic, and abrasion resistant, and exhibits high reflectivity when lapped.

Properties

A number of industry, national, and ISO standards have been developed for determining the selected properties of cemented carbides (Table 8).

Table 8 Test methods for determining the properties of cemented carbides

Property	Test method		
	ASTM/ANSI	CCPA ^(a)	ISO
Abrasive wear resistance	B 611	P112	...

Young's modulus	E 111	P106	3312

(a) Cemented Carbides Producers Association

Hardness determines the resistance of a material to abrasion and wear. It is affected not only by composition but also by the level of porosity and microstructure. For straight WC-Co alloys of comparable WC grain size, hardness and abrasion resistance decrease with increasing cobalt content (Fig. 17a and 17b). However, because both composition and microstructure affect hardness, cobalt content and grain size must be considered. At a given cobalt level, hardness improves with decreasing WC grain size (Fig. 17a).

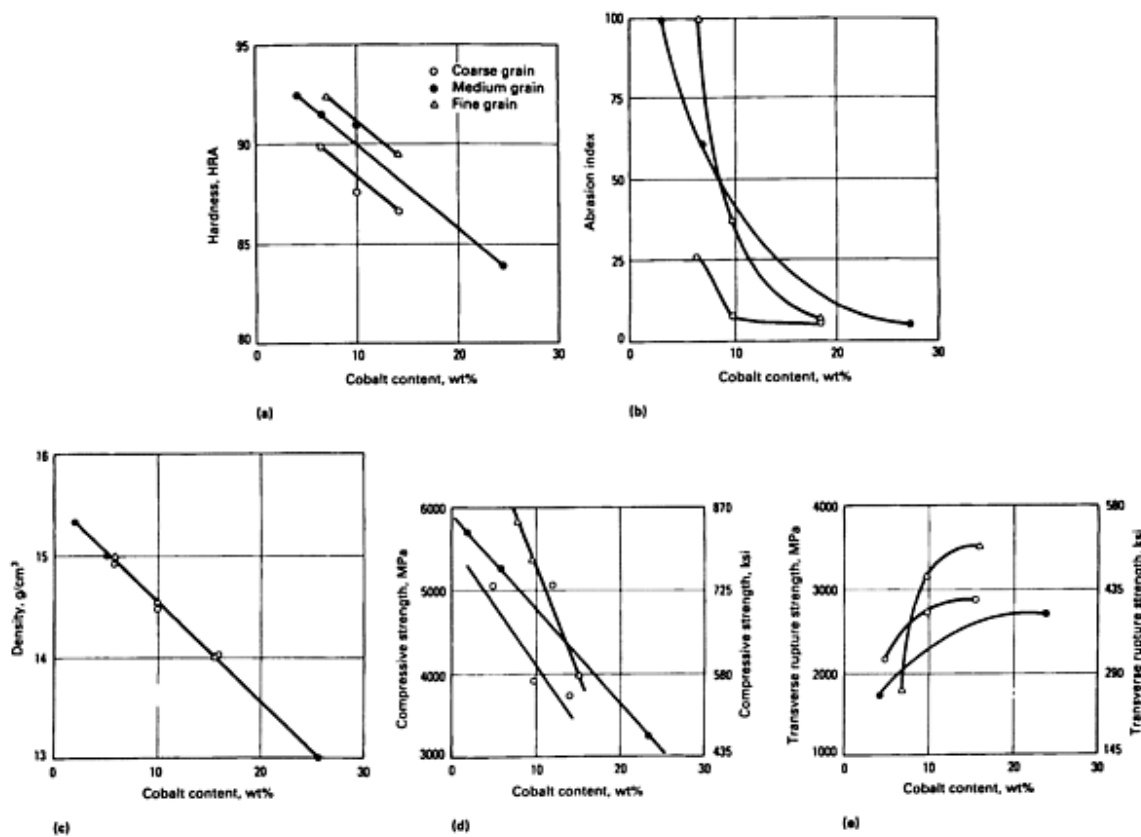

Fig. 17 Variation in properties with cobalt content and grain size for straight WC-Co alloys. (a) Variation in hardness. (b) Variation in abrasion resistance. (c) Variation in density. (d) Variation in compressive strength. (e) Variation in transverse rupture strength

In cemented carbides, hardness is measured by the Rockwell A-scale diamond cone indentation test (HRA) or by the Vickers diamond pyramid indentation test (HV). Both tests are performed on a finely ground, lapped, or polished planar surface placed at right angles to the indenter axis. The Rockwell A test employs a load of 60 kg, whereas a range of loads can be used in the Vickers test. For cemented carbides used in machining applications, hardness values range from 88 to 94 HRA and from 1100 to 2000 HV.

Although the Rockwell scale has been used for decades as a measure of hardness, a true indication of the resistance to plastic deformation in metal cutting operations can be obtained only by measuring hardness at elevated temperatures. Measurements of hardness over a wide range of temperatures are therefore valuable for tool selection.

Hardness testers with high-temperature capability (up to 1200 °C, or 2200 °F) are commercially available and are being increasingly used by the cemented carbide industry. Figure 18 shows hot hardness data for a number of cemented carbides. The hardness of these materials decreases monotonically with increasing temperatures.

Fig. 18 Variation in microhardness with temperature. Microhardness is based on a 1 kg load, and all alloys are of medium WC grain size. A, 97WC-3Co alloy; B, 94WC-6Co; C, 80WC-12(Ti,Ta,Nb)C-8Co; D, 86WC-2TaC-12Co

Compressive Properties. One of the unique properties of cemented carbides is their high compressive strength. Uniaxial compression tests can be performed on straight cylindrical samples or on cylinders having reduced diameters in the middle to localize fracture. The compressive strengths of cemented carbides are greater than those of most other materials. Typical values of compressive strength range from 3.5 to 7.0 GPa (0.5 to 1.0×10^6 psi).

The ductility of cemented carbides is generally low at room temperature, so there is little difference between their yield strength and fracture strength. At higher temperatures, however, these materials exhibit a small but finite amount of ductility. Measurement of yield strength is therefore more appropriate at elevated temperatures. High-temperature compressive yield strength is typically measured at 0.2% offset strain. Compression tests are performed in a high-temperature furnace (typically with resistance heating) under a vacuum or in an inert atmosphere. Figure 19 shows yield strength data for selected straight and alloyed WC-Co grades. Like hardness, the compressive yield strengths of cemented carbides decrease monotonically with increasing temperature; the rate of decrease depends on the composition and the microstructure. As in metallic materials, fine-grain alloys tend to lose their yield strengths more rapidly with increasing temperature than coarse-grain grades, although at room temperature the former can exhibit high yield strengths.

Fig. 19 Variation in compressive yield strength with temperature. Measured at 0.2% offset strain; all alloys characterized by medium grain size. A, 73WC-22(Ti,Ta,Nb)C-5Co alloy; B, 80WC-12(Ti,Ta,Nb)C-8Co; C, 86WC-8(Ti,Ta,Nb)C-6Co; D, 86WC-2TaC-12Co

Transverse Rupture Strength. The most common method of determining the fracture strength of cemented carbides is the transverse rupture test. In this test, a rectangular test bar is placed across two sintered carbide support cylinders, and a gradually increasing load is applied by a third carbide cylinder at the midpoint between the supports. Transverse rupture strength is determined from the dimensions of the test bar, the distance between the supports, and the fracture load. A disadvantage of this test is the large scatter in the experimental data resulting from surface defects introduced into the test specimens during processing. Nevertheless, it is an excellent quality control test, and it is particularly useful for large carbide components. Figure 17(e) shows the variation in transverse rupture strength with cobalt content.

Fracture toughness is less sensitive than transverse rupture strength to such extrinsic factors as specimen size, geometry, and surface finish. Fracture toughness is measured by the critical stress intensity factor (K_{Ic}), which indicates the resistance of a material to fracture in the presence of a sharp crack and thus provides a better measure of the intrinsic strength of the cemented carbide than transverse rupture strength. A variety of specimen geometries have been used in this test, including the single-edge notched beam, the double cantilever beam, the compact tension specimen, and the double torsion specimen. The carbide industry in the United States generally uses commercial equipment for fracture toughness evaluation. The fracture toughness of cemented carbides increases with cobalt content and with WC grain size (Fig. 20). On the other hand, cubic carbide additions lessen the fracture toughness of WC-Co alloys.

Fig. 20 Variation in toughness (K_{Ic}) with cobalt content for WC-Co alloys with different WC grain sizes. Source: Ref 29

As with the other mechanical properties, attention is focused on the development of test techniques to evaluate fracture toughness at elevated temperatures. Figure 21 shows K_{Ic} data for a number of cemented carbides from room temperature to about 1000 °C (1800 °F). Depending on the composition of the cemented carbide, the K_{Ic} parameter is insensitive to temperature, up to about 600 °C (1100 °F), but increases rapidly at higher temperatures. This behavior is reminiscent of the ductile-to-brittle transition observed in quenched-and-tempered steels.

Fig. 21 Variation in fracture toughness (K_{Ic}) with temperature for a number of WC-Co base alloys. A, 86WC-2TaC-

12Co; B, 85WC-9(Ti,Ta,Nb)C-6Co; C, 80WC-12(Ti,Ta,Nb)C-8Co; D, 96WC-4Co

The density, or specific gravity, of cemented carbides is very sensitive to composition and porosity in the sample and is widely used as a quality control test. Density values of cemented carbides range from 15 g/cm³ for low-cobalt straight WC-Co alloys to about 10 or 12 g/cm³ for highly alloyed carbide grades (Fig. 17c).

Magnetic Properties. Tungsten carbide-cobalt alloys lend themselves to the analysis of magnetic properties because cobalt is ferromagnetic. The properties measured are magnetic saturation and coercive force. Both free cobalt and solid solutions of cobalt and tungsten contribute to magnetization. The magnetic saturation of pure cobalt is $201 \times 10^{-6} \text{ T m}^3/\text{kg}$. With additions of tungsten to cobalt, the magnetic saturation decreases steadily from 201×10^{-6} to about $151 \times 10^{-6} \text{ T m}^3/\text{kg}$. In this range, the cemented carbide is characterized by two or three phases (WC and Co, or WC, a solid-solution carbide, and Co). Values below $151 \times 10^{-6} \text{ T m}^3/\text{kg}$ indicate the presence of η phase. The solubility of tungsten in cobalt is inversely proportional to carbon content. Lower-carbon alloys have more tungsten dissolved in cobalt and are characterized by lower magnetization. Magnetic saturation thus provides an accurate measure of the changes in carbon content in the cemented carbide alloy and is widely used as a quality control test.

The coercive force varies considerably with increasing sintering temperature and indicates the structural changes that take place during sintering. The coercive force of WC-Co alloys reaches a maximum at the optimum sintering temperature and decreases at higher temperatures because of grain growth. Therefore, measurement of the coercive force permits control of the sintering process. The factors influencing the coercive force are complex, varied, and interactive. For a given cobalt and carbon content, the coercive force provides a measure of the degree of distribution of the carbide phase in the microstructure. Commercial units are available for the rapid measurement of magnetic saturation and coercive force in cemented carbides.

Porosity. The properties of a cemented carbide are dependent on its density, which in turn is critically dependent on composition and porosity. Porosity is evaluated on the as-polished material. The American Society for Testing and Materials (ASTM) has established a standard procedure (B 276) that rates three types of porosity:

- Type A, covering pore diameters less than 10 μm
- Type B, covering pore diameters between 10 and 25 μm
- Type C (Fig. 13), covering porosity developed by the presence of free carbon

Type A porosity is rated at a magnification of 200 \times , while types B and C porosity are rated at 100 \times . The degree of porosity is given by four numbers ranging in value from 02 to 08. The number provides a measure of pore volumes as a percentage of total volume of the sample.

Thermal Shock Resistance. Resistance to thermal shock is an important property that determines tool performance. No laboratory test has yet been developed that can consistently predict the resistance to thermal shock of a tool. However, empirical parameters have been suggested that can be used to evaluate tool materials for their probable resistance to thermal shock (Ref 30). A commonly used parameter is $\sigma k/E\alpha$, where σ is the transverse rupture strength, k is the thermal conductivity, E is Young's modulus, and α is the coefficient of thermal expansion. Table 9 lists representative values of this parameter for a number of WC-Co alloys. In general, the higher the value of $\sigma k/E\alpha$, the better the thermal shock resistance.

Table 9 Thermal shock resistance parameters for cemented carbides

Composition, wt%	WC grain size	Transverse rupture strength, σ		Thermal conductivity (k), W/m · K	Young's modulus, E		Coefficient of thermal expansion (α), $\mu\text{m/m} \cdot \text{K}$	Thermal shock resistance ($\sigma k/E\alpha$), kW/m
		MPa	ksi		GPa	10^6 psi		
97WC-3Co	Medium	1590	230	121	641	93	5.0	60
94WC-6Co	Medium	2000	290	100	648	94	5.4	57
90WC-10Co	Fine	3100	450	80	620	90	6.0	67
71WC-12.5TiC-12TaC-4.5Co	Medium	1380	200	35	565	82	6.5	13
72WC-8TiC-11.5TaC-8.5Co	Medium	1720	250	50	558	81	6.8	23

Abrasive Wear Resistance. Most producers of cemented carbides use a wet-sand abrasion test to measure abrasion resistance. In this test, a sample is held against a rotating wheel for a fixed number of revolutions while the sample and wheel are immersed in a water slurry containing aluminum oxide particles. Comparative rankings are reported, usually on the basis of a wear rating based on the reciprocal of volume loss (Fig. 17b).

Abrasion resistance is also measured by Cemented Carbide Producers Association procedure CCPA-112 with an abrasion resistance index as shown in Fig. 22. The lower the binder content and finer the tungsten carbide grain size, the harder and more abrasion resistant is the final product. Small additions of tantalum carbide (less than 1%) do not affect abrasion resistance, because tantalum carbide is a softer carbide than tungsten carbide. Large additions of tantalum carbide, however, lower abrasion resistance. Nickel binder grades have lower abrasion resistance than comparable cobalt binder grades.

Fig. 22 Effect of tungsten carbide grain size and cobalt content on the relative abrasion resistance of cemented carbides

Although standard test procedures are available, carbide producers have not agreed on a single test method, and so the values of abrasion resistance cited in the literature vary widely. Because of this variance, it is almost impossible to make valid comparisons among test results reported by different producers. It is also fallacious to use abrasion resistance as a measure of the wear resistance of cemented carbide materials when they are used for cutting steel or other materials; abrasion resistance in a standard test does not correspond directly to wear resistance in machining operations.

Generally, the abrasion resistance of cemented carbides decreases as cobalt content or grain size is increased (Fig. 17b). Abrasion resistance is also lower for complex carbides than for straight WC grades having the same cobalt content.

Impact strength, or shock resistance, is a function of cobalt binder content and tungsten carbide grain size. Higher cobalt levels and larger tungsten carbide grain sizes increase impact strength (Fig. 23). Tantalum carbide additions do not affect impact strength, however. Conditions that increase impact strength also increase thermal shock resistance

Fig. 23 Effect of cobalt content on the impact strength of cemented carbides. Average tungsten carbide grain size: 3 μm

Corrosion Resistance. In corrosive attack of cemented carbides, the tungsten carbide component usually is not affected. The binder metal corrodes, exposing the angular tungsten carbide grains. A roughened surface results, which may cause tool wear or work material galling. To increase corrosion resistance, less binder metal should be exposed to attack. This can be accomplished by using a finer tungsten carbide grain size and lower binder metal content. Finer tungsten carbide grain size also yields more tungsten carbide surface area and results in a higher dissolved tungsten content in the binder metal, with improved corrosion resistance. Frequently, nickel binder grades exhibit higher corrosion resistance than comparable cobalt binder grades (Table 10). Small additions of chromium to both nickel and cobalt increase corrosion resistance, but cause embrittlement of the cemented carbide.

Table 10 Corrosion rates of cemented carbide test samples immersed for 48 h at 22 °C (72 °F)

Material	Tungsten carbide grain size, μm	Corrosion rate in:

Powder Metallurgy Beryllium

James M. Marder, Brush Wellman

Introduction

BERYLLIUM, due to its unique mechanical and physical properties, is used in various nuclear, x-ray, aerospace, and consumer fields. Interest in beryllium parts was stimulated with the advent of the nuclear energy program. Current and past uses include diverse applications such as:

- Moderator material in nuclear reactors
- Neutron source in nuclear weapons
- Lightweight and dimensionally stable material in inertial guidance systems
- Use in reentry systems with the ability of beryllium to efficiently absorb heat
- Heatsink material for brakes on C5A, F-14, B-1B, F-18, and S3A aircraft
- Structural material in aerospace applications that require superior strength, thermal diffusivity, and rigidity at elevated temperatures in conjunction with light weight

Other applications include precision instruments; x-ray windows; satellite structures including antennas, control rods, small rocket nozzles, mechanical fasteners, and high-speed rotating shafts. Consumer products include laser mirrors for bar code readers. The wide acceptance of beryllium by the optical industry for use as support structures and mirror substrates is directly related to the density, stiffness, and reflectivity of beryllium.

During the last 20 years, efforts have increased to overcome the problem of brittleness associated with beryllium. New grades of beryllium with strength and ductility significantly superior to those available in the 1960s have been developed.

Breakthroughs in P/M technology have been achieved with the use of balanced iron and aluminum levels, the introduction of impact attritioning as a means of beryllium powder production, and the use of cold and hot isostatic pressing techniques for consolidation. Additional information on beryllium processing can be found in the article "Production of Beryllium Powders" in this Volume.

Powder Metallurgy Beryllium

James M. Marder, Brush Wellman

Physical Properties

Beryllium, with a density of 1.8477 g/cm³, is a light metal with a combination of physical properties that is not found in any other metal or alloy. Beryllium has a high melting point (1283 °C, or 2341 °F), high modulus of elasticity (up to 300 GPa, or 44 × 10⁶ psi), high specific heat (1.88 kJ/kg · K, or 0.45 Btu/lb · °F at room temperature), and a low coefficient of thermal expansion (average of 10.66 × 10⁻⁶/ °C in the temperature range of 2 to 38 °C, or 36 to 100 °F). The strength-to-weight ratio for wrought beryllium is higher than titanium. The following properties make beryllium one of the more desirable structural materials in the aerospace field:

Density, g/cm ³	1.8477
Melting point, °C (°F)	1283 (2341)
Modulus of elasticity, GPa (10 ⁶ psi)	275-300 (40-44)
Specific heat, kJ/kg · K (Btu/lb · °F)	1.88 (0.46)
Thermal conductivity, W/m · K (Btu · ft/ft ² · h · °F)	190 (104)
Linear coefficient of thermal expansion, 10 ⁻⁶ /°C	
At 25-100 °C	11.6
At 25-300 °C	14.5
At 25-600 °C	16.5
At 25-1000 °C	18.4

The following physical characteristics also contribute to the versatility of beryllium and its wide usage in a variety of applications:

- A protective oxide surface film, similar to that of aluminum, is formed in air.
- Oxidation at elevated temperature is not excessive below about 700 °C (1290 °F).
- Its electrical conductivity is 40% IACS.
- It is nonmagnetic.
- It reflects light (optical reflectivity, 50%; ultraviolet reflectivity, 55%; infrared (10.6 μm) reflectivity, 98%).
- It transmits sound (velocity of sound in beryllium is 12,600 m/s, 41,300 ft/s, 2 $\frac{1}{2}$ times that of steel).
- It is transparent to x-rays.

The low thermal neutron absorption cross section of beryllium (0.009 b) and high neutron scattering cross section (6.9 b) make it useful as a moderator and a reflector for nuclear reactors. Beryllium is particularly well suited for reactor applications in which weight and space economy is important. Neutron economy and flux density are increased by the use of beryllium in nuclear reactors.

Mechanical Properties

The mechanical properties of beryllium are consistent with its application as an aerospace structural material. Tensile properties for various grades of beryllium are presented in Table 1. It is apparent that the yield and ultimate strengths compare quite favorably with those of aluminum alloys and are comparable to structural titanium alloys on a strength-to-weight basis.

Table 1 Room-Temperature tensile properties of commercial beryllium grades

Grade	Pressing method	Orientation	Ultimate tensile strength		0.2% Offset yield strength		Elongation, %
			MPa	ksi	MPa	ksi

I-220H	HIP	L	523	75.9	448	65.0	3.7

VHP, vacuum hot pressed; HIP, hot isostatic; L, longitudinal; T, transverse

Historically, the use of beryllium in structural applications was somewhat limited by low ductility values. Within the past twenty years, however, ductility levels have significantly increased, so that elongation values of 4 and 5%, a typical value for many titanium and aluminum alloys, are no longer considered highly unusual. A great deal of process development was required in order to achieve this level of ductility. Improvements in purity were superseded by the realization that balancing the levels of impurity elements such as iron and aluminum was a more effective method of eliminating embrittling phases. In addition, powder making techniques such as impact grinding and inert gas atomization were shown to be effective in reducing the anisotropy of the final consolidated product. Use of hot isostatic pressing (HIP) as a powder consolidation process has likewise improved the isotropy and grain size control required to impart significant ductility. Methods to improve beryllium ductility at room temperature have included control of preferred orientation, improved purity, reduction of inclusions (beryllium oxide content, for example), altering inclusion distribution, and reducing grain size.

Preferred Orientation. Hot upsetting or rolling beryllium tends to align the basal planes parallel to the plane of rolling. This alignment of basal planes improves the ductility in the plane of sheet or block, because longitudinal stresses are mostly sustained by prism planes. Stresses resolved across the basal planes also are lower for a given applied load.

Grain Size. Strength of beryllium is related directly to grain size (Fig. 1) which is primarily a function of the particle size, oxide content, and consolidation temperature of the powder used. Historically, attempts to produce fine-grained, high-ductility beryllium by reducing the size of the source powder have met with only moderate success. Although the grain size is reduced, conventional powder manufacturing techniques such as disk mill attritioning and ball milling increase oxide content rapidly as particle size of the powder decreases. This has an embrittling effect, which often nullifies the effect of reduced grain size.

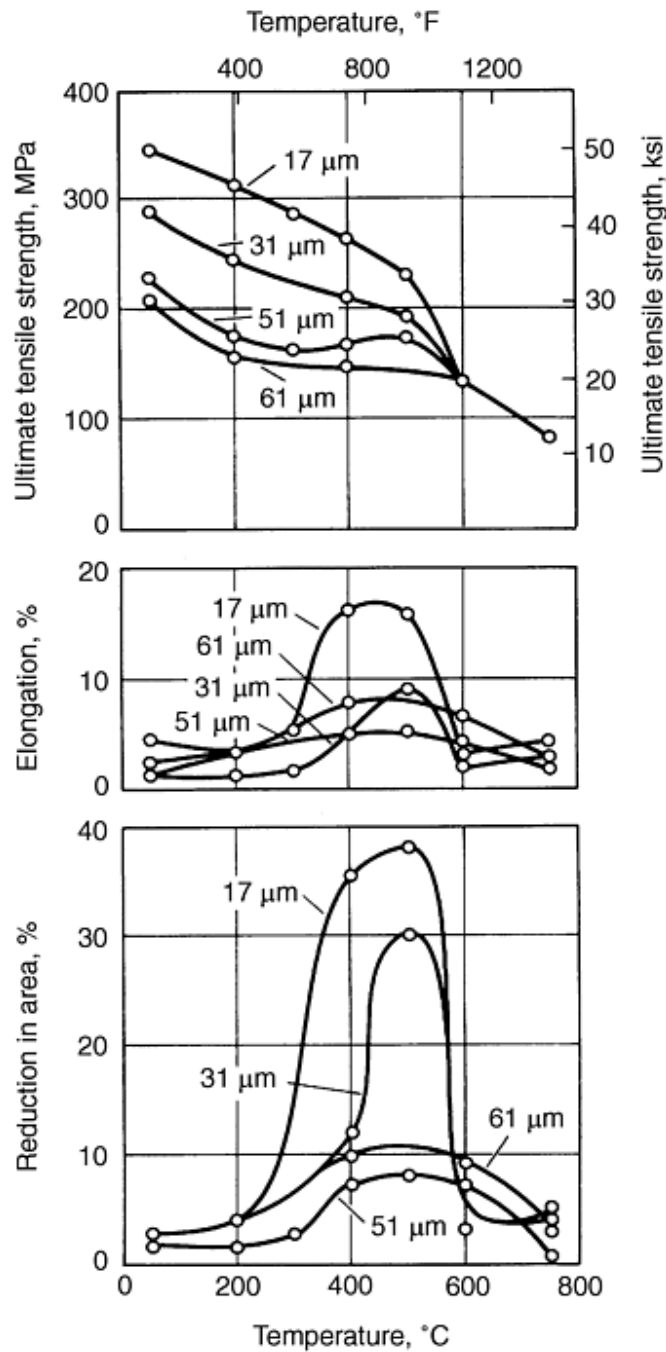

Fig. 1 Effect of grain size on the elevated-temperature tensile properties of vacuum hot pressed beryllium

The impact attrition system, which is illustrated in Fig. 2, currently is used for production of beryllium powder. In this system, coarse powder from the feed hopper is fed into the gas stream, and the gas-borne powder is carried through the nozzle, where the velocity of the gas and powder mixture increases. The powder impacts the beryllium target and is comminuted. Gas-borne powder is transported to the primary classifier, where coarse particles drop out, and fines are carried to the secondary classifier. In this stage, the coarse particles (the product) drop out, and ultrafines (powders with high oxides and intermetallic contaminant contents) are discarded. High-pressure gas is turned off when the feed hopper is empty. When the system returns to ambient pressure, the valve at the bottom of the primary classifier is opened to deposit the coarse particles into the feed hopper for the next cycle.

Fig. 2 Impact attrition mill

Impact attritioning has enabled consistent control of powder composition by reducing impurity contamination and oxidation of powder particles. The process also results in improved powder configuration and morphology, resulting in improved isotropy and cleaner microstructure of the consolidated product.

Powder Metallurgy Beryllium

James M. Marder, Brush Wellman

Microalloying

Impurity elements that affect the behavior of beryllium include aluminum, iron, silicon, magnesium, copper, cobalt, nickel, oxygen, and carbon. Aluminum and iron can cause deleterious effects in beryllium. When present at the grain boundaries, aluminum causes reduced ductility in components for high-temperature applications.

Iron forms an intermetallic compound, FeBe_{11} , which results in precipitation hardening. Yield point phenomena observed in beryllium have been attributed to the pinning of dislocations by FeBe_{11} precipitates. If the pinning of dislocations persists until the ultimate strength is reached, the metal fractures with little plastic deformation. However, moderate yield points that peak before the fracture stress may have little effect on the mechanical behavior of beryllium and may be of considerable advantage where elastic limit is a design factor. Aluminum and iron, when present together in beryllium, can form an FeAlBe_4 compound. The proper balancing of iron and aluminum content can eliminate the embrittling effects of aluminum or FeBe_{11} precipitation without resorting to ultrahigh-purity materials.

Silicon acts as a sintering aid in the consolidation of beryllium powder. In practice, the hot pressing of beryllium powder with low silicon content (<100 ppm) to full density is difficult because of the pressure tolerable with graphite dies. The high-pressure capability of hot isostatic pressing often is used for the consolidation of low-silicon, high-purity electrolytic

powders. Alternatively, the material is doped with silicon either by elemental additions at the vacuum melting stage or by adding trichlorosilane at the vacuum hot pressing stage.

When present at grain boundaries, silicon, along with other low-melting constituents such as aluminum and magnesium, also affects the morphology, size, and distribution of beryllium oxide. In general, these elements cause agglomeration and growth of beryllium oxide particles and also affect recrystallization, grain growth, and creep strength of beryllium. Copper, cobalt, and nickel exhibit extensive solubility in beryllium.

Among the nonmetallic impurities, only carbon and oxygen are present to any appreciable extent. Both have minimal solubility in beryllium. Carbon occurs as the cubic refractory compound beryllium carbide, which usually is found within the grains. This carbide accelerates the corrosion of beryllium, as it slowly hydrolyzes in the presence of moisture.

Oxygen forms stable beryllium oxide, which is primarily a grain-boundary constituent. However, it may also be found in the matrix. Typical concentrations of beryllium oxide in beryllium range from 0.7 to about 2% in commercial products.

Powder Metallurgy Beryllium

James M. Marder, Brush Wellman

Powder Production and Consolidation

The production of beryllium powder begins with extraction of beryllium from ore by chemical, thermal, and mechanical processing. Extraction produces beryllium "pebble," a relatively impure product containing magnesium fluoride and other impurities. These pebbles are vacuum remelted and cast into ingots, which exhibit a coarse grain size, low ductility, and low resistance to fracture. The vacuum cast ingots are cut up into chips by lathe turning. Chips are subsequently comminuted by impact attritioning (Fig. 2) to a particle size suitable for P/M fabrication. Table 2 gives the nominal compositions for nuclear and structural grades of beryllium powders. Production of other grades of beryllium is possible by varying the powder particle size, chemical composition, and processing pressure and temperature. Beryllium is one of the few metals that is fabricated exclusively by P/M techniques. Beryllium powders are consolidated to near-theoretical density by:

- High-vacuum/high-temperature sintering
- Vacuum hot pressing
- Cold isostatic pressing followed by vacuum hot pressing
- Cold isostatic pressing followed by pressureless sintering
- Cold isostatic pressing followed by hot isostatic pressing
- Direct hot isostatic pressing

Table 2 Nominal compositions of nuclear and structural grades of beryllium powders

(a) Minimum.

(b) Maximum

The most common methods of consolidation, vacuum hot pressing and hot isostatic pressing, are described below.

Vacuum hot pressing was the most frequently used technique for producing commercial beryllium billet. Graphite dies are commonly used because they have a low coefficient of thermal expansion, which simplifies removal of the beryllium block after cooling. Graphite is available in sufficiently large sizes to produce vacuum hot pressings at more than 560 mm (22 in.) in diameter. Pressings that are too large in diameter for graphite dies are produced in nickel-alloy dies. IN-100 dies allow pressings up to 1830 mm (72 in.) in diameter.

Beryllium powder is vibratory loaded into the dies to achieve a density of about 55%. The die assembly is then placed in a vacuum hot pressing chamber. Vacuum, heat, and pressure are applied concurrently. Typical pressing temperatures range from 1000 to 1100 °C (1830 to 2010 °F), and pressure ranges from 3.5 to 14 MPa (500 to 2000 psi) with vacuum conditions below 500 torr, depending on powder characteristics and size of the compact. High-purity and fine particle size powder require much higher pressures.

Hot isostatic pressing offers advantages over vacuum hot pressing in that higher pressures are available and the limitations imposed by graphite dies are eliminated. Hot isostatic pressing has superseded vacuum hot pressing as the highest production volume process. The 3.5 to 14 MPa (500 to 2000 psi) pressure normally considered the maximum for graphite dies is marginal for some grades of beryllium and inadequate for high-purity grades. Hot isostatic pressing is generally done at 103 MPa (15 ksi) at temperatures varying from 760 to 1100 °C (1400 to 2010 °F).

High-purity beryllium powders lack sufficient concentration of impurity elements such as aluminum and silicon that act as sintering aids in the vacuum hot pressing of normal-purity powders. Although normal-purity beryllium powder can be vacuum hot pressed to nearly theoretical density by pressing at about 7 MPa (1000 psi) at 1050 °C (1920 °F), high-purity powder can be consolidated to only 98% density at the same temperature even when employing pressures as high as 24 MPa (3500 psi) or more.

These pressures are close to the upper limit at which consolidation can be carried out using graphite die tooling. Hot isostatic consolidation at pressures of about 103 MPa (15 ksi) and a temperature of 1100 °C (2010 °F) offers the only effective means of reliably consolidating high-purity powders to full theoretical density. High-temperature isostatically pressed beryllium has somewhat lower strength and better elongation. Optimal properties of strength and ductility are obtained by isopressing at lower temperatures.

Improved isotropy of both microstructure and mechanical properties is a major advantage of isostatic pressing. Because pressure is applied from all sides, shrinkage is uniform in all directions, and directionality originating from the pressing operation is prevented. However, there is some preferential alignment of powder particles in the starting powder bed, which results in some anisotropy in the hot isostatically pressed part. When hollow parts are hot isostatically pressed against a mandrel (usually made of copper), there is more shrinkage in the thickness direction, because friction between the mandrel and the part impedes free movement in the axial direction. Thus, the basal planes become aligned in the circumferential direction.

Isostatic consolidation of high-purity powder products improved physical and mechanical properties, including fine grain size, well-distributed oxide content, clean microstructure, good tensile and elongation properties, a smooth stress-strain curve that is free of yield point, a high degree of isotropy, good compression creep properties, good high-temperature properties, and no grain growth below 1260 °C (2300 °F).

Powder Metallurgy Beryllium

James M. Marder, Brush Wellman

Wrought Product Forms

After powder is consolidated, beryllium is readily processed by conventional metalworking methods. Wrought forms of beryllium with optimal properties are produced from vacuum hot pressed P/M billets by conventional hot-working techniques. Wrought products exhibit improved mechanical properties in the predominant direction of metal flow. Mechanical properties of wrought products depend greatly on crystallographic orientation. Biaxial or triaxial deformation procedures frequently are used to produce parts with balanced directional properties.

Sheet, plate, and foil are the most commonly produced wrought forms of beryllium. These flat-rolled products are produced by encasing beryllium rolling blocks in steel jackets, followed by cross rolling at a moderate temperature. Biaxial deformation is accomplished by alternating the direction of the rolling pack through the rolling mill. This procedure produces flat-rolled products with uniform biaxial properties. See Table 3 for typical tensile properties of beryllium sheet. The standard condition that sheet and plate are supplied in is hot rolled, stress relieved, ground, and pickled.

Table 3 Typical tensile properties of beryllium

- (a) 0.2% offset.
- (b) Elongation in 50 mm (2 in.), except 250 mm (10 in.) for wire.
- (c) Structural grade contains about 1.8% BeO and thermal or brake grade about 0.9%.

Beryllium foil is available in thicknesses from 0.025 to 0.5 mm (0.001 to 0.019 in.) and panel sizes up to 125 by 300 mm (5 by 12 in.). Beryllium foil is also available in disk form in diameters up to 200 mm (8 in.) for x-ray window applications.

Beryllium extrusions are available with consistent mechanical properties. Sections are supplied to dimensions that are within commercial tolerances. Mechanical properties of extrusions are superior to the mechanical properties of hot pressed block in the direction of metal flow. Directional properties are produced in varying degree, as a function of crystallographic orientation.

Input billets for extrusions usually are machined from hot pressed block. Vacuum cast ingots and unsintered powder can be extruded for custom applications. Extrusion billets are jacketed in low-carbon steel cans that have shaped nose plugs and are extruded through a steel die between 900 to 1065 °C (1650 to 1950 °F). Warm extrusions are produced at about 425 °C (800 °F) when the volume of the product is large enough to justify the special tooling. Steel jackets are chemically removed from the extrusions.

Rod, tubing, and structural shapes are also available. Rod is produced in sizes from 9.5 to 135 mm (0.375 to 5.250 in.) in diameter. Tubing is available from 6.4 mm ($\frac{1}{4}$ in.) outside diameter by 10 mm (0.040 in.) wall thickness up to 150 mm (6 in.) outside diameter by 3.20 mm (0.125 in.) wall thickness. A wide variety of structural and special shapes are also available. Current applications include structural shapes for aerospace applications, finned tubing for nuclear reactors, bar stock for forging and finish machining, fastener stock, rotating shafts, fuel element cladding, and draw stock for wire. Table 3 lists typical tensile properties of beryllium extrusions.

Applications of Beryllium

Aerospace Applications. The low density and high modulus of elasticity of beryllium make it an ideal choice as a structural member in aerospace components. The development of higher ductility grades of beryllium in various wrought forms, including sheet metal, has increased the potential application of beryllium in the aerospace field. Figure 3 illustrates a beryllium thrust tube (cone) assembly for the Japanese CS-2 satellite. Tests to determine the structural load-carrying capacity indicated that this structure has carried uniform loads at and/or above yield strength limits. Posttest analysis and inspection of the beryllium assembly indicated that it was flight qualified; loads were increased to over 160% of the theoretical limit. Another aerospace application is the Hughes MODIS satellite, which uses a beryllium structure as well as a beryllium optical system.

Fig. 3 Beryllium thrust tube assembly for the Japanese CS-2 Satellite. Courtesy of Brush Wellman

The low density, high elastic modulus, and dimensional stability of beryllium are also exploited in the optical bench for the McDonnell Douglas mast-mounted helicopter sight system. Laser, television, and infrared sensors are mounted to the bench, which must maintain precise alignment for proper operation of the target detector and designator system. Figure 4 shows the location of the mast-mounted sight on a Bell-OH-58D helicopter.

Fig. 4 Mast-mounted sight system (positioned above rotor) using a beryllium optical bench

X-ray and Nuclear Applications. Because it has excellent transparency to soft x-rays and other radiation such as gamma rays, beryllium is used in x-ray tube windows. Because of its low atomic weight, beryllium passes x-rays 17 times better than an equivalent thickness of aluminum. Beryllium x-ray windows allow the use of long-wave x-rays that have greater density. Most of these applications require disks that are thinner than 0.25 mm (0.01 in.) and are cut from sheet or machined from vacuum hot pressed blocks.

The stiffness of beryllium and its transparency to x-rays are combined in medical radiation detection devices such as computerized axial tomographic scanners and other related equipment with pressurized detection chambers. A stiff beryllium window resists the internal gas pressure with minimum deflection. The capability of rolling beryllium to a thin foil permits the transparency of beryllium to electromagnetic radiation to be used to the greatest advantage.

The growth of the nuclear energy field has provided new applications for beryllium components. Beryllium continues to be used as a reflector material in research and fast reactors. Beryllium has also been used to some degree in power reactors, for moderators, reflectors, and fuel cladding material.

Instrument Applications. Beryllium is used in precision-machined components in inertial guidance systems. Since its initial use in the mid-1950s, beryllium has come to be accepted as the baseline structural material for precision navigational instruments. It is now used in precision navigational aides for aircraft, spacecraft, missiles, ships, and submarines. The high modulus, high precision elastic limit, and dimensional stability under high G-forces make beryllium the material of choice for this application.

High-Temperature Applications. Beryllium has the highest specific heat of all structural materials, good thermal conductivity, relatively high melting point, and resistance to oxidation up to about 700 °C (1290 °F). It is a highly efficient heatsink, heat shield, and aircraft and automobile brake material. Beryllium is also used for making rocket engine nozzles and switchgear components. Beryllium has been used successfully for load-carrying disc brakes in military cargo and fighter aircraft and for making thrust chambers of rocket engines.

Nuclear Fusion Application. Beryllium has a unique combination of properties that dramatically improves the control of nuclear fusion energy reactors such as the Joint European Torus (JET). The combination of the excellent oxygen gettering performance of beryllium with its low atomic number eliminates plasma density disruptions, increases the time scale of magnetohydrodynamic effects, and reduces runaway photoneutron production. The JET has used S-65C beryllium extensively in belt limiters, target plate tiles, and the radiofrequency antenna.

Aluminum-Beryllium Alloys. AlBeMet 162 is an alloy of aluminum with 68 wt% beryllium. It was first used for the ventral fin of the SR-71 aircraft, when it was known as Lockalloy. Renewed interest in this alloy as part of the National Aerospace Plane effort led to its widening use in aerospace and commercial applications. The elastic and thermal-management properties of AlBeMet are significantly better than those of aluminum, although they do not equal those of beryllium. Physical properties of AlBeMet 162 are presented in Table 4, and mechanical properties of the three commercial available forms--extrusions, sheet, and hot isostatically pressed block--are presented in Table 5. The production process for sheet and plate and extrusions is shown in Fig. 5.

Fig. 5 AIBeMet aluminum-beryllium alloy sheet and plate manufacturing sequence

The properties of AIBeMet make it a meaningful candidate for many applications in which aluminum or titanium could also be used. In addition, fabrication such as welding and joining of AIBeMet can be easier than with beryllium. This makes it an attractive alternative when the properties of beryllium are well in excess of required values. Current aerospace uses include electronic modules for the F-22 tactical fighter, and antenna and structures of a variety of commercial communication satellites such as the OrbComm system. In commercial products, AIBeMet served as the voice coil actuator in high-performance hard disk drives (Fig. 6) in the early 1990s because of its light weight and high stiffness. In addition, the brake calipers of Formula I automobiles have been manufactured in AIBeMet and used by many racing teams.

Mechanical Properties of High-Performance Powder Metallurgy Parts

John C. Kosco, Keystone Powdered Metal Company

Introduction

POWDER METALLURGY was first developed for processing refractory and other special materials and has now expanded into a competitive forming method for a wide variety of parts in automobiles, aircraft, lawn and garden equipment, sporting goods, and appliances. In terms of parts production, P/M bearings were the first part application, in the late 1920s, in response to a need for low-cost bearings for the electric motor business. In this case, it was found that the porosity inherent in early P/M materials could be filled with oil so a self-lubricating bearing material resulted.

The P/M bearing remains a major product to this day, but the scope of powder metallurgy has expanded from that beginning to encompass a wide variety of applications from low-density filters to fully dense structural components with properties equal to and, in some cases superior to, wrought alloys. For high-performance P/M structural materials, the single most significant characteristic of P/M materials is density and its effect on mechanical properties as shown in Fig. 1 and 2 for various iron compacts. There is a slow increase in properties as density increases from 6.8 to 7.4 g/cm³. At that point, properties (especially Izod impact, Fig. 2) increase exponentially as density approaches the theoretical limit of steel (about 7.87 g/cm³).

Fig. 1 Elastic modulus of ferrous sintered materials as a function of density. Source: Ref 1

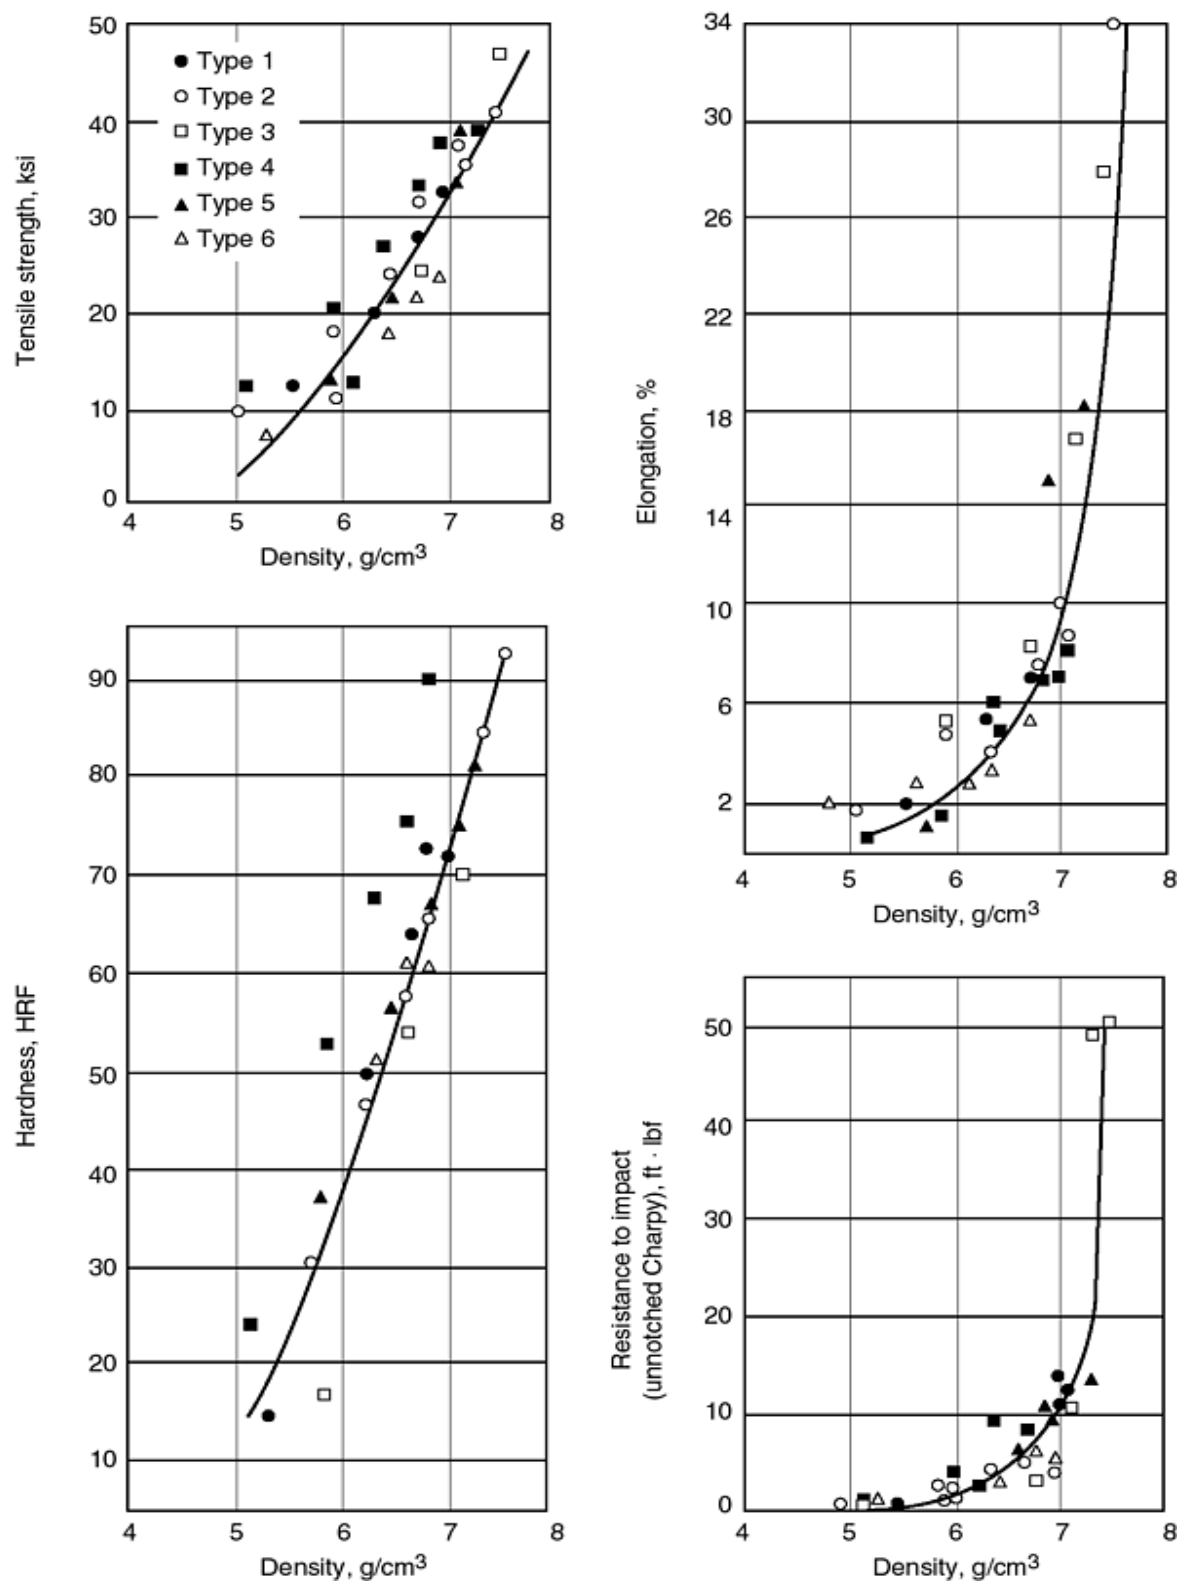

Fig. 2 Mechanical properties of iron compacts as a function of sintered density. Source: Ref 2. (See also Fig. 1 in the article "Hot Isostatic Pressing of Metal Powders.")

The traditional and least expensive method for producing P/M parts is a single press and sinter. By cold pressing and sintering only, ferrous P/M parts are produced to density levels of about 6.4 to 7.1 g/cm³, about 80 to 90% of theoretical density, which for iron or low-carbon steel is 7.87 g/cm³. Additional processing, such as infiltration or double press/double sinter, can be used to increase densities at somewhat higher cost relative to single press-and-sinter operations (Fig. 3). However, higher density is crucial in obtaining sufficient mechanical properties for high-performance parts. Therefore, this article briefly reviews P/M processes for higher-density parts followed by a compilation of mechanical property data as a function of density and processing. The mechanical property data are intended to show the influence of composition, processing, and heat treatment for ferrous parts. Other P/M materials and additional data on ferrous P/M materials are covered elsewhere in this Volume.

Fig. 3 Relative cost versus ferrous part density of several p/m processes. Note: Cost also depends on die/part size (e.g., see Fig. 2 in the article "Hot Isostatic Pressing of Metal Powders.")

Mechanical Properties of High-Performance Powder Metallurgy Parts

John C. Kosco, Keystone Powdered Metal Company

High-Density Processing

Powder metallurgy parts with theoretical densities less than 75% are considered to be low density, those above 90% are high density, and those in between are classified as medium density. Generally, structural parts have densities ranging from 80 to above 95%. The types of P/M processes and corresponding densities for ferrous structural parts are:

Process	Method	Density, g/cm ³
Single press sinter	Mold at 415-690 MPa (30-50 tsi) and sinter 1120-1260 °C (2050-2300 °F)	6.8-7.0
Sinter harden	Same as single-press sinter but using an alloy that will harden while cooling in the sintering furnace	6.8-7.1
Copper infiltration	Infiltration of porosity with copper	7.0-7.3
Warm mold	Uses a polymeric binder and molding at about 150 °C (300 °F)	7.2-7.4
DP/DS	Double press/double sinter	7.2-7.5
HFA	High-fatigue alloy via mold-sinter-size-heat treat	7.5-7.65
HF	Hot formed, forged at 760-980 °C (1400-1800 °F)	7.7-7.85

This section briefly summarizes only those processes capable of reaching at least 95% theoretical density, which would be a density in excess of 7.4 g/cm³ for iron and low-alloy steel compacts. This excludes copper-infiltrated parts, even though Fig. 3 indicates densities in excess of 7.4 g/cm³ for copper-infiltrated parts. Densities of copper-infiltrated steels can exceed 7.4 g/cm³ (see the article "Infiltration" in this Volume). However, standard grades of copper-infiltrated steels have typical densities around 7.3 g/cm³ (see "Appendix 1" in this Volume). From a practical point of view all commercially infiltrated steel parts have a density of less than 7.5 g/cm³. Higher densities can be achieved, but special processing requirements have to be met, otherwise severe sticking of residue is experienced. A process has been developed for such high density infiltration, but it is not commercial (see the article "Copper-Infiltrated Steel" in this Volume).

Double Press/Double Sinter

For high-density P/M parts, secondary operations such as re-pressing are commonly used. In the re-pressing process, pressed parts are presintered 760 to 900 °C (1400 to 1650 °F). The presintered parts are then re-pressed to a higher density and sintered at a conventional temperature. Typical density levels of presintered parts are 6.8 to 7.0 g/cm³, and this level is increased to 7.3 to 7.5 g/cm³ after re-pressing. Consequently, mechanical properties of re-pressed P/M parts are increased, allowing them to be used for intermediate-stress applications.

A wide range of properties can be achieved with the double-press/double-sinter (DP/DS) process by varying the molding and sizing pressures. In this process, an iron/carbon-alloy element powder mix is compacted, then sintered at about 870 °C (1600 °F) to anneal the compact without putting carbon into solution. It is then remolded (sized) to increase density and improve dimensional control and sintered at conventional sintering conditions, 1120 to 1260 °C (2050 to 2300 °F) in a protective atmosphere. Table 1 illustrates a typical molding and sizing matrix and the properties obtained with the specific combinations involved. A complete listing of DP/DS grades can be found in MPIF standard 35 from the Metal Powder Industries Federation.

Table 1 Molding and sizing matrix for elemental nickel steel (2Ni-0.5C) powder FN-0205

Mold pressure		Property ^(a)	Sized at:			
MPa	tsi		0 MPa (0 tsi)	415 MPa (30 tsi)	620 MPa (45 tsi)	825 MPa (60 tsi)
415	30	Sintered density, g/cm ³	6.67	7.13	7.32	7.43
415	30	Hardness, HRC	28	40	45	48
415	30	Modulus of rupture, MPa (ksi)	1040 (151)	1580 (229)	1820 (264)	1895 (275)
415	30	Izod impact toughness, J (ft · lbf)	3.8 (2.8)	6.1 (4.5)	8.1 (6.0)	8.8 (6.5)
415	30	Size change in sintering, in./in.	0.001	0.002	0.002	0.003
415	30	Ultimate tensile strength, MPa (ksi)	570 (83)	870 (126)

(a) Sintered at 1120 °C (2050 °F) and heat treated

Figure 4 is an example of data on hardness, modulus of rupture (transverse bending strength), and ultimate tensile strength (UTS) as influenced by the mold/size history of the part. Referring to the UTS plot, it is apparent that one could obtain a UTS value of 448 MPa (65 ksi) either by molding at 690 MPa (50 tsi) and sintering or by molding at 415 MPa (30 tsi), presintering, sizing at 415 MPa (30 tsi), and sintering. Normally, one would favor the single mold-sinter cycle for economics, but factors such as the complexity of the part and cost of the die might provide reason to go the other route. Table 2 summarizes typical properties for FN-0205 (2Ni-0.5C) steel processed to equal densities via different combinations of

mold/size pressures. Regardless of the manner in which the density was achieved, properties are essentially the same. Figure 5 summarizes hardness, modulus of rupture and impact properties for heat treated 2Ni steel. Again, a range of properties is possible depending on processing conditions.

Table 2 Equidensity properties of FN-0205

Molding/sizing pressures		Condition	Sinter density ^(a) , g/cm ³	Rockwell hardness	Modulus of rupture		Izod impact toughness		Ultimate tensile strength	
MPa	tsi				MPa	ksi	J	ft · lbf	MPa	ksi
415/690	30/50	Sintered	7.40	77 HRB	1105	160
550/620	40/45	Sintered	7.40	77 HRB	1205	175
690/550	50/40	Sintered	7.40	77 HRB	1190	173
415/345	30/25	Sintered	7.10	68 HRB	90	130
690/0	50/0	Sintered	7.10	68 HRB	815	118

Fig. 5 Effect of sizing pressure on mechanical properties of DP/DS quenched-and-tempered nickel steel (FN-0205/QT400) with a final sinter at 1120 °C (2050 °F). (a) Hardness. (b) Modulus of rupture. (c) Izod impact toughness

As with wrought materials, alloying affects P/M properties. Figure 6(a) plots the sintered density for two common P/M alloys, FN-0205 and FL-4205. The former is made by blending elemental atomized iron with elemental nickel and graphite powders. FL-4205 is similar in chemistry, although it does contain 0.5% Mo, but the major difference is that 4205 is prealloyed prior to atomization. The final alloy is obtained by blending in graphite. The presence of the nickel and molybdenum in solution hardens the base powder and makes it harder than pure iron. As a result, it is more difficult to densify the prealloyed powder. Figure 6(a) gives data for these two alloys, both molded at 550 MPa (40 tsi), presintered and sized. Note that higher sizing pressures are required to obtain equal sintered density with FL-4205. In Fig. 6(b-d), properties

for FN-0205 and FL-4205 are plotted as a function of density. It is obvious that the alloy addition has a beneficial effect at equal density. However, this is not necessarily true for equal processing conditions.

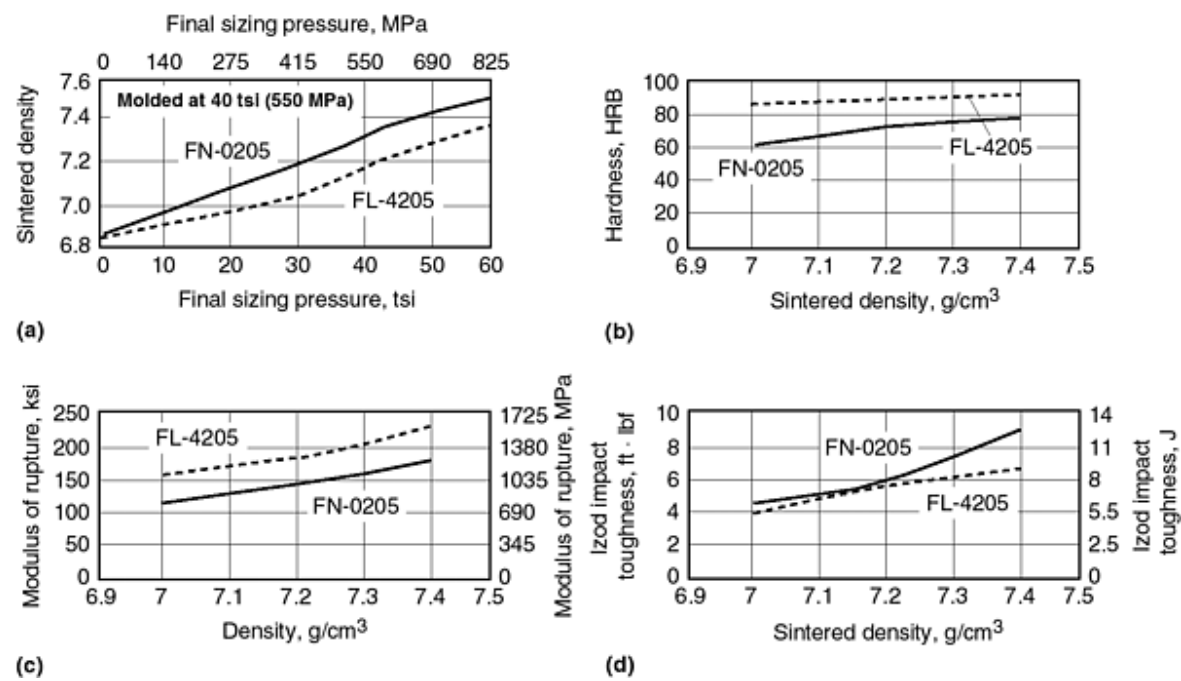

Fig. 6 Comparison of elemental nickel steel (2Ni-0.5C) FN-0205 with prealloyed nickel-molybdenum steel FL-4205. (a) Sintered density versus sizing pressure. (b) Hardness versus density. (c) Modulus of rupture. (d) Izod impact toughness. Final sintering at 1120 °C (2050 °F)

In recent years, there has been a shift toward high-temperature sintering capacity in the P/M industry. Belt furnaces are limited to about 1150 °C (2100 °F) max, but new pusher and walking beam and vacuum furnaces now permit sintering to 1315 °C (2400 °F). The higher temperatures lead to increased diffusion and rounding of porosity with property improvements as indicated in Table 3. More information on high-temperature sintering is provided in the article "High-Temperature Sintering" in this Volume.

Table 3 Effect of high-temperature sintering on impact toughness of FN-0205

Molding/sizing pressures		Sintered density, g/cm ³	Sinter temperature		Sinter atmosphere	Izod impact toughness	
MPa	tsi		°C	°F		J	ft · lbf
690/0	50/0	7.05	1140	2080	N ₂	5.2	3.8
690/415	50/30	7.27	1140	2080	N ₂	9.5	7.0
690/825	50/60	7.47	1140	2080	N ₂	10.8	8.0

Warm Compaction

Warm compaction is a relatively new P/M production method that utilizes heated tooling and powder during the compaction step. The powder and tooling are typically heated between 130 and 150 °C (260 and 300 °F). In order for the powder premix to perform at these temperatures, proprietary lubricants have been developed that provide better compressibility and lower die ejection forces than conventional lubricants. Lubricants can also incorporate polymeric binders to limit segregation and provide enhanced flow characteristics of the powder premix (see the article "Warm Compaction" in this Volume).

Warm compaction has several advantages including better compressibility and higher green strengths than conventional cold pressing and sintering. The increased green strength reduces green chipping and cracking due to part handling prior to sintering and makes possible the crack-free compaction of complex multiple-level parts. Additionally, the higher green strength provides an opportunity to machine the P/M part in the green state. This capability is critical in the use of high-performance alloy systems that achieve high hardness in the as-sintered state.

However, warm compaction also enables P/M fabricators to single press and single sinter (SP/SS) ferrous P/M parts to densities slightly above 7.4 g/cm³. Final densities depend to a large degree on the compaction pressures and chemistry. Single-press/single-sinter warm compaction is also competitive with conventional DP/DS densities (Fig. 7).

Fig. 7 Sintered density versus compaction pressure for a prealloyed nickel-molybdenum steel powder (Acorsteel 85HP) by warm compaction and conventional cold press and sinter. Final sinter at 1260 °C (2300 °F) for 30 min, 90% Na/10% H₂ atmosphere

Warm compaction can also be combined with DP/DS methods to achieve densities well above 7.4 g/cm³ for ferrous P/M parts. In DP/DS warm compaction, the first press is at typical warm compaction temperatures followed by a presinter similar to conventional DP/DS. The second compaction can be at ambient temperature, followed by the final sinter. A comparison of properties and densities are summarized in Fig. 7 and Table 4.

Table 4 Effect of SP/SS and DP/DS processing on the density and transverse rupture strength

Base material	Processing technique	Compaction pressure		Sintered density, g/cm ³	Transverse rupture strength		Hardness, HRB

- (a) Ancorsteel 85HP is a prealloyed steel powder containing 2.0% Ni, 0.85% Mo, 0.4% graphite, and 0.6% lubricant. Compacts were sintered at 1260 °C (2300 °F).
- (b) Distaloy 4800A is a diffusion-alloyed steel powder containing 4.0% Ni, 1.5% Cu, 0.50% Mo, 0.5% graphite, and 0.6% lubricant. Compacts were sintered at 1120 °C (2050 °F).

Surface Densification

Surface densification is a promising method for developing high density in P/M parts. To a great extent, the structure and properties of the zone within about 0.25 to 1 mm (0.010 to 0.040 in.) of the surface determine the performance of components. For example, the wear properties of a sliding member depend primarily on the surface and much less so on the core. This principle is applied with much success in coated cutting tools and flame sprayed parts. In heavily loaded gears and cams, the highest Hertzian stresses are usually manifest within 0.05 to 0.25 mm (0.002 to 0.010 in.) of the surface so, again, properties of the surface dominate performance. Thus it may not be necessary to densify the entire part; instead, selective densification of specific areas may suffice.

A number of techniques have been developed to increase the density of near-surface areas to wroughtlike levels. These include hot working, rolling, swaging, shot peening, and other such processes. Each of these provides heavy mechanical working to a localized zone with the net effect that pores are eliminated. In addition, the surfaces of those voids are forced into close contact and bonded together.

Mechanical Properties of High-Performance Powder Metallurgy Parts

John C. Kosco, Keystone Powdered Metal Company

Fully Dense Ferrous Parts

Ferrous parts of near and full theoretical density can be produced by a variety of thermomechanical methods. These methods involve various amounts of heat and mechanical work to aid densification of the powder mass. For production of low-alloy steel parts, powder forging and injection molding have received the most attention. Both of these powder process technologies are formulated specifically to yield a product as close to full density as possible. This contrasts significantly with the conventionally processed products where attainment of full density is not the primary goal.

Powder Forging

Powder forging involves fabrication of a preform by conventional press-and-sinter processing, followed by hot forging of the porous preform into a final shape with substantial densification. Forging is generally performed in one blow in confined dies

to eliminate flash formation and achieve net shapes. Thus, parts containing through holes and complex configurations can be manufactured with little or no material loss due to trimming, hole punching, machining, or grinding.

Powder forging is used to obtain higher density in P/M parts for high-stress applications, where pores must be minimized or completely eliminated by hot upsetting and/or hot re-pressing. In hot upsetting, the preform experiences a significant amount of lateral material flow, which results in a combination of normal and shear stresses around the pores. Thus, spherical pores become flattened and elongated in the direction of lateral flow. The sliding motion due to shear stresses breaks up any residual interparticle oxide films and leads to strong metallurgical bonding across collapsed pore interfaces. This enhances dynamic properties such as fracture toughness and fatigue strength.

In hot re-pressing, densification is mainly in the direction of pressing. This results in very little material movement in the horizontal direction and thus limited lateral flow. As densification proceeds, the stress state approaches a pure hydrostatic condition. A typical pore simply flattens, and the opposite sides of the pore are brought together under pressure. Hot re-press forging requires higher forging pressures than does hot upset forging for comparable densification. The decreased interparticle movement compared with upsetting reduces the tendency to break up any residual interparticle oxide films and may result in lower ductility and toughness.

Powder Forging Methods. The development of a viable powder forging system requires the consideration of many process parameters. The mechanical, metallurgical, and economic outcomes depend to a large extent on operating conditions, such as temperature, pressure, flow/feed rates, atmospheres, and lubrication systems. Equally important consideration must be given to the types of processing equipment, such as presses, furnaces, dies, and robotics, and to secondary operations, in order to obtain the process conditions that are most efficient. These considerations are detailed in the article "Powder Forging and Hot Pressing" in this Volume.

In general, however, there are three methods of forging from metal powder compacts (Fig. 8):

- *Hot pressing:* Preform for precise weight, hot re-press and machine
- *Precision forging:* Preform for weight and shape, closed-die forge flashless and finish machine
- *Conventional forging:* Preform for weight and shape, forge with flash, trim and machine

These general methods are briefly described below.

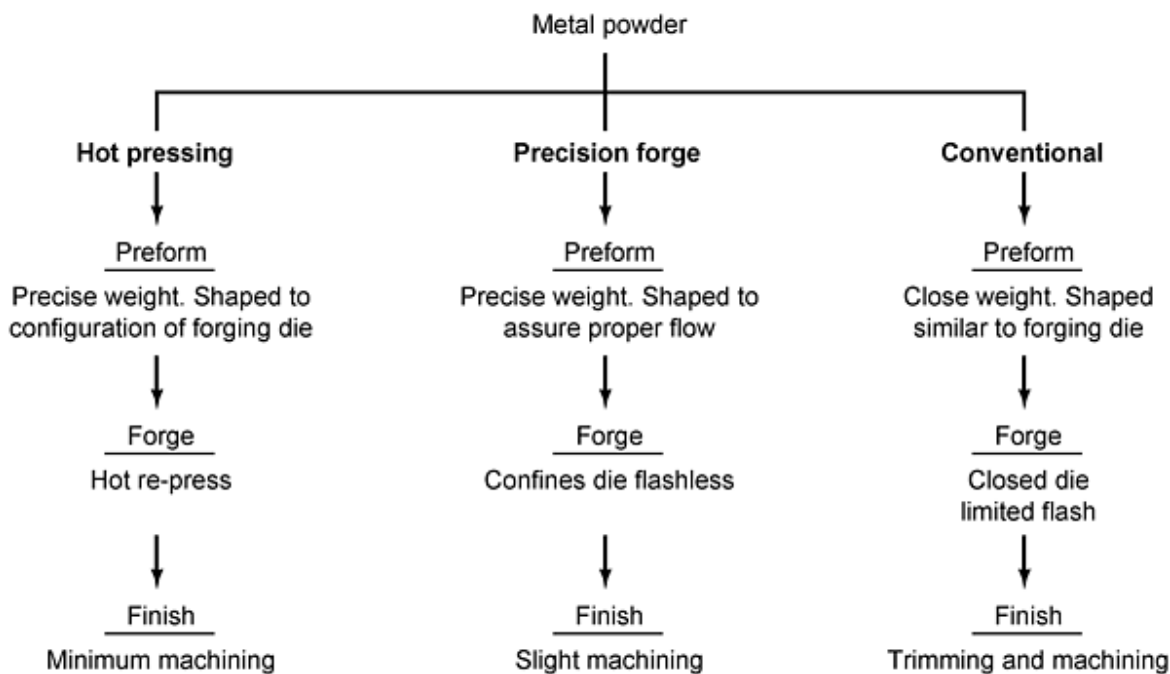

Fig. 8 Typical sequences of P/M forging processes. Hot pressing is closely related to the present P/M practice. Precision forging combines the advantages of P/M and forging. The last process is an extension of the present forging practice.

Hot re-pressing requires a preform shape close to that of the final part except for its height in the forging direction. However, the weight of the preform needs to be tightly controlled. In this process, the friction between die and preform during hot forging is high, and therefore, the pressure needed to get complete densification would also be high, which would involve rapid wear of forging tools. Hot re-pressing is used in applications where densities on the order of 98% of theoretical density are satisfactory.

Precision forging is the most widely used method in industry. Precision forging is a flashless process, and the shape of the preform is simpler than that of the final part. The desired final shape is produced to closely controlled dimensions in the hot forging step. The lateral flow during deformation improves densification. Because this process is precise, tight control of preform weight and shape is required.

Conventional forging is a process to be considered more from the point of view of the conventional forge shop. This process involves flash, and the part is not produced to net shape (Fig. 9). In this case, relative to the other two processes, weight and shape control is not as critical.

Fig. 9 Forging with flash such as in conventional forging

Mechanical Properties of Ferrous Powder Forged Materials. Unlike the extensive deformation in wrought metalworking, powder forged materials undergo relatively little material deformation, and their mechanical properties have been shown to be relatively isotropic. The mechanical properties of powder forged materials are usually intermediate to the transverse and longitudinal properties of wrought steels. The rotating-bending fatigue properties of powder forged materials have also been shown to fall between the longitudinal and transverse properties of wrought steel of the same tensile strength.

While the performance of machined laboratory test pieces follows the intermediate trend described above, in the case of actual components powder forged parts have been shown to have superior fatigue resistance. This has generally been attributed not only to the relative mechanical property isotropy of powder forgings, but also to their better surface finish and finer grain size.

Typical mechanical properties of various powder forged steels are listed in Table 5. Additional mechanical data obtained from standard machined testpieces are shown in Tables 6, 7, 8, and 9 for four primary powder forged materials. The first two material systems are based on prealloyed powders (P/F-4600 and P/F-4200). The other alloys are based on Fe-Cu-C, which was used by Toyota in 1981 to make powder forged connecting rods; Ford Motor Company introduced powder forged rods with a similar chemistry in 1986.

Effects on Mechanical Properties (adapted from Ref 12). In powder forging, porosity occurs near part surfaces where die chilling occurs and also where cracking occurs during the early stages of forging due to the presence of tensile stresses. Preform redesign and providing suitable friction conditions aid in eliminating or reducing residual porosity.

The effects of small amounts of residual porosity on the mechanical properties of P/M forgings were first investigated by Kaufman and Mocarski in the 1970s (Ref 13). Compacted preforms of two different size iron powders and 0.57% graphite were forged at a constant pressure of 440 MPa (32 tsi). Density variations were produced by forging between 700 to 1040 °C (1300 and 1900 °F). Figure 10 shows almost a linear relationship, with density increasing with an increase in forging temperature. Figure 11 shows that the yield strength decreases rapidly as porosity concentration increases for normalized steel and for samples held at a temperature below the eutectoid and spheroidized condition.

(a)

(b)

Fig. 11 Effect of porosity on (a) yield strength and (b) ultimate tensile strength. Source: Ref 13

Particle size distribution in the initial powder does not have much effect if samples are forged at the same temperature. The effects of porosity and second-phase dispersions were additive, but independent of one another. Tensile strength was found to monotonically decrease at about the same rate as yield strength with pore concentration (Fig. 11).

Toughness. In steels, the lower initial preform density (75 to 83% of theoretical) results in optimal toughness in fully dense forgings. This is attributed to the fact that the lower density preforms have a significantly larger amount of interconnected porosity; during sintering, the oxide reducing gas can penetrate the lower density preforms to a greater extent, thus lowering the final oxide content prior to forging and thereby raising the final toughness after forging. Observations of Ferguson et al. (Ref 14) have shown that toughness (Charpy energy) is enhanced by lateral flow produced by upsetting in fully dense ferrous powder forgings.

Fatigue strength and resistance to crack propagation under conditions of cyclic loading also are enhanced by lateral flow at full density. An extensive experimental study and analysis were conducted by Ferguson et al. (Ref 15, 16) in terms of microstructure and stress state using specimens hot forged in plane-strain conditions. Figures 12 and 13 represent the increase in fatigue strength with increased strain (lateral flow) in as-forged and heat treated conditions from axial fatigue tests (Ref 17). Figure 14 represents the increase in endurance ratio in the case of upset versus re-pressed specimens in the forged and heat treated conditions. Figure 15 compares the *S-N* curves for a high-flow P/M prototype part with corresponding parts made by re-pressing and parts machined from a cast and wrought stock. Axial and rotating bend fatigue data are discussed in Ref 17.

Fig. 14 Endurance ratio of 4620 powder forgings in axial fatigue as a function of height strain. Source: Ref 17

Fig. 15 *S-N* curves for simulated axial fatigue on prototype powder forged parts. C and W indicate cast and wrought, respectively. Source: Ref 17

Heat treatment of powder forged steels is similar to that of wrought steel. For ferrous forgings, conventional quench-and-temper cycles can be used to heat treat parts. Figure 16 shows that tensile and yield strengths are comparable for 4640 bar stock and 4640 powder forged material heat treated to the same hardness. Hardenability is slightly lower in powder forged steels, owing to the finer grain sizes of powder forged parts as compared to wrought forms. Typical hardenability curves for some common powder forged steels are in Fig. 17.

Fig. 16 Tensile properties of P/M forged 4640 and typical properties of wrought 4640. Source: Ref 18

Fig. 17 Jominy hardenability curves for (a) P/F-4600, (b) P/F-4200, and (c) Fe-Cu-C materials at various forged carbon levels. Vickers hardness was determined at a 30 kgf load. Testing was carried out according to ASTM A 255. Specimens were machined from upset forged billets that had been sintered at 1120 °C (2050 °F) in dissociated ammonia.

Injection Molding

Finely divided (1 to 10 μm) powders can be mixed with organic binder and injection molded like plastics. After binder removal, metal preforms can be sintered to near-full density. Mass transport mechanisms during sintering are enhanced by the high surface area of the powder and the elevated temperatures of 1150 to 1315 °C (2100 to 2400 °F). Densification is

accompanied by more than 10% linear shrinkage. High final densities, often 95 to 99%, result in improved dynamic properties compared to conventionally pressed and sintered materials.

Current metal injection molded (MIM) ferrous grades include both prealloyed powders and admixtures of iron powder and alloying elements such as nickel, molybdenum, and carbon. Chemical compositions of MPIF ferrous grades include:

MPIF designation	Composition, wt %				
	Ni	Mo	C	Other	Fe
MIM-4600	1.5-2.5	0.0-0.5	0.0-0.1	2.0	bal
MIM-4650	1.5-2.5	0.0-0.5	0.4-0.6	2.0	bal

Depending on the fineness of the starting powder and the sintering temperature, densities of 93 to 98% of full density are obtained. Minimum and typical mechanical property values for 95 and 96% dense MIM low-alloy steels are given in Table 10. As these data indicate, ductility of MIM-processed parts is very high, with elongation values of 30% or higher.

Table 10 Mechanical properties of MIM low-alloy steels

Material designation/condition	Minimum values					Typical values						
	Ultimate tensile strength		0.2% yield strength		Elongation in 25 mm (1 in.), %	Ultimate tensile strength		0.2% yield strength		Elongation in 25 mm (1 in.), %	Density, g/cm ³	Apparent hardness ^(a)
	MPa	ksi	MPa	ksi		MPa	ksi	MPa	ksi			
MIM-4600 as-sintered	255	37	110	16	20.0	290	42	125	18	40	7.6	45 HRB

MIM-2700 as-sintered	380	55	205	30	20.0	415	60	255	37	26	7.6	69 HRB

(a) Where applicable, the matrix (converted) hardness is also given in parentheses.

Fully Dense Stainless Steels

High-density stainless steels can be produced by P/M forging, but high-temperature sintering is the preferred fabrication method. At high temperatures (1315 to 1425 °C, or 2400 to 2600 °F), austenitic and ferritic stainless steels densify during sintering. With minor variations in composition, near-theoretical density can be achieved in pressed-and-sintered parts. Table 11 provides typical mechanical property data for nearly dense (>98% of theoretical density) stainless steels.

Table 11 Typical mechanical properties of nearly dense P/M stainless steel

Based on high-temperature sintering

Alloy	Condition	Ultimate tensile strength		0.2% yield strength		Elongation in 25 mm (1 in.), %	Hardness	Impact strength		Density, g/cm ³	Theoretical density, g/cm ³

An alternative process for forming stainless steel into mill shapes, such as tubing, is to begin with clean, gas-atomized powder. Powder is packed in cans, sealed, cold isostatically pressed to reduce bulk, and extruded into tubing. The cold isostatically pressed cans may be hot isostatically pressed to full density, thus eliminating extrusion. Table 12 gives mechanical property data for extruded and hot isostatically pressed materials compared to wrought (ingot metallurgy) materials.

Fatigue and Fracture Control for Powder Metallurgy Components^{*}

Randall M. German and Richard A. Queeney, The Pennsylvania State University

Introduction

POWDER METALLURGY (P/M) is one of the most diverse approaches to metalworking. The main attraction of P/M technology is the ability to fabricate high-quality, complex parts to close tolerances in an economical manner. In essence, P/M converts a metal powder from a semifluid state into a strong, precise, high-performance shape. Key steps include the shaping or compaction of the powder and the subsequent thermal bonding of the particles by sintering. These two steps can be combined into a single operation, for example in hot powder forging or hot isostatic pressing. All P/M processes are fairly automated with relatively low energy consumption, high material utilization, and low capital costs. These characteristics align P/M with current concerns over manufacturing productivity. Consequently, the field is experiencing growth and progressively replacing traditional metalforming operations over a wide range of applications and materials. As illustrations, P/M is used in the fabrication of lamp filaments (tungsten), dental restorations (precious metals), self-lubricating bearings (bronze), automotive transmission gears (steels), armor piercing projectiles (tungsten alloys), welding electrodes (copper), nuclear power fuel elements (uranium dioxide), orthopedic implants (cobalt and titanium alloys), high-temperature filters (stainless steels), aircraft brake pads (iron-copper-tin-carbon), rechargeable batteries (nickel), and jet engine components (superalloys).

There are three basic approaches to powder metallurgy processing (Ref 1). The most common method, termed pressing and sintering, is to fill a die cavity with loose powder and apply a uniaxial compaction pressure to the powder. This pressure deforms and densifies the powder to approximately 85 to 90% of theoretical density. Subsequently, the pressed powder is heated to a temperature where atomic diffusion gives rise to interparticle bonding, but with little densification. Accordingly, the final product is porous. Such a technique is in widespread use for forming moderately complex shapes for mechanical systems using ferrous powders. The open continuous pore structures that exist in these P/M products dominate fracture and fatigue behavior. Additionally, many filters, electrodes, capacitors, batteries, and other porous structures are formed in a similar manner using low compaction pressures. Such high-porosity structures should not be employed in a fatigue-sensitive environment.

Alternatively, small particles are shaped into useful components at low pressures with the assistance of an organic binder, such as wax, by injection molding, tape casting, or extrusion. The particle-packing density is relatively low, typically only 60% of theoretical. After shaping, the binder is removed by either heat or solvent extraction, and the powder is densified by sintering at a high temperature. These approaches give a final density that is usually between 94 and 100% of theoretical. They are slower and more costly than die compaction, but they deliver greater shape complexity and improved mechanical response measures. Thus, techniques such as powder injection molding are in widespread use for computer, biomedical, and firearm applications, especially using stainless steels. Because the pores are small, closed, and spherical, they have less detrimental effect on fracture and fatigue properties.

Finally, a powder can be subjected to a combination of heat and stress simultaneously. This allows full densification and is widely employed in the fabrication of structural metals, composites, and high-temperature alloys. Variations include forging, hot pressing, hot isostatic pressing, extrusion, and roll forming. Alloys fabricated this way are usually based on aluminum, titanium, steel, nickel, or refractory metal systems, but include composites and intermetallics. Because there is no residual porosity, fracture and fatigue properties are totally dependent on the microstructure, especially any inhomogeneities or contaminants. When properly performed, these processes result in full-density P/M products that have mechanical responses superior to those of their wrought equivalents, largely because of the microstructure homogeneity.

Fatigue and Fracture Control for Powder Metallurgy Components*

Randall M. German and Richard A. Queeney, The Pennsylvania State University

P/M Materials

Many metals are available via P/M techniques. Aluminum and its alloys are highly compressible as powders; green densities of 90% of theoretical are common. They can be sintered or hot consolidated using extrusion, forging, hot pressing, and hot isostatic pressing. As summarized in Table 1, typical strengths for the press and sinter approach are in the 200 MPa (29 ksi) range with 2% elongation to fracture. Higher strengths are available by dispersion strengthening and deformation processing, including hot isostatic pressing and extrusion. In the best cases, fatigue endurance limits (or fatigue strength at about 10^7 cycles) approach about 200 MPa (29 ksi). Some of the high-performance rapidly solidified P/M products provide excellent strength retention to high temperatures.

Table 1 Properties attainable in aluminum P/M alloys

Composition ^(a) , wt%	Fabrication ^(b)	Density, g/cm ³	Yield strength, MPa	Tensile strength, MPa	Elongation, %

(a) Balance Al.

(b) MA, mechanically alloyed; HIP, hot isostatically pressed; P+S, pressed and sintered

Copper, brass, and bronze are sintered from particles, where the typical applications are not fatigue sensitive. Cemented carbides, such as WC-Co and TiC-Ni, are sintered using a liquid phase to deliver a full-density structure, often by the application of high pressure at the end of the sintering cycle. The elimination of residual pores has considerable impact on fracture resistance, giving a fracture strength in the 1700 to 3000 MPa (245 to 435 ksi) range. Unfortunately, the basic materials are brittle, so fracture toughness is usually in the range of 10 to 20 MPa $\sqrt{\text{m}}$, depending on cobalt (or other matrix phase) content and carbide grain size.

Stainless steel P/M products are usually selected for their corrosion resistance. However, they are capable of highly variable final response measures, depending on the composition, density, and microstructure. For precipitation-hardenable alloys such as 17-4 PH, yield strengths of 1100 MPa (160 ksi) with 12% elongation are possible with fatigue endurance limits in the 500 MPa range (72 ksi). Alternatively, for austenitic stainless steels such as 316L, a sintered yield strength of 250 MPa (36 ksi) and considerable ductility (30% or more) are common.

By far the largest segment of the P/M applications rely on iron-base alloys. Generally, a powder is pressed in uniaxial tooling to near-final dimensions, but not to full density. Dimensional control during sintering is very important, and usually size can be held to within ± 0.025 mm of specification, with concentricity to 0.1 mm, squareness to 0.05 mm, and density to 0.1 g/cm^3 . Strength typically exhibits a small scatter of ± 35 MPa (± 5 ksi) and elongation exhibits a scatter of $\pm 2\%$. In most sintered structural steel components, over 90% of the composition is iron. Table 2 gives examples of common P/M alloy compositions. In all cases, the mechanical properties increase with the final density.

Table 2 Common ferrous P/M alloy classes

Designation	Composition
Pure iron (steel)	max 1% C
Copper steel	1-22% Cu, max 1% C
Iron-nickel	1-3% Ni, max 2.5% Cu, max 0.3% C
Nickel steel	1-8% Ni, max 2.5% Cu, max 1% C
Low-alloy steel	0.3-2% Ni, 0.5-1% Mo, 0.4-0.8% C
Infiltrated steel	8-25% Cu, max 1% C
Phosphorus steel	0.4-0.8% P, low C
Sinter-hardened steel	1-3% Cr, 1-2% Mn, 2% Ni, 0.4-0.8% C

Iron-copper-carbon compositions are the most common in production, because copper forms a liquid phase during sintering that greatly aids particle bonding. This system illustrates the properties possible with P/M. Copper and graphite (carbon) are mixed with iron, and during sintering the copper forms a liquid phase. Wrought materials of equivalent compositions are not possible due to extensive segregation in the molten state. The mechanical properties are degraded by whatever pores remain after sintering. Tables 3 and 4 provide examples of the property degradation by listing the hardness, strength, ductility, and impact energy versus density for two Fe-Cu-C alloys. Table 3 shows a density effect for an Fe-2Cu-0.8C alloy, while Table 4 includes both density and heat treatment effects for an Fe-10Cu-0.3C alloy. In these tables the fatigue life was measured at 10^7 fully reversed cycles ($R = -1$). Note that, for example, hardness and strength actually change less with increases in density than does the fatigue endurance strength. This reflects the greater sensitivity of the dynamic properties to pore structure as compared with the quasistatic tensile properties.

Table 3 Sample mechanical properties for Fe-2Cu-0.8C P/M alloys

Nickel is another common addition to ferrous P/M alloys for improved strength. In low concentrations, phosphorus is used due to its potent hardening of iron and formation of a liquid phase at temperatures above 1050 °C (1920 °F). The liquid aids sintering, pore spheroidization, and alloy hardening, but usually these additives are selected for magnetic properties, not mechanical properties, with a popular composition containing 0.45% P. Most of these alloys are formed by mixing powders that are alloyed as part of the sintering cycle, because of the higher compressibility of the elemental powders as compared with that of prealloyed powders.

There are several other widely employed P/M materials. Tool steels are usually fabricated to full density by liquid-phase sintering or hot isostatic pressing. Cobalt-base alloys, titanium alloys, and superalloys are fabricated to full density by hot isostatic pressing. Table 5 compares the mechanical properties of Ti-6Al-4V alloys fabricated by three processing routes. A very useful group of P/M alloys are the tungsten heavy alloys. These are based on W-Ni-Fe mixtures that are densified by liquid-phase sintering. Table 6 gives the typical mechanical properties of sintered tungsten heavy alloys. These are full-density products, but despite the high-sintered density they lack good fatigue properties due to the two-phase microstructure. Like tungsten, most of the other refractory metals (molybdenum, tantalum, titanium, chromium, niobium, and rhenium) are fabricated from powders.

Table 5 Mechanical property comparison for Ti-6Al-4V processed by various P/M Techniques

Process	Porosity, %	Yield strength, MPa	Tensile strength, MPa	Elongation, %	Reduction in area, %

Low-cost composites are fabricated using P/M techniques. Particle reinforcement requires mixing of the constituents and consolidation to full density. A popular combination is Al-SiC. Sample mechanical properties of this composite as fabricated by vacuum hot pressing are given in Table 7, where the SiC content ranges from 0 to 40 vol%. Again, the fatigue properties of these composites are not very attractive because of the differential elastic modulus between the reinforcement and matrix.

Table 7 Mechanical properties of Al-SiC P/M composites

Porosity Effects

An inherent physical characteristic of P/M materials is the presence of pores. The role of porosity in determining fatigue endurance in powdered metals is akin to that of porosity that is induced through metal solidification in casting or welding. However, the porosity that is characteristic of sintered powdered metals, and of those materials subsequently deformation processed, may differ in character and influence from solidification porosity. In all cases, porosity catches the attention of the design engineer because it immediately conjures up images of classical stress concentrators. In addition, porosity featuring sharp re-entrant corners, a possibility for marginally equilibrium-sintered powder particle boundaries, may be more accurately viewed as crack precursors. Pore geometry can be altered by modifications to the sintering cycle, such as a longer hold time or higher temperature, wherein the smoother pores improve strength, fatigue life, and fracture resistance.

Ductility is sensitive to the pore structure, but impact, fracture, and fatigue behavior have the greatest sensitivities. In general, dynamic strength responses are the most sensitive. Even in those materials possessing full density, inferior properties can occur due to microstructural defects. Recent applications have pushed P/M into very demanding applications, a good example being the automotive connecting rod. Such rods are formed by hot forging a porous P/M preform using an alloy of Fe-2Cu-0.8C. They weigh nearly 650 g. The ultimate tensile strength is 825 MPa (120 ksi), with a yield strength of 550 MPa (80 ksi) and fatigue endurance limit of 255 MPa (37 ksi). With expansion of P/M fabrication technology into dynamically loaded components, there arise performance limitations associated with fracture and fatigue. For static tensile properties, there is a good basis for predicting the effect of residual porosity on strength (Ref 2, 3, 4, 5). Recent research has had an emphasis on fatigue and fracture behavior to fill the database void.

Porosity is especially important to the high-cycle fatigue life (Ref 6, 7, 8, 9). Pores play a role in both crack initiation and propagation, typically increasing the threshold stress intensity for crack initiation but lowering the resistance to crack propagation (Ref 10). For an alloy of Fe-2Ni-0.8C the fatigue endurance limit at 10^7 reverse cycles is between 200 and 250 MPa at a density of 7.1 g/cm^3 (approximately 10% porosity). That is approximately 35% of the tensile strength, and many porous injection-molded materials exhibit similar ratios of fatigue strength to tensile strength. Closed pores are less detrimental than those that are interconnected and open to the external surface. Surface pores act as the preferred site of fatigue crack initiation by acting as stress concentrators (Ref 11). The simplest view of a pore would be that of a spherical hole embedded in a continuous matrix whose response parameters are identical with that of a fully dense form of exactly the same metallurgical state. Since the maximum, most positive, principal stress is the controlling load parameter for high-cycle fatigue endurance, the embedded pore in a tensile field is a reasonably approximate model for a stressed porous metal without interacting stress fields (one of less than 10% porosity). The local pore-dominated stress field can be expected to control local events such as crack initiation and threshold stress intensity values (ΔK_{th}). For an embedded pore, the local stress fields are related to the far-field (applied) design stresses (Ref 12):

$$\sigma_{\text{local}} = \sigma_{\text{design}} \left[\frac{27 - 15\nu}{2(7 - 5\nu)} \right] \quad (\text{Eq 1})$$

Note that, for the average steel, $\nu = 0.30$, and the local stresses are magnified by a factor of about 2. The concentrated stress field does not persist far beyond the embedded pore, being reduced to 105% of the design value at a distance of $2a$ (where a is the pore radius) from the pore center, thus possibly exerting little influence on far field parameters.

If the pore features sharp re-entrant corners, the elastic concentrated stresses are more accurately predicted from an elliptical hole example. However, these same pores are unlikely to exhibit smooth ellipsoidal morphologies, and their concentration effects can be more usefully predicted by the proportionality (Ref 13):

$$\sigma_{\text{local}} \approx 2\sigma_{\text{design}} \sqrt{\frac{a}{\rho}} \quad (\text{Eq 2})$$

Here, a is the major pore length normal to the maximum principal stress direction, and ρ is the radius of curvature at the sharp corner. Suffice to say that the calculated stress concentration value can be large for a nonspheroidized pore.

Due to the stress-raising properties of pores, and the fact that most fatigue failures originate at free surfaces, treatments aimed at surface densification and serendipitous surface strengthening (e.g., coining, shot peening, ausrolling) raise the fatigue endurance limit (Ref 14, 15, 16). As a consequence, the current models for fatigue response in porous sintered materials have a major dependence on the pore microstructure: the models address the total porosity, alloying homogeneity in near-pore regions, pore size, pore shape, and interpore separation distance (Ref 6, 17, 18, 19, 20, 21, 22, 23, 24). Round pores provide improved resistance to crack propagation. Pores act as linkage sites through which cracks can propagate. Microstructure-based fatigue models for ferrous alloys have had to address seemingly contradictory porosity effects: round pores retard stable fatigue crack propagation but increase crack extension growth rates by contributing linkage sites. While extant theories successfully explain some porosity effects on crack propagation, no total predictive model has been created that embraces microstructure effects (Ref 18, 20, 22). The presence of pores in the reversed plastic zone that is the site of propagating crack damage does not lend itself to facile analysis.

Pore structure changes are obtainable through processing and material variations: powder variables (particle size distribution, particle shape); compaction variables (type of lubricant, amount of lubricant, tool motions, maximum pressure); sintering variables (hold time, maximum temperature, atmosphere); and postsintering treatments. Figure 1 compares the pore structure in two sintered stainless steels to emphasize this point. Smaller particles result in faster sintering and higher strengths and toughness. Associated with the smaller particle sizes are smaller final pores. At lower densities (around 6.6 g/cm³ or 18% porosity in steels), a high-relative content of small particles is beneficial to fatigue resistance, while at higher densities (over 7.1 g/cm³ or less than 10% porosity), larger particles prove beneficial. The difference relates to the ligament size between pores, which is the determinant of fatigue. There are three pore microstructure parameters relevant to the fatigue resistance of porous P/M materials: pore size, pore curvature, and pore spacing. These largely reflect the role of stress concentration with respect to the advancing fatigue crack, as noted above (Ref 6). Thus, lower porosity contents, smoother (rounder) pores, and wider interpore separations increase the fatigue endurance strength.

Fig. 1 Two stainless steels fabricated by P/M, as demonstrations of the microstructure variations possible by tailoring the powder, compaction, and sintering variables. (a) A high-porosity microstructure useful for filtration, formed by press and sinter. 1000×. (b) A closed-porosity, high-density microstructure useful for mechanical components, formed by injection molding and high-temperature sintering. 200×

Fatigue cracks have been successfully analyzed with regard to their propagation response, and the cyclic growth of a crack can be predicted by the modified Paris growth law:

$$\frac{da}{dN} = A (\Delta K_{\text{eff}})^n \quad (\text{Eq 3})$$

where the material parameters A and n must be experimentally determined for any given material microstate, including different distributions of porosity. The stress analytical variable ΔK_{eff} , the effective stress intensity range, factors out that portion of the total stress range that relieves the stresses holding the crack flanks closed, the opening stress range $\Delta \sigma_{\text{op}}$, leaving only the stress range component that displaces the crack faces relative to each other. In the presence of appreciable levels of mean stress, the relation between load design parameters and fatigue crack propagation rates is given by:

$$\frac{da}{dN} = \frac{C \Delta K^n}{(1 - R)K_c - \Delta K} \quad (\text{Eq 4})$$

Here, the total stress-intensity factor range ΔK is the load variable, but the fatigue ratio $R = \sigma_{\text{min}}/\sigma_{\text{max}}$ and the fracture toughness K_c , or K_{Ic} for a low-ductility sintered member, enter into the fatigue crack propagation response, as do the material constants C and n .

Regardless of which of the three fatigue crack propagation relations are relevant in a particular service context, their collective utility lies in predicting member lifetimes, or precise segments of that lifetime. Thus, in the case of the Paris law:

$$N = \int_0^{N_f} dN = \int_{a_0}^{a_c} \frac{da}{A(\Delta K)^n} \quad (\text{Eq 5})$$

The calculated endurance cycles to failure, N , can be from an initial flaw size a_0 that may be the minimum detectable to final fracture at $a = a_c$, where:

$$K_{Ic} = \sigma_{\text{max}} \sqrt{\pi a_c} \quad (\text{Eq 6})$$

Again, the fracture toughness of the material plays a role in determining structural endurance. The fracture resistance K_{Ic} , or K_R in the case of more ductile sintered materials (Ref 25), is known to be porosity sensitive (Ref 26). As a first estimate, the sensitivity is about a $100 \text{ MPa} \sqrt{\text{m}}$ gain in toughness per percentage point of porosity reduction in quenched and tempered steels. Copper-infiltrated steels have toughnesses that run from 40 to 50% those of wrought steels (Ref 27, 28). However, their static strengths are equivalent, reflecting the inability of the steel skeleton to absorb the same level of strain energy release as a fully dense body of the same material.

The material parameters in the modified Paris equation (Eq 3) are sensitive to the porosity state, a not unexpected result since the coefficient and exponent are related to the plastic zone size r_p ahead of the advancing crack, the only region of irreversible deformation. The coefficient A in Eq 3 increases with increasing porosity fraction (Ref 29), resulting in faster growth rates for comparable ΔK_{eff} values. With higher coefficient measures but constant exponent n values, the threshold stress intensity range ΔK_{th} , below which no crack growth is thought to occur, also decreases with porosity increase. However, ΔK_{th} values for fully dense materials are sufficiently low that it is not at all clear in what way they could be successfully employed in design practice if service stresses are to be set at appreciable fractions of the yield or tensile strength. The reversed plastic zone size is given by (Ref 30):

$$r_p = \frac{K_I^2}{6\pi\sigma_y^2} \quad (\text{Eq 7})$$

When the plastic zone size is of the same size as the average pore diameter, it is effectively enlarged by the high strain field in the vicinity of the pore. The net result of the enlarged effective plastic zone is reflected in higher values of the exponent n (Ref 11), and the enlarged zone is even more pronounced in the response of short cracks driven by the locally raised stress/strain fields associated with design stress concentrators (Ref 15). Copper-infiltrated steels (Ref 27, 28) are as fatigue and fracture resistant as fully dense wrought medium-strength steels. Although the performance standards are not up to those of fully dense martensitic steels, copper infiltration represents a considerable cost savings over forging to full density, while maintaining the cost advantage inherent in press and sinter P/M.

Typical fatigue endurance limits (or fatigue strengths at about 10^7 cycles) are collected in Table 8 for several P/M materials. This compilation includes several ferrous alloys, reflecting the high interest in P/M fatigue for automotive applications. There are variations in density, alloying, and sintering cycles to show the relative effects on sintered properties. Systematic testing of various alloys has shown that slight changes in the particle size distribution or alloying homogeneity can affect these properties. For example, in the Fe-2Ni-0.8C alloy system, shifts in just the iron powder source lead to ± 33 MPa (± 4.8 ksi) variations in the fatigue endurance strength. Accordingly, the values in Table 8 are for relative ranking purposes only and cannot be used as an accurate basis for design of fatigue-sensitive components.

Table 8 Representative P/M materials, processing cycles, and fatigue endurance limit

Composition, wt%	Processing	Density, g/cm ³	Testing	Endurance limit, MPa
Al-5Cu-0.5Mg-0.8Si	P+S, 600 °C, 1 h	2.6	. . .	53

Fracture studies of P/M alloys are usually restricted to impact testing, and often this is performed in the unnotched condition because of the low toughness of porous materials. Fracture toughness measurements on P/M materials are relatively rare. Tables 9 and 10 summarize some prior findings. Table 9 demonstrates the density effect on tensile properties and K_{Ic} , for an Fe-Ni-Mo-C steel. Note that as the porosity decreases, the strength essentially doubles, ductility increases substantially (a nearly tenfold gain), the impact energy goes up by a factor of 4, and fracture toughness increases threefold. Table 10 collects several examples of the mechanical properties of ferrous alloys and one titanium alloy as representative values obtainable via P/M. Clearly, porosity negatively affects the fracture toughness in most materials. The fracture toughness of P/M steels is essentially a linear function of density (Ref 18), with sensitivities of about $100 \text{ MPa} \sqrt{\text{m}}$ gain in toughness per percentage point of porosity reduction. In low-density P/M materials, the fracture crack propagation is rapid because the pore structure amplifies the stress and provides an easy path. At low porosity levels, an advancing fracture crack can be blunted by the pores, effectively forming microcracks that improve toughness (Ref 31).

Table 9 Mechanical properties of pressed and sintered Fe-1.8Ni-0.5Mo-0.5C P/M compacts

Other Factors Determining Fatigue and Fracture Resistance

It is well established that porosity is the major detriment to fatigue life for P/M materials. Beyond porosity, the sintered microstructure is a factor. Even in full-density materials fabricated by hot isostatic pressing, microstructure has a role. Weak links in the microstructure become evident during fracture. For porous structures, these weak links prove to be microstructural inhomogeneities, typically resulting from incomplete diffusional homogenization. Often powders (such as iron, nickel, and graphite) are mixed in the compaction stage. During heating the intent is for the mixed powders to homogenize to form a uniform microstructure, but this often is inhibited by too short a hold time at the peak temperature. Consequently, the alloying elements are poorly distributed and give point-to-point composition and microstructure changes, which are especially evident in postsintering heat treatment response. Accordingly, during fatigue or fracture, the weak links become the preferred failure paths. Most notable are the negative effects from inadequate homogenization of carbon to ensure uniform strength (Ref 18).

Little is known about the sensitivity of fatigue and fracture to loading conditions for P/M material. Table 11 compares the 2×10^6 fatigue endurance strengths for Fe-1.5Cu-0.6C at 7.1 g/cm^3 density using bending and axial fatigue tests. The table also includes a comparison with two loading stress ratios (half-cycle and fully reversed, $R = -1$) and two notch conditions (unnotched and notched) (Ref 18). In these cases the unnotched loading shows little sensitivity to axial versus bending fatigue, but a large sensitivity is evident in the presence of notches. The notch sensitivity factor is reported to range between 0.32 and 0.43 for many of the common pressed and sintered P/M alloys (Ref 32).

Table 11 Fatigue properties of Fe-1.5Cu-0.6C

Notch factor, K	Stress ratio, R	Endurance strength, MPa at 2×10^6 cycles
Axial		
1.0	-1	165
	0	130
2.8	-1	84
	0	64
Bending		
1.0	-1	160
	0	127
2.8	-1	137
	0	102

Note: Sintered to 7.2 g/cm^3 at $1120 \text{ }^\circ\text{C}$ for 30 min. Elastic modulus, 153 GPa; yield strength, 418 MPa; tensile strength, 483 MPa. Source:

Full-density materials also suffer from residual microstructure artifacts that degrade the microstructure. In hot isostatically compacted powders, the achievement of 100% density is still insufficient to guarantee competitive fracture toughness, fatigue life, or even impact toughness. Thermally induced porosity is a subtle problem in many full-density P/M products. After consolidation the material is pore free, but it may contain small quantities of adsorbed gas. Once the product is put into high-temperature heat treatment or service, this residual gas precipitates to form pores if there is no compressive stress. In hot isostatically pressed titanium alloys, gas precipitation reportedly gives a 10 to 20% decrement in fatigue endurance strength (Ref 33).

Another difficulty rests in slight contaminants located on the interfaces that were previously particle surfaces, a feature termed prior particle boundary decorations. Figure 2 shows such decorations in a fully densified P/M steel. Improper powder

handling or cleaning prior to consolidation are the primary detriments. These contaminants remain on the powder interfaces, even though the structure is fully densified. Consequently, a small contamination film runs throughout the structure, providing an easy fracture path that is often traced to a trivial impurity level. The fracture path is along the prior particle boundaries and has a characteristic morphology, as shown in Fig. 3. In hot isostatically pressed Ti-6Al-4V there is substantial fatigue life improvement due to removal of the contaminant, with a change from 450 MPa endurance strength to 600 MPa due to powder cleaning prior to consolidation (Ref 34).

Fig. 2 Prior particle boundary precipitates formed on a hot isostatically pressed steel as the result of contamination during powder fabrication. 500×

Fig. 3 A fracture surface showing preferential failure along prior particle boundaries. 150×

One option for limiting the detrimental effects from prior particle boundary decorations is to forge the structure after hot isostatic pressing, a process often used in producing aerospace structures to ensure ultimate reliability. The forging operation upsets the microstructure and breaks apart the continuous films of contamination. The alternative is to resort to clean handling and processing, where the powder is produced by rapid solidification and kept under inert conditions during handling. These steps, which minimize segregation and contamination, are employed in the production of aerospace components, microelectronic structures, and high-performance filters.

Steps to Improve Fatigue and Fracture Resistance

Surface pores are particularly detrimental to sintered materials with respect to fatigue life (Ref 35). Accordingly, carbonitriding and other surface strengthening and sealing treatments are most useful. Common treatments include shot peening, case hardening, repressing and resintering, coining, sizing, surface ausrolling, and postsintering heat treatments. For example, in pressed and sintered ferrous alloys, the endurance limit can be increased on small cross sections (6 by 6 mm) by at least 20% through shot peening. Carbonitriding is even more effective and can double the fatigue endurance limit. A typical carbonitride cycle involves heating to 940 °C in a mixture of ammonia and carbon dioxide for 4 h to form a 0.5 mm deep carbon-rich layer. Surface grinding is another approach to improved fatigue strength. The larger the cross section of the material, the less benefit possible from surface treatments, because bulk material states will dominate mechanical response.

The double press and double sinter approach was largely the only viable option for improving density and strength in traditional press and sinter P/M. This is more costly and involves extra tooling. A newly employed technique for improved fatigue life and fracture toughness in pressed and sintered ferrous alloys is to sinter at higher temperatures. The typical sintering temperature for steels is about 1120 °C, largely because of conveyor belt limitations in the furnaces. New materials of construction (ceramic belts) and new conveyor mechanisms (pusher plate and walking beam designs) allow higher-temperature processing regimes. Additionally, vacuum sintering usually is not limited in temperature, so it is viable for high-performance components. There is more sintering densification at the higher temperatures, so the density gain alone improves properties. Induced changes in the pore shape and size also improve fracture and fatigue properties. Several examples of the property gains are evident in Table 8. In a comparison of density gains versus sintering temperature effects, it is usually concluded that a change from 1120 to 1280 °C is equivalent to a density gain from 7.1 to 7.4 g/cm³ in terms of both fracture toughness and fatigue endurance strength.

For small components the surface treatments are most useful, because the compressive forces extend through a major portion of the microstructure. However, for the porous materials with large cross sections, the need is to sinter at higher temperatures to improve fatigue and fracture. Further, designs that minimize density gradients will assist in minimizing fatigue failure. The high-density regions have a higher fatigue strength, and the difference in strength with density often results in failure at the interface between high- and low-density regions. For fatigue-sensitive components, the tolerable range of densities is less than 0.05 g/cm³ within the structure. As with all fatigue-sensitive components, consideration must be given to surface finishing and processing optimization. The keys to improved performance are reduction in the total porosity, elimination of segregation and contamination, and manipulation of the pore microstructure.

There are some unique design opportunities where the microstructure of P/M materials offers a fatigue advantage in spite of the porosity. Because many alloys are formed from mixed powders, there is often an enrichment of the alloying addition near pores. The resulting higher strength aids local strength and fatigue life. Surprisingly, when properly exploited this effect gives higher fatigue and fracture strength to porous structures formed from mixed elemental powders, compared to those formed from prealloyed powders (Ref 36). Unfortunately, pores reduce the elastic modulus, strength, ductility, hardness, and other mechanical properties, so a high-density structure usually proves most successful in fatigue-sensitive applications. Indeed, the high sensitivity to porosity mandates that porosity be tightly controlled (density held within 0.05 g/cm^3) in regions of high stress concentrations. At a given strength level the P/M steels exhibit less notch sensitivity than wrought steels, because pores inherently act to blunt cracks and redistribute the load, especially under complex loading. Open pores, which dominate the sintered microstructure for densities below 92% of theoretical, retard fatigue crack propagation. Surface densification of P/M steels from shot peening, sizing, coining, surface rolling, or carbonitriding all prove beneficial in improving fatigue strength because of pore closure and surface compressive stresses.

Safety Factors for P/M Materials

Several factors contribute to scatter in the fracture and fatigue properties of P/M materials. There is the obvious error in testing, where the range of highest fatigue strength to lowest fatigue strength for a single test condition may be 4%. Further, there is typically a notch sensitivity and test error. Consequently, a safety factor of 1.4 is often cited as appropriate for sintered P/M alloys (Ref 18). This means that a peak cyclic stress of about 70% of the fatigue endurance strength is the maximum recommended in service.

Wear Resistance of Powder Metallurgy Alloys

Zhigang Fang, Smith Tool, Smith International, Inc.

Introduction

WEAR is the progressive loss of material due to relative motion of two or more surfaces. Wear of materials belongs to the science and technology field of tribology, which includes the study of friction, wear, and lubrication. For many years, study of tribology has focused on mechanical system optimization with respect to friction characterization, component design, and lubrication. An equally important subject, which may be less amenable to quantitative analysis, is the dependence of friction and wear behavior on intrinsic properties and microstructure of materials. While wear resistance of a material is a function of its hardness and toughness, large differences in wear resistance can occur at the same hardness. In other words, for a set of intrinsic mechanical properties, different microstructures can yield different friction and wear behavior. Powder metallurgy technology stands unique in its flexibility to create desired microstructures and compositions, which would be difficult or impossible by conventional processes, to meet demands of friction and wear properties.

Engineering materials subjected to wear applications include different metal alloys, ceramics, and polymers. Powder metallurgy is a class of processing technologies. More and more engineering materials and mechanical components are being fabricated by P/M processes. Any material processed by P/M that suffers wear loss is the subject of this article. However, it is a formidable task to cover all materials that can be manufactured using P/M techniques and subjected to wear during application. Instead, this article focuses on effects on wear of property and microstructure factors that are unique to P/M materials, such as metal alloys and metal matrix composites.

There are two approaches to reduce wear: reduce friction between rubbing objects or increase wear resistance of the materials involved. In sliding wear applications, introduction of friction reduction elements into material composition could be the most effective approach in certain specific applications. Reduction of friction can be accomplished by lubricant or compositional changes of the material; however, increasing wear resistance is the subject of this article.

There are numerous books including handbooks on wear behavior of materials. Suggested reading materials listed in Ref 1, 2, 3, 4, and 5 discuss general theory on wear behavior of materials. Metallic components fabricated using P/M technology follow the general rules and trends of those theories. What P/M technology offers is special composition and microstructure that cannot be fabricated by other conventional processing methods. Factors that effect wear properties and are unique to P/M materials are discussed in this article; however, a brief discussion on wear classifications will help in understanding the effects of those factors.

Wear Resistance of Powder Metallurgy Alloys

Zhigang Fang, Smith Tool, Smith International, Inc.

Wear Classifications

Wear can be classified by four main mechanisms: adhesive, abrasion, surface fatigue, and tribochemical reactions. Wear can also be classified by different types of relative movements between mating surfaces, such as sliding, rolling, oscillation, impact, and erosive wear.

Adhesive wear is defined as the formation and breaking of interfacial adhesive bonds (e.g., cold-welded junctions). The tendency to incur adhesive wear depends on physical and chemical properties of the materials in contact. There are five different mechanisms proposed for adhesive wear: (1) mechanical interlocking, (2) diffusion theory, (3) electronic theory, (4) adsorption theory, and (5) chemical adsorption theory. Adhesive wear is considered the primary wear mechanism for sliding wear, but it is not equivalent to sliding wear because other mechanisms contribute to wear loss during relative sliding motion between two objects. Common terms such as material transfer, galling, scuffing, and scoring are examples of adhesive wear, although scuffing and scoring can mean scratching by abrasive particles.

Abrasive wear is the dislodging of material caused by hard particles between or embedded in the surfaces in relative motion, or by hard protuberances on one or both of the relatively moving surfaces. Mechanisms responsible for abrasive wear include microplooughing, microcutting, and microcracking on the surfaces of metals. Abrasion is further divided into two-body or three-body abrasion. Abrasion can also be described by high-stress or low-stress abrasion. In general, during high-

stress abrasion, abrasive particles are crushed, while during low-stress abrasion, the particles remain unbroken. Erosion is one kind of abrasion which refers to wear caused by impact of particles. The hard particles striking the surface are carried by a gas stream or entrained in a flowing liquid. The terms "gouging" and "scratching" are often used to describe wear scars left by abrasive action.

Surface fatigue results from repeated alternating loading of solid surfaces. Most often it occurs during rolling and impact contacts, which causes cyclic surface stressing. Mechanisms responsible for surface fatigue wear are undersurface crack formation and flaking material. The commonly observed pits are typical of surface fatigue.

Tribochemical reactions proceed by continual removal and new formation of reaction layers on the contacting surfaces, such as oxide layers formed in the presence of oxygen. The reaction from rubbing surfaces can be caused by gas or liquid in the environment.

Wear Resistance of Powder Metallurgy Alloys

Zhigang Fang, Smith Tool, Smith International, Inc.

Factors Affecting Wear Resistance

Root causes of any wear behavior are microstructure and chemical composition, as for any mechanical property. However, wear behavior is best understood from three different perspectives: fundamental mechanical properties of the material, microstructure features, and specific wear environments and mechanisms. In many cases, wear resistance of a material is largely the function of its intrinsic mechanical properties (i.e., elastic modulus, strength, hardness, and fracture toughness). Depending on wear action, different mechanical properties dominate the rate of wear loss, and different microstructure is desired. However, microstructure can also affect wear resistance independently without changing chemical composition or altering basic relationships between mechanical properties and microstructure. For example, large differences in wear resistance can occur at the same hardness. In other words, changing microstructure features can alter the rate of wear loss of a material with or without concurrent change in common mechanical properties. The relationships among wear resistance and mechanical properties and microstructure are also affected by specific wear environments (i.e., specific wear mechanisms). For example, wear resistance against sliding abrasive particles has different requirements for mechanical properties and microstructure than against impact fatigue or some other wear mechanism. Wear resistance depends on interrelated mechanical, microstructural and environmental factors (Fig. 1).

Fig. 1 Factors affecting wear resistance of materials

Mechanical Properties. Mechanical properties affecting wear resistance of a material include hardness, fracture toughness, elastic modulus, tensile/compressive strength, and impact fatigue strength. In many cases, wear resistance is primarily a function of hardness not of toughness, especially for metal alloys which have sufficient fracture toughness. The higher the hardness, the higher the resistance to abrasion by hard particles, surface plastic deformation, debonding, and microploughing. For wearing systems where plastic deformation is the main mechanism and impact is not prevalent, hardness controls wear rate of the material. In cases where fracture toughness of the material is relatively low, the wear application involves impact and repeated loading condition changes, and wear mechanism involves microfracturing, the role of fracture toughness in determining wear rate becomes more important. As a general principle, both wear mechanisms--plastic flow and fracture, can result in excavation and detachment of material. Raising the material hardness will reduce plastic flow but can increase the danger of fracture. Hence, it is more often that some compromise between high hardness and high fracture toughness gives the best wear resistance.

Microstructure. Materials can be categorized as those having homogeneous microstructures and those having multiphase inhomogeneous materials. Homogeneous P/M materials are similar to what can be achieved by traditional processing techniques, such as casting, forging, and heat treatment. Homogeneous microstructure indicates that the material is composed of one single phase or multiple phases that act like a single phase structure with respect to wear. Wear resistance is primarily proportional to its hardness and fracture toughness. Alloys or composites composed of at least two different phases have microstructures formed either by blending different powders together or one or more phase forms in situ. The boundary between a homogeneous microstructure and multiphase structure can be gray. For example, cemented tungsten carbide (WC-Co) is a two-phase composite, except for those with extremely fine grains and small mean free path (MFP). Powder metallurgy tool steel is mostly a homogeneous material, although its wear resistance depends on carbide particles in its microstructure. The various carbide particles are in situ precipitates. The two-phase or multiphase microstructure makes P/M technique unique with regard to tailoring microstructure to phases that cannot be created by casting, forging, or heat treatment in order to achieve desired wear resistance. Microstructure factors that affect wear include volume fraction, particle size, particle size distribution, MFP, and the ratio between MFP and abrasive particle sizes.

Volume fraction of hard phase particles in a multiphase microstructure is the most important factor affecting mechanical properties such as strength and fracture toughness. Wear resistance is influenced by volume fraction's influence on strength and toughness. No other direct effects of volume fraction on wear resistance have been reported. In general, wear

resistance is proportional to volume fraction of hard phase particles. However, wear resistance levels off when hard phase particles reach certain volume fraction in some alloy systems and applications.

Particle size or grain size and particle size distribution of hard phase particles affect both microstructure and fundamental mechanical properties. At any given volume fraction, finer particle size results in smaller mean free path (MFP), i.e., smaller spacing between hard phase particles. When MFP is sufficiently small, the finer the particle size, the more the composite resembles homogeneous material (i.e., the higher the hardness, and the higher the wear resistance). A larger spacing is likely to cause preferential wear of the softer matrix which leads to uprooting of hard particles. In such cases, larger particle size is beneficial for wear resistance. Size distribution also affects wear resistance. For a given average particle size, wider particle size distribution is likely to give larger MFP. However, the effect of different powder size blend is strongly related to wear applications. In some cases, multiple wear mechanisms are in effect. Therefore, different powder particle sizes may be needed for different roles.

Mean free path (MFP) is a function of particle size and volume fraction of hard particles given by:

$$\lambda = 4 \cdot (1 - V_V) / S_V$$

The effects of MFP on wear resistance reflect the combined influence of hard phase volume fractions and particle sizes. MFP affects basic mechanical properties including hardness, strength, and fracture toughness. As a general rule of thumb, hardness and strength increase with the decrease in MFP. Wear resistance is proportional to hardness in most cases; therefore, wear resistance is inversely proportional to MFP. The increase of wear resistance as MFP decreases is attributed to the resistance to plastic deformation, which accounts for various wear mechanisms, especially during abrasive and adhesive wear situations. However, in cases where microchipping and fracturing is responsible for material loss, an optimum MFP has to be achieved to maximize wear resistance. Microchipping and cracking resistance is proportional to MFP. The balance between microchipping and local plastic deformation resistance yields optimum wear resistance. Another important factor during abrasive wear is the ratio between MFP and abrasive wear particles. When abrasive particle size is smaller than mean free path between hard phase particles, preferential wear of metal phase between them is dominant. When abrasive particle size is larger than MFP, overall hardness of the microstructure becomes a dominant factor.

Type of Hard Phase Particles. Many hard particles are known to be used in wear applications, including carbides, borides, nitrides, oxides, and other ceramics. Among carbides, tungsten carbide (WC), chromium carbides, and titanium carbide (TiC) are most widely used. Vanadium carbide (VC), molybdenum carbides, and tantalum carbides are often used as additives. Titanium diboride is known to be extremely wear resistant. Usage of TiB₂ powder has been on the rise recently. Relative hardness of hard phase particles to that of abrasive particles is an important factor attributed to the interaction between the microstructure and wear environment.

Wear Environment/Mechanisms. Factors to consider include mechanical loading conditions, wearing mechanisms, harshness of abrasive particles, and hardness and size/shape of abrasive particles. In cases of abrasive wear, relative size between the hard phase particles, d_c , and abrasive particle d_a , is an important factor. In general, if the $d_c < d_a$, rate of wear loss is greater than it would be if $d_c > d_a$. Wear mechanisms depend on the wear environment and the material. In cases of sliding wear, relative hardness between the two mating surfaces, the chemical affinity between the two mating surfaces, and abrasive particles contained in the materials are all important factors that affect the final outcome. Depending on the wearing system, different mechanical properties (e.g., resistance against plastic deformation, crack formation or crack propagation) have to be considered. Depending on which wear mechanism is dominant, different material properties and microstructure may be desired. Other environment factors, such as corrosive fluid and potential chemical interactions, need also be considered.

Wear-Resistant P/M Alloys

Wear resistant P/M alloys include cemented tungsten carbide, P/M steels, and P/M metal-matrix composites.

Cemented Tungsten Carbide

Cemented tungsten carbide and cermet are the most widely used P/M materials for wear applications. Cemented tungsten carbide and cermet are used in all types of wear applications including abrasive wear, sliding wear, and erosive wear situations. Cemented tungsten is a composite of tungsten carbide, WC, and cobalt metal, Co. In most commercially available grades of WC-Co, cobalt contents range from 6.0 to 16.0%. There are applications using as low as 3% cobalt or as high as 25% cobalt, although those are not common. Tungsten carbide grain size range from submicron to 10 μ m. Commercially available ultrafine WC powder has nanometer size grains such as NanoCarb (Nanodyne, Inc., New Jersey).

Most cemented tungsten carbide manufacturers have their own designations for different grades that are used by suppliers and customers. For metal removal cutting tool applications, there are internationally accepted grade designation systems that are used as category reference only. For example, the P-M-K system found in Ref 5, and the "C" system in which C-1 through C-4 are used for abrasion resistant grades and C-5 through C-8 are used for crater and deformation resistant grades. C-1 through C-4 are straight WC-Co grades, and C-5 through C-8 contain cubic carbides, such as TiC and TaC for cutting tool applications.

A schematic flowchart of processes for cemented tungsten carbide is illustrated in Fig. 2. One of the critical factors and an occasional problem in industry today is the carbon control during liquid phase sintering. In recent years, low pressure (around 1000 psi) hot isostatic pressing has been used in combination with the standard vacuum liquid phase sintering to improve quality and properties of cemented tungsten carbide products.

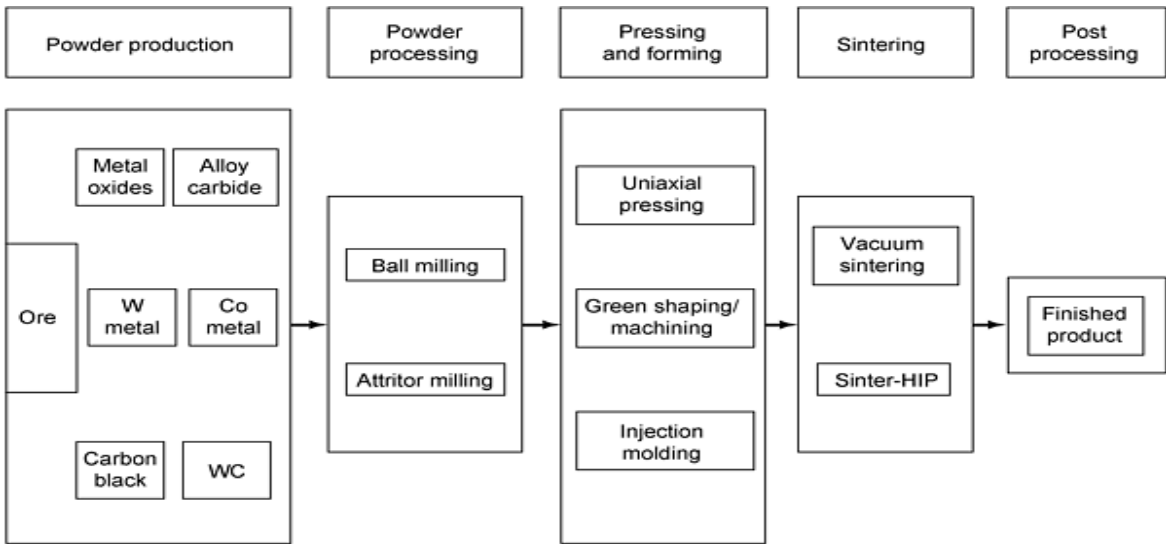

Fig. 2 Schematic flow chart of manufacturing processes for cemented tungsten carbides

Fundamental mechanical properties of cemented tungsten carbide include hardness, fracture toughness, transverse rupture strength (TRS), compressive strength, and wear resistance. Hardness and TRS are widely used in day-to-day engineering activities for selection and quality control, while fracture toughness is mostly used in developing new grades. Hardness is proportional to compressive strength and inversely proportional to fracture toughness. Transverse rupture strength depends on both strength and toughness of the material. When there is significant volume percent of defects such as porosity in microstructure, TRS becomes very defect-sensitive. Figure 3 shows the interrelationships between hardness, fracture toughness, and TRS. Transverse rupture strength is affected by both crack initiation and crack propagation processes; therefore, it exhibits an apex as hardness increases. Wear resistance is more closely related to hardness. Figure 4 demonstrates that the higher the hardness, the higher the abrasive wear resistance. It also demonstrates that the higher the fracture toughness, the lower the wear resistance. The trade-off between wear resistance and toughness has to be made when selecting cemented tungsten grades for specific engineering applications.

Fig. 3 Mechanical properties of WC-Co alloys

Fig. 4 Dependence of wear resistance of WC-Co alloys on their hardness and fracture toughness

Microstructure of most cemented tungsten carbide belongs to the category of dual-phase composites, in which tungsten carbide grain is the hard phase, and cobalt metal in between WC grains are the ductile phase. In submicron super fine grain, the MPF is so small that the composite material behaves more like homogeneous materials. Because cobalt content normally ranges from 6 to 20% (8 to 30% vol), it can also be categorized into ductile phase reinforced brittle materials. Hardness of the materials decreases and toughness increases as cobalt content increases. Grain size of WC also affect properties. As grain size increases, hardness decreases and toughness increases. Influence of microstructure on properties is reflected in the dependence of hardness, toughness, and wear resistance on MFP. The larger the MFP, the lower the hardness and the higher the toughness (Fig. 5). In considering wear, different mechanical properties (e.g., resistance against plastic deformation, crack formation or crack propagation) have to be considered.

Fig. 5 Dependence of hardness and fracture toughness on mean free path of tungsten grains in WC-Co alloys

In the sequence from crack formation to crack propagation and finally fracture, crack propagation plays the determining part in most metallic alloys. In contrast, crack formation seems to be the most important part in ceramics. For cemented tungsten carbide, both plastic deformation and microfracturing mechanisms are important. However, the dependence of wear resistance on hardness suggests that its resistance to local deformation is dominant at the onset of a wear process. Due to limited ductility, initial plastic yield on the wear surface evolves into microfracturing quickly. The surface plastic yield is apparently controlled by the cobalt content. Preferential wear of cobalt also occurs as cobalt content increases. Another important mechanism is the pullout of carbide grains, WC, as a result of preferential wear of cobalt phase. The larger the grain size, the less the tendency of carbide grain pullout. Therefore, within a certain range of hardness and toughness, larger grain size grades can be more wear resistant than finer grain size grades at an equivalent hardness level.

Major categories of applications of cemented tungsten carbide include metal removal cutting tools, rock and earth drilling tools, drawing and punching dies and punches, wear components, and other engineering specialty applications.

For metal cutting tools, wear progresses very quickly under high temperature and heavy load. Tool life is limited to a very small amount of wear loss, usually indicated by the change in radius of the cutting edge. Crater wear on the top surface of a cutting insert is the result of a chemical reaction between metal chips and tungsten carbide under high heat. Titanium carbide and tantalum carbide additions are prevalent in most cutting tool grades to combat crater wear. Modern cutting tools are often coated by chemical vapor deposition (CVD) with TiN, TiCN, TiC, and in combination with Al_2O_3 . Physical vapor deposition (PVD) is utilized to coat drills, end mills, etc. with TiN, TiCN, and CrN.

Cutting tools are categorized based on their specific cutting application, such as general purpose grades, rough turning grades, or finish turning grades. Trade-offs are often made in designing as well as selecting grades between chipping resistance and wear resistance. For example, KC-850 (Kennametal, Inc., PA) is a general purpose turning grade used in industry which combines good wear resistance with good chipping resistance. GC4015 (Sandvik Coromant Co., Fair Lawn, NJ) is a finishing turning grade with high hardness and crater resistance but moderate chipping resistance. It is not suitable for interrupted turning. Twist drills often use fine grain (submicron) high hardness grade. RTW 2606 (Roger Tool Works, Inc., Rogers, AR) is a grade for printed circuit board drills with a hardness in the range of 93.5 to 95 Ra.

P/M cutting tool materials also include the cermet. Cermet is commonly used to describe (TiC, TiCN)-(Ni, Ni/Mo) alloys. Cermet has better high temperature hardness than cemented tungsten carbide. They are mostly used for finishing turning cutting applications. A comprehensive review on cutting tool materials and their wear resistance can be found in the article "Friction and Wear of Cutting Tools and Cutting Tool Materials" in *Friction, Lubrication, and Wear Technology*, Vol 18 of the *ASM Handbook*.

Earth drilling tools include petroleum drilling bits, mining bits, coal mining tools, and construction tools that use cemented tungsten carbide as cutting inserts. Earth boring bits operate under very heavy load and in extremely abrasive environments. Cutting structure of such tools must have very high compressive strength, very high abrasive wear resistance, and sufficient fracture toughness. Cemented tungsten carbide offers the best choice. In typical grades used for earth boring applications, cobalt content ranges from 6 to 16%, and grain size range from 1 to 10 μm . Hardness of these grades ranges from 85.0 to 91.0 HRA. Corresponding fracture toughness is from 10 to 18 $\text{MPa}\sqrt{\text{m}}$. Selection of a specific grade depends on the application. For example, 6% cobalt grades with relatively low toughness are often used in applications where mechanical impact is minimum and sliding abrasive wear resistance is the main concern. In applications where mechanical impact is unavoidable, grades with higher fracture toughness (by increase cobalt content or grain size) are used.

Abrasive wear is considered the primary mechanism for earth boring applications. However, depending on different types of rock drilling tools (rotary, percussive, or rotary and percussive), impact and/or impact fatigue can play a major role in causing material loss during drilling. Contribution of impact fatigue and abrasion to wear can be separated to a certain extent. Figure 6 shows the dependence of impact wear and abrasion wear on cobalt content, respectively. The impact wear resistance shows a maximum of 6 to 8% Co, which is similar to the relationship between compressive strength and transverse rupture strength versus cobalt content. For abrasion resistance during rock drilling, the general principle for the effects of grain size, cobalt content, and MFP applies. Very hard cemented carbides containing a high volume fraction of carbides exhibit lower abrasive wear loss on fine grain structures. Softer, more ductile cemented carbides, containing less volume fraction of carbides, exhibit lower wear loss in the case of coarse grain structures. In short, the abrasive wear resistance is generally related to hardness and cobalt content, while the impact wear appears to be closely related to bulk compressive strength and transverse rupture strength. Another important factor affecting tool life during earth boring is the size of abrasive particles and its relative ratio to grain size or mean free path of the microstructure. Figure 7 shows that there is optimum λ/D_{eff} where wear loss is minimum, where D_{eff} is the effective diameter of abrasive particles. The optimum values of λ/D_{eff} for fine grain and coarse materials are different indicating differences in wear mechanisms.

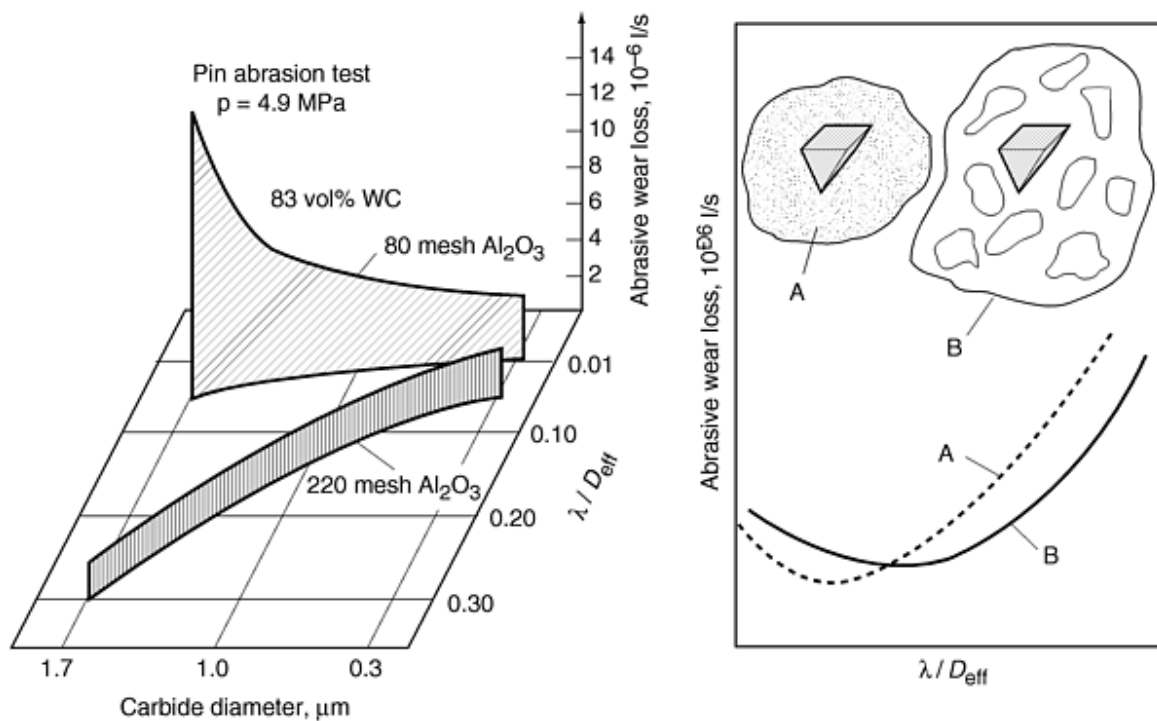

Fig. 7 Abrasive wear loss of cemented tungsten carbides in a pin abrasion test vs. grain size and the ratio of mean free path λ to the effective diameter D_{eff} of abrasive particles. Source: Ref 1

Metal forming tools and dies, structural components, and a wide variety of wear parts constitute roughly one-third of total tonnage of cemented tungsten carbide shipped. Metal forming tools and dies include hardmetal dies for drawing wire, rod, bar, tube, and special sections. For wire drawing dies, crucial properties are abrasive wear resistance and compressive strength. High surface finish requirements often dictate selection of fine grain and low cobalt grades. However, for larger cross section drawing, such as rods and special sections, toughness is important. The biggest market for pressing dies is the carbide industry itself, because nearly all cutting inserts and cemented carbide components are formed by the uniaxial die pressing method. Other metal forming tools include pressing dies used for synthetic diamond and cubic boron nitride manufacturing, and rolls for the rolling of steel rod and sections, wire, tape, and foils. Foil rolls require perfect mirror surface finish. Fine grain and porosity free microstructure, which yields improved rupture strength and fatigue resistance of rolls, is extremely important.

Structural components made of cemented carbide include mechanical seals, compressor plungers, lathe jaws, boring bars, grinding spindles, pulverizing pins, and bearing journals. Wear parts include nozzles, guides, plungers, balls, slitting wheels and cutters for paper industry, and many other applications.

Wear for most metal forming tools, structural, and wear components are classified as "sliding" wear based on their mechanical function. Almost all wear mechanisms could occur during sliding wear applications. However, depending on specific application, only one or two mechanisms may be dominant. For most cemented carbide sliding wear applications, abrasive wear and adhesive wear are the primary mechanisms. For metal rolls, obviously, rolling fatigue should be considered in analyzing wear mechanisms.

P/M Steels

There are various P/M tool steels engineered with respect to wear applications. The steel compositions vary in carbon and alloying elements such as manganese and phosphorous contents. By far the most recognized P/M steels for wear applications, however, are P/M tool steels. Compared to conventional tool steels, P/M grades offer distinctive advantages in terms of finer

grain size and homogeneous microstructure with less segregation. The powder metallurgy approach also lends to near-net shape manufacturing important for components made of tool steel from the perspectives of machinability and cost. A list of commercially available P/M tool steel grades with their typical composition and characteristics are found in Table 1 and in the article "Particle Metallurgy (PM) Tool Steels" in this Volume. A number of P/M high speed steels have been developed that cannot be made by conventional methods because of their high carbon, nitrogen, or alloy contents. Examples include CPM Rex 20, CPM Rex 25, CPM Rex 76, and ASP 60. The P/M hot isostatic pressing (HIP) process is the only way to produce such highly alloyed high speed steel (HSS) as Rex 76 and ASP 60.

(a) HCHS, high carbon, high sulfur; HS, high sulfur

Figure 8 schematically illustrates P/M processing routes for tool steels. The most critical processing steps are manufacturing of prealloyed powder by atomization and consolidation by HIP. There are two competing processes in making powder: water atomization and gas atomization. Typical advantages of gas atomization over water atomization include cleanliness and particle shape control. Tool steels produced by HIP are normally conducted in argon at 7 to 200 MPa pressure and 1000 to 1200 °C. Powder metallurgy tool steels and other ferrous P/M alloys can also be manufactured by nonpressurized sintering techniques, such as solid state, transient, or super-solidus liquid phase sintering. Standard sintering techniques have the distinct advantage of low cost and therefore wide application areas; but, in general, substantial compromise is made in terms of mechanical properties due to presence of significant levels of porosity. Lower strength and lower hardness dictate that wear resistance is lower than that of HIP alloys.

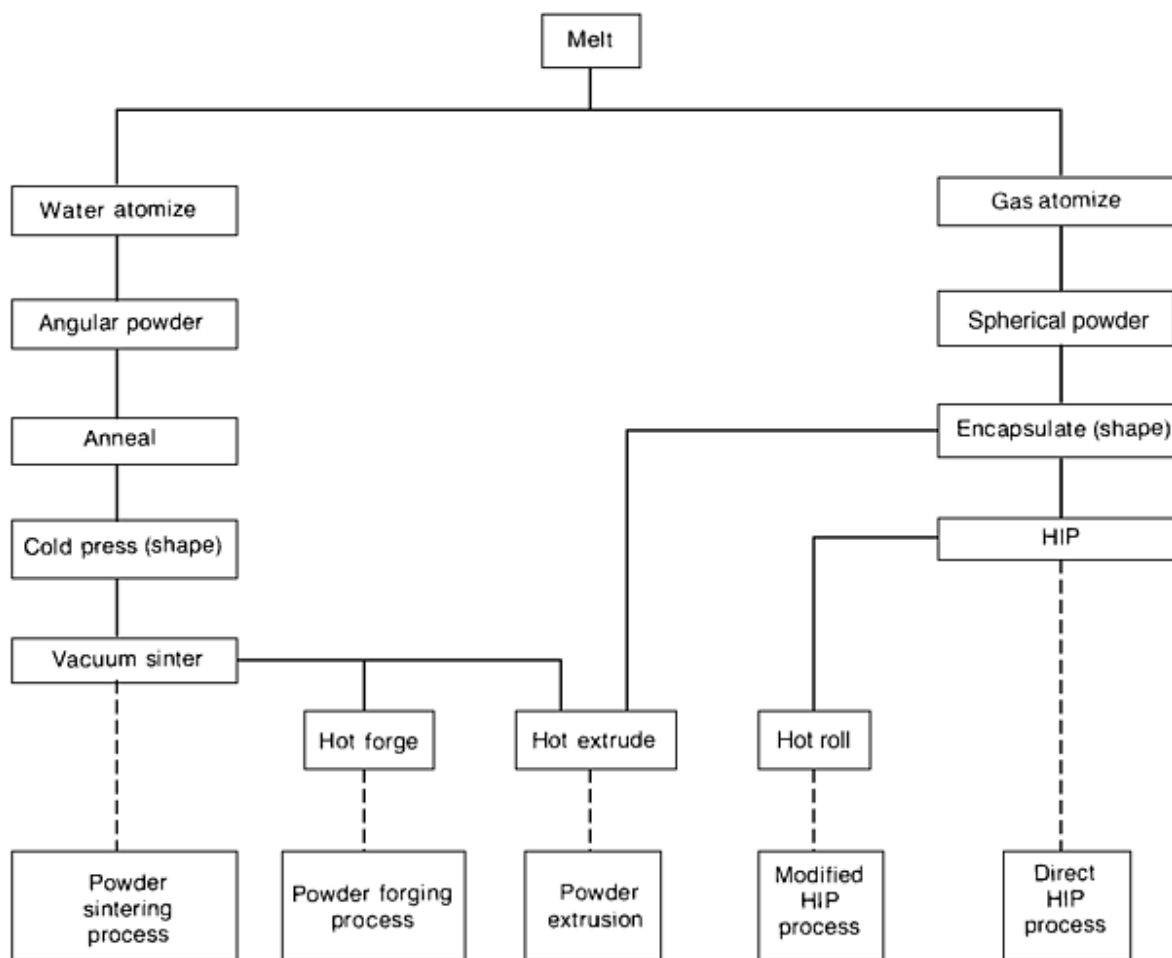

Fig. 8 Typical processing flow chart of P/M tool steels. Source: Ref 7

Powder metallurgy tool steels utilize the same basic heat treatment as their conventional counterparts, but they tend to respond more rapidly and with better predictability to heat treatment because of their more uniform microstructure and finer carbide size. Powder metallurgy tool steels also have superior machinability to conventional tool steels due to generally higher sulfur content in P/M alloys.

Wear resistance of P/M tool steels is largely associated with its hardness. Figure 9 illustrates the relationship between impact toughness and hardness. Balance in toughness and wear resistance must be considered in selecting a specific tool steel grade for applications. Figure 10 is a representative view of the wear resistance of a range of sintered alloy steels against average hardness. Variations in wear resistance versus hardness are due to specific alloys with respect to carbide contents, carbide particle sizes, size distributions, and shapes.

Fig. 9 Compilation of fracture toughness of tool steels

Fig. 10 Wear rates of a range of sintered alloy steels against average hardness. Source: Ref 9

P/M tool steel is essentially a homogeneous material. Volume fraction of carbides in a tool steel is <50% (10 to 20% in most cases) and particle size of carbide particles is usually very small, ranging from submicron to a few microns. Although wear resistance is proportional to volume fraction of carbides, studies show that the rate of increase in wear resistance diminishes >30% by volume for specific ferrous-base alloy systems and applications.

On the other hand, the tool steels including high speed steels can be considered as composite materials with a martensitic steel matrix and a harder, particulate reinforcement consisting of primary carbides. Wear resistance of P/M tool steels is therefore similar to that of cemented tungsten carbide. Microstructure factors controlling wear resistance include carbide volume fraction, carbide type, carbide particle size and size distribution, carbide particle shape, and steel matrix microstructure.

Carbide types in tool steels include MC, M_2C , and M_6C types, where M could be V, W, Mo, or Cr. The presence of M_2C or MC type carbides is considered to impart a greater wear resistance to these materials than M_6C type carbides. Vanadium carbide plays an important role in P/M tool steel. PM 10V and PM 15V are primary examples of P/M tool steels with high vanadium content of 9.75 and 14.5 vol% respectively, which is impossible for conventional tool steels. The microstructure of PM 15V contains ~ 22 vol% primary vanadium carbides with the majority having a size of $3\ \mu\text{m}$ or finer. Table 2 compares high vanadium P/M tools to others. It is apparent that wear resistance increases rapidly as vanadium content increases at the expense of impact toughness. In general, carbide particle sizes range from submicron to a few microns ($<10\ \mu\text{m}$), depending on processing history including heat treatment. Particle size and volume distributions are important in the wear behavior, a high proportion of M_2C /MC carbides of large size ($6\ \mu\text{m}$) give a greater wear resistance.

Table 2 Wear resistance and toughness of high vanadium content steels and other wear resistant steels

Grade	Hardness, HRC	Pin abrasion resistance weight loss, mg	Cross cylinder wear resistance, $\times 10^{10}\ \text{lb/in.}^2$	Toughness Charpy C-notch impact energy, ft/lb
PM 15V	64	24	124	8
PM 10V	64	32	90	14
PM M4	61	49	31	31.5
PM D7	59	46	11	22
PM 8Cr4V	60	56	30	27

Compared to cemented tungsten carbide, tool steels are perceived as tougher and less wear resistant. Figure 11 illustrates relative wear resistance of P/M tool steels compared to cemented tungsten carbide with 8% cobalt (Ref 10). However, although the relation is generally true, attention must be given to the specific environment in which wear occurs. For example, the American Society for Testing and Materials (ASTM) has two widely used abrasive wear tests. ASTM G 65 is considered a low stress abrasion test, during which wear coupons are abraded by loose sand particles against a lightly loaded rubber wheel under dry conditions. ASTM B 611 is considered a high stress abrasion test, during which wear coupons are abraded by alumina against a heavily loaded steel wheel under wet medium. Table 3 compares wear resistance of a few typical tool steels to WC-Co alloys with average grain size $\sim 4\ \mu\text{m}$ using the two different abrasion tests. It shows that cemented tungsten carbides have higher wear resistance under both low stress and high stress conditions. Tool steels have significantly lower wear resistance under the low stress dry sand abrasion condition. However, the differences between tool steels and WC-Co alloys are much smaller under high stress abrasion conditions. It indicates that toughness plays a larger role in high stress abrasive resistance than in low stress abrasion resistance. This is the result of complex wear mechanisms and their interrelationship with hardness or fracture toughness. It is also the result of complex interaction between wear environment and microstructure features, such as carbide particle size, volume fraction, and MFP. Therefore, in selecting materials for wear applications, not only wear tests data are considered, other overall effects of basic mechanical properties and actual wear environment have to be considered too. Table 4 qualitatively compares properties of P/M tool steel to cemented tungsten carbide.

Table 3 Wear resistance comparison between P/M tool steels and typical WC-Co grades

Materials	Wear resistance under low stress abraision (ASTM G 65), 1000 rev/cc	Wear resistance under high stress abraision (ASTM B 611), 1000 rev/cc
WC-15%Co, grain size 5 μm	0.435	3.3
WC-16%Co, grain size 6 μm	0.238	1.8
A2	0.087	1.95
D2	0.186	1.8
CPM M4	0.590	1.9
S7	0.036	1.95

Table 4 Qualitative comparison of mechanical properties of P/M tool steel and cemented tungsten carbide

Property	P/M tool steel	P/M tool steel	WC-Co	WC-Co
Hardness	50-58 HRC	59-68 HRC	>88 HRA	<87 HRA
TRS	Medium	High	Medium/high	Medium
K_{Ic}	High	Medium	Low	Medium
Impact resistance	High	Medium-low	Low	Medium
Wear resistance	Low	Medium	High	Medium
Thermal shock resistance	Low	Low	High	Medium

Fig. 11 Relative comparison of pin-on-disc wear resistance of PM 24Cr9V, PM 440V, PM 10V, PM D7, and T440B stainless WC-8Co. Source: Ref 10

Thermal fatigue cracking resistance and corrosion resistance are sometimes the primary cause for material loss and fracture. Final selection of a material for an application depends on the mechanisms responsible for material loss versus consideration of combined effects of all properties.

Applications of P/M tool steels and high speed steels include metal removal cutting tools and tooling for metal forming and shaping operations. Cutting tools include milling inserts, hole machining reamers, taps, drills, and broaching tools. Typical P/M tool steel grades for cutting tools include ASP 30, ASP 60, and the CPM Rex M3 and M4. At similar hardness levels, P/M grades offer superior impact toughness to similar grades processed by conventional means. Table 5 compares CPM Rex 20 and CPM Rex M42 to conventional M42. As the result of better basic mechanical properties and more uniform finer microstructure, wear life of P/M tool steel tools are longer than their counterparts. Figure 12 is one example of the tool life of milling inserts of ASP 30 and ASP 60 compared to conventional M42.

Table 5 Charpy C-notch impact and bend strength of CPM alloys comparing to conventional M42 alloy

Alloy grade	Hardness, HRC	Charpy C-notch impact energy, J	Bend fracture strength, MPa
CPM Rex 20	67.5	16	4006
CPM Rex M42	67.5	16	4006
Conventional M42	67.5	7	2565

Fig. 12 Comparison of P/M tool steel ASP 30 vs. conventional M42 during end mill tests in Ti-6Al 4V. Source: Ref 7

Cold- and hot-work rolls are another primary application of P/M tool steels. High vanadium P/M tool steel such as CPM 9V and 10V are used for high wear and cold work applications. Similar to cutting tools, the more uniform microstructure of P/M cold-work steel yields better toughness. Higher vanadium content makes it possible that higher wear resistance is achieved at an improved toughness simultaneously. CPM 10V has proved to be more wear resistant than any commercially available high-alloy tool steel. CVP 10V has far superior wear resistance and equivalent impact toughness when compared to conventional D2, M2, and CPM M4 (Fig. 13). For hot-work applications, superior thermal fatigue resistance is very important. The absence of segregation in P/M tool steels is an advantage over conventional alloys, because premature failure due to thermal fatigue is often attributed to segregation and heterogeneous microstructure. H13 and H19 are typical tool steel grades for hot-work applications. The P/M versions, P/M H13 and H19 have more uniform properties and equivalent or better toughness. Again, high vanadium content can improve wear resistance and toughness.

P/M Metal Matrix Composites

The concept of metal-matrix composite (MMC) refers to a large class of materials with at least one type of reinforcement situated in a metal matrix. In general, the scale of the reinforcement is large compared to that of the microstructure. The reinforcement can be in the form of continuous fiber, short fiber, or particulate. Although it is recognized that MMCs offer considerable potential for enhanced wear resistance, understanding of their wear characteristics is still far from complete.

This is due in part to the inherent complexity of many wear processes, but the problem is compounded by an interplay with microstructure variables in MMC, such as reinforcement content, size, orientation, interface strength, etc.

Many MMCs are fabricated by powder metallurgy, in other words, the composites are formed by consolidating constituent powders together. Particulate MMC is especially suitable for P/M processing. In a narrower sense, MMC refers to modern low-density high-strength alloy systems such as aluminum- or titanium-base composites (e.g., Al-SiCp, Al-Al₂O₃, Ti-SiCp, and Ti-6Al-4V-SiCp). However, it is clear from the previous discussion that many P/M materials for wear resistant applications bear the same basic microstructure characteristics of MMCs. Therefore, many P/M materials can be considered MMC, and many particulate MMCs can be considered P/M materials. Hence, general principles governing wear behavior of two or multiphase P/M materials apply to many MMCs.

Key factors affecting wear resistance of MMC include volume fraction of reinforcement particles, particle size of the reinforcement, and the diameter of reinforcement relative to the size of the abrading particles. Figure 14 illustrates that specific wear rates of aluminum-base composites decrease with the increase of volume fraction of different hard particle reinforcements. This behavior is true under either abrasive or adhesive wear situations. For a given volume fraction of particles, composites that contain harder particles exhibit a lower wear rate. Similar results can be expected for tool steel-base composites such as steel-base TiC particle composites. Figure 15 demonstrate the effects of the size of the hard particles. Larger ceramic particles and higher contents give greater wear resistance. Larger abrasive particles cause significantly more wear to composites because of the increasing chances of fracturing of reinforcement particles under the heavy load exerted by large abrading particles. In the case of erosive wear, situations are more complex. Factors such as the impact angle play a very important role as well as volume fraction. For example, it was found that the minimum erosive wear rate appeared at 34 vol% binder in WC-Co cermets. MMC can also contain soft reinforcement. Al-Sn alloys, for example, have long been used as bearing alloys. In general, when improvements to the wear resistance are obtained in this way, it is normally accompanied by a reduction in the coefficient of friction.

Hardfacing and Thermal Spray

Applications. Metal alloy powders are used for hardfacing and thermal spray coatings for wear-resistant applications. Hardfacing is the application of hard, wear-resistant material to the surface of a component by welding, thermal spraying, or a similar process for the main purpose of reducing wear. Metal alloy powders used for hardfacing include WC-Co powders, other carbide-metal alloy powders, cobalt-base wear-resistant alloy powders such as Stellite (Deloro Stellite, Inc., Belleville, ON) series of alloys, and some nickel- or iron-base wear-resistant alloy powders.

Thermal spray coatings are themselves a major engineering field. Numerous different techniques for applying hardmetal powders onto a substrate can be categorized as thermal spray coating. Thermal spray techniques include but are not limited to traditional oxyacetylene torch spray, plasma thermal spray, detonation gun (D-gun and super D-Gun) thermal spray, and more recent technologies such as high velocity oxy-fuel (HVOF) thermal spray. Figure 16 is a schematic illustration of the plasma spray coating process. Common features of thermal spray coatings, differing from other hardfacing processes (such as welding processes), are thickness of thermal spray coating is usually limited to 0.025 to 0.5 mm and bonding between coating and substrate is primarily mechanical. Key advantages of thermal coatings over welding are geometry, flexibility, and process temperature of substrate components can be maintained so low that the coating can be applied to finished products.

Fig. 16 Schematic of plasma spray hardfacing process

Hardfacing materials are often applied by various welding techniques. The welding techniques for hardfacing include oxyacetylene torch, gas metal arc, gas tungsten arc, plasma arc, and plasma transfer arc welding. Plasma transferred arc process is illustrated in Fig. 17. Characteristics of weld-on hardfacing are that coatings are thicker than thermal spray

coatings, and coatings are metallurgically bonded to the substrate. Welded-on wear-resistant hardfacing has wide ranging applications from earth moving equipment to precision bearing and seal surfaces.

Fig. 17 Schematic of the plasma transferred arc hardfacing process

Another category of hardfacing techniques is cladding. Hardfacing materials can be cladded onto substrates by furnace fusing prearranged layers of loosely bonded hardmetal onto substrate (Fig. 18). Two layers of metal and metal carbide tapes are stacked over the substrate. The tape is made from powder bonded by polytetrafluoroethylene (PTFE) or other polymers. One of the two layers is a carbide powder tape and the other is high temperature brazing alloy powder tape, such as a nickel-base brazing alloys. Coating is formed by heating the assembly to brazing temperature and infiltrating the brazing alloy into the carbide layer. The final coating of nickel alloy bonded carbide particles is bonded to the substrate during the process. Cladding can also be done by HIP. Advantages of furnace cladding include better dimensional and thickness control. Disadvantages are that the entire components are exposed to high temperature (typically 1000 to 1250 °C) for an extended period of time.

Fig. 18 Flow chart of a tape cladding process. Source: Ref 13

Metal carbides are the most widely used materials for wear-resistant coatings and hardfacings. Among various types of carbides, tungsten carbide is the most popular one. Chromium carbide is also very common. Other carbides, such as vanadium carbide and molybdenum carbides, are often the choice for additives.

Sintered cemented tungsten carbide (WC-Co) powders are widely used for thermal spray coatings and torch welding hardfacing. WC-Co powder can be a product of crushing bulk WC-Co alloys or specifically made spherical shaped pellets. Tungsten carbide powders for thermal spray coatings usually contain from 6 to 18% cobalt. Table 6 lists typical compositions of carbide powders for thermal spray coatings. Cr_3C_2 powder and its alloys are also popular for thermal

applications. Particle sizes of WC-Co and other alloy powders for thermal spray coatings range from 5 to 150 μm . Powders for torch welding hardfacing ranges from 150 μm to 1.2 mm.

Table 6 Typical thermal spray alloy powders for wear applications

Powders	Composition, %						
	WC	Cr ₃ C ₂	Co	Ni	Fe	Cr	Other
WC-12Co	bal	...	12
WC-10Co-4Cr	bal	...	10	4	...
WC-17Co	bal	...	17
WC-10Ni	bal	10
Cr₃C₂	...	bal
Cr₃C₂-25NiCr	...	bal	24-26NiCr
Cr₃C₂-FeCrAlY	...	bal	14-16FeCrAlY
Ni-718	bal	...	17-21	Mo 2.8-3.3, Nb 4.8-5.5, Fe 14-21, Ti 0.75-1.15
Stellite 6	bal	28	4W-1Si-1C
Stellite 1	bal	31	12.5W-1Si-2.5C
Stellite 12	bal	29	8.5W-1.5Si-1.5C

Macrocrystalline tungsten carbide powders are a special kind of tungsten carbide powder manufactured by high temperature thermit process during which ore concentrate is converted directly to WC. Macrocrystalline tungsten carbide maintains carbon content of 6.13% by weight, the correct stoichiometric amount. Macrocrystalline tungsten carbide is grown in crystals ranging from 1 μm to 5 mm. Coarse mesh sizes of macrocrystalline carbide are extensively used in abrasion and erosion protection applications. The finer size is employed as wear rate modifiers. Coarse grain tungsten carbide powder can also be obtained by conventional dry-carburizing tungsten metal method. Examples include commercial grades of MAS 2000, MAS 3000, and MAS 5000 by H.C. Starck (Newton, MA). Particle sizes of these powders range from 20 to 50 μm .

Cast tungsten carbide is another category of carbide that has wide applications in hardfacing. Cast carbide refers to eutectic of WC and W₂C that can range in carbon content from 3.5 to 4.5% by weight. It is manufactured by melting mixtures of tungsten metal, tungsten carbide, and carbon ingredient at temperatures above 3000 °C. The melt is cast into billets, which are then crashed into specified size ranges of powder. Cast carbide can be crashed to as coarse as 20 mesh and as fine as -325 mesh powder. Cast carbide, mostly used in torch welding hardfacing and infiltrated drag bit matrix body, is often used in combination with sintered tungsten carbide and other carbides to enhance wear resistance. Addition of cast carbide tends to degrade toughness of coating.

Spherical cast tungsten carbide is a relatively new product in the marketplace with increasing applications. Spherical cast carbide has all the basic characteristics of crashed cast carbide. Spherical cast carbide has extremely high wear resistance and higher resistance to chipping and cracking than crushed cast carbide due to its spherical shape. Spherical cast carbide is manufactured by patented solidification technique (Ref 14), during which molten eutectic carbide droplets are rapidly cooled. Spherical cast carbide can be used alone or in combination with other carbides.

Wear Resistance of Powder Metallurgy Alloys

Zhigang Fang, Smith Tool, Smith International, Inc.

Hardfacing Alloy Powders

Cobalt-base hardfacing alloy powders are best known as Stellite powders. Typical compositions and wear resistance of Stellite powders are found in Table 7. Cobalt alloys for hardfacing have advantages for use in combined wear-resistant, corrosion-resistant, and high temperature applications. Cost of cobalt-base alloys tends to be higher than nickel- and iron-base alloy powders. Cobalt alloys are typically used for overlay applications, deposited readily by plasma transfer arc process.

Table 7 Typical cobalt-, nickel-, and iron-base hardfacing alloys

Alloy category	Content	Hardness	Abrasion resistance	Impact resistance	Adhesion resistance	Applications
Iron based low-alloy	0.3-1.0C, 1.7-7.0W, 3.5-5.0Cr, 4.0-9.0Mo, bal Fe	55-60 HRC	More wear resistant than low carbon steels	Moderate	Good	Cutting tools, sheer blades, reamers, dies, ingot tongs
Iron-chromium	3.0-5.0C, 4.0-8.0Mn, 26-32Cr, 2.0Mo, bal Fe	51-62 HRC	Excellent for low stress abrasion	Good for light impact	Excellent	Agricultural machinery, coke shutes, brick-making equipment
Cobalt-chromium	0.7-3.0C, 2Mn, 3-14W, 3Ni, 19-33Cr, 5Fe, bal Co	28-65 HRC	Excellent in low stress abrasion. 5-20% of wear rate of carbon steel	Fair. Deteriorates as carbon increases	Excellent for low stress. Poor for high stress	High temperature, high corrosion applications, pump shafts, engine valves
Nickel-chromium	0.3-1.0C, 1.0-1.5Co, 8-18Cr, 1.25-5.5Fe, 2-4.5B, 1.25-5.5Si, bal Ni	24-62 HRC	Excellent in low stress. Increases with carbon content	Good for light impact. Decreases as carbon increases	Excellent for low stress	Seal rings, cement pump screws, valves, cams
Tungsten carbide	60% carbide granules, 40% steel tube	90-95 HRA (granules), 30-60 HRC matrix	Superior to all others	Good under light impact	Poor	Cutting teeth and edge holding surfaces of rock drill bits, quarrying, digging, earth moving equipment

Nickel-base hardfacing alloy powders are usually Ni-Cr-B-Si system based. Additions of boron and silicon to nickel suppress the melting point so that less heat is required to deposit the nickel-base hardfacing alloy onto substrates. However, excessive additions of boron and silicon lower plasticity. Most of these alloys contain nickel boride (Ni₃B), chromium borides (CrB, Cr₅B, and Cr₂B), and other complex borides as hard phases. Typical alloy compositions and wear resistance are listed in Table 7. Deposit hardness in these alloys is as high as 60 HRC, depending on the chromium, boron, and silicon contents. Nickel-base hardfacing alloys are particularly popular in oil pumping and in glass, ceramic, cement, and plastic industries.

Iron-base hardfacing alloys can be classified into Pearlitic steels, Austenitic steels, Martensitic steels, and high-alloy irons. The high alloy irons usually contain high carbon and high chromium content. More iron-base hardfacing alloys are used in various industries than cobalt- and/or nickel-base hardfacing alloys, primarily due to the lowest cost and highest availability. Typical composition and wear resistance comparison is shown in Table 7.

Wear Resistance of Powder Metallurgy Alloys

Zhigang Fang, Smith Tool, Smith International, Inc.

Full Density Cobalt Alloys

Alloys based on cobalt chromium-tungsten-carbon, such as the Stellite family of alloys, are extremely versatile, wear-resistant materials (Ref 15, 16). Full density P/M components also can be manufactured by hot isostatic pressing or extruding operations (Ref 17, 18) for near-net shape processing and refined microstructures.

Material Descriptions and Applications. Table 8 gives the nominal chemical analysis for the most popular Stellite P/M materials. The microstructure of Stellite alloys contains complex combinations of M_7C_3 , M_6C , and $M_{23}C_6$ carbides embedded in a cobalt-chromium-tungsten superalloy matrix.

Table 8 Nominal chemical analysis of most widely used Stellite P/M materials

Alloy	Composition, %

Stellite 98M2	30	18.5	3.5	0.8	1	1	5	2	1	2, 4.2 V

(a) Maximum; all materials cobalt base

For highly abrasive conditions, alloys such as Stellite 3, 98M2, and Star J are preferable because they contain a large volume fraction of carbides. The lower carbon grades are more ductile and are suitable for applications involving shock loading or impact.

Typical applications include precision balls, bearing race blanks, valve seat inserts, saw tips, cutters, spacer bushings, and wear pads. Stellite 3 is also used in medical instruments. Stellite 12 P/M has proved to be exceptional for cutting timber.

Material Properties. Tables 9 and 10 show the physical and mechanical properties of Stellite materials. The physical properties were measured on castings but are thought to be representative of P/M parts. It should be noted that Stellite materials are only weakly magnetic under most conditions.

Table 9 Physical properties of Stellite materials

The excellent hot hardness of the materials is particularly important to prevent the dulling of cutting tools where frictional heating is typically extreme at the sharp edge. It may be noted that some grades, such as Stellite 31, are relatively soft and ductile. This grade is used when high-temperature strength, shock loading, fatigue, and fretting are concerns.

Heat Treatment. Stellite P/M materials are not generally considered heat treatable nor is heat treatment required. Stress relief treatment involves a slow heat-up and soaking at 900 °C (1650 °F) for at least 2 h, followed by furnace cooling. Stellite 6 can be solution annealed by soaking at 1200 °C (2190 °F) for 2 h followed by rapid cooling. This maximizes the corrosion resistance and ductility of Stellite 6. Stellite 31 can be age hardened using a 2 day aging treatment at 800 °C (1470 °F).

Joining. Stellite materials can be joined to other materials by brazing or welding. Flame brazing is typically done with silver solder and an oxyacetylene flame. Vacuum furnace brazing uses a nickel-base brazing alloy such as AMS 4777.

Gas tungsten arc and gas metal arc resistance welding are commonly used for Stellite P/M materials. For the fusion processes, a preheat of 810 °C (1490 °F) is required for the harder grades, such as Stellite 3, 19, 98M2, and Star J. The softer grades, such as Stellite 6 and 31, should be preheated to 540 °C (1005 °F). Furnace cooling is required for the harder grades, whereas cooling in still air is satisfactory for the softer grades. Stellite 25 or Nistelle W filler metals are recommended for joining Stellite material to mild steel or stainless steel.

Machining. With the proper machine setup, Stellite alloys can be rough machined. Alloys having hardnesses of <55 HRC can usually be machined, whereas alloys having hardnesses >60 HRC are normally ground. For better surface finishes, any of the Stellite wear-resistant alloys should be ground.

These alloys are usually machined with tungsten carbide tools. Tools for turning should have a 5° end relief, 10° side relief, and a side cutting edge angle of 45°. Tools for facing and boring are essentially the same, except for greater clearance where needed. For best results in drilling, the drill web should be kept as thin as possible, using carbide-tipped drills. In reaming, a

45° side cutting edge angle should be used. The tapping of holes is not recommended for any of the harder alloys, but threads can be produced by electrical discharge machining techniques.

Table 11 is a guide to machining these alloys; it has been written to cover the machining of all the alloys and does not necessarily represent the optimum conditions for each. In general, the harder alloys should be machined, starting at the lower end of the speed and feed ranges shown in Table 11. Softer alloys or more rigid setups will allow higher speeds and feeds.

Table 11 Guide for machining Stellite alloys

Operation	Speed		Roughing				Finishing			
			Feed		Depth of cut		Feed		Depth of cut	
	mm/min	ft/min	mm/rev	mils/rev	mm	mils	mm/rev	mils/rev	mm	mils
Turning^(a)	9-15	30-50	0.203-0.305	8-12	0.127-5.08	5-205	0.152-0.254	6-10	≤0.635	≤25
Facing^(a)	9-15	30-50	0.203-0.305	8-12	0.127-2.54	5-100	0.152-0.254	6-10	≤0.635	≤25
Boring^(a)	6-15	20-50	0.127-0.203 ^(b)	5-8	0.635-2.54 ^(b)	25-100	0.127-0.203	5-8	≤0.635	≤25
Drilling^(c)	3-8	10-26	0.025-0.127 ^(d)	1-5
Reaming^(e)	3-9	10-30	0.025-0.127 ^(f)	1-5	0.762-1.52	30-60	0.025-0.076 ^(f)	1-3	0.254-0.635	10-25

- (a) C-3 tungsten carbide tools should be used. Coolant is water-base fluid diluted 15 parts water to one part fluid. Tools for facing and boring are basically the same as turning tools, except for greater clearances where needed.
- (b) Depends on bar and size of tool.
- (c) C-2 tungsten carbide twist drills should be used, with drill web kept as thin as possible. Coolant is same as in (a).
- (d) Depends on size of drills.
- (e) C-3 tungsten carbide tools should be used. Reamers should have a 45° side cutting edge angle. Coolant is same as in (a).
- (f) Per tooth

Grinding. Whenever close tolerances are required, grinding is recommended for finishing Stellite wear-resistant alloys. Recommended wheels and coolants are listed in Table 12. Grinding speeds should be kept between 14 and 31 m/s (45 and 100 ft/s). Alloys being ground dry should not be quenched because this may cause surface checking. Care should be taken in grinding Stellite 98M2, Star J, and Stellite 3 P/M because they are more sensitive to thermal shock than are the other alloys, and flood cooling is recommended.

Table 12 General recommendations for grinding wheels

Purpose	Recommended wheels	Coolant
Peripheral wheels, Stellite alloy deposits	A60JV	Emulsifying oil
Form grinding (finer grits recommended for sharper forms)	A100GV, A120KV, A150GV	Emulsifying oil
Ring wheels		
Mixed Stellite alloy and steel	A46DZB	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Stellite alloy only	A50BB	...
Segmental wheels		
Mixed Stellite alloy and steel	A46DZB	0.45 kg (1 lb) sal soda to 190 L (50 gal) water
Stellite alloy only	A50BB	...
Tool and cutter grinding		
Cup wheels for peripheral wheels (see above)	A46JV	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Internal grinding bores greater than ~100 mm	A54JV, A54MV	3.8 L (1 gal) good grade of water-soluble oil plus 190 L

(4 in.) diam		(50 gal) water
Centerless grinding less than ~ 115 mm (4.6 in.) diam	A60L-V	3.8 L (1 gal) good grade of water-soluble oil plus 190 L (50 gal) water
Off-hand grinding	A46MV	Dry
Cutting off Stellite alloy	A46QB	1 part water-soluble oil to 60 parts water
Surface grinding, general Stellite alloy grinding		
For wheels ≤ 305 mm (12 in.)	A60JV	1 part water-soluble oil to 60 parts water
For wheels > 305 mm (12 in.)	A46JV	...

Note: Wheels carrying the same marking from different manufacturers do not necessarily have the same cutting action. Wheel descriptions based on ANSI B74.13-1970 and BS 4481

Corrosion-Resistant Powder Metallurgy Alloys

Barbara Shaw, Penn State University

Introduction

POWDER METALLURGY COMPONENTS produced from corrosion-resistant alloys constitute a relatively small, but rapidly growing, segment of the P/M market. Applications for corrosion-resistant P/M alloys, especially stainless steel alloys, span a variety of industries including aerospace, automotive, chemical processing, medical, and recreational. Stainless steels, nickel-base superalloys, and titanium and titanium-base alloys are the primary corrosion-resistant P/M alloys in use today. Among these, P/M stainless steels currently find the widest range of applications.

The corrosion resistance of stainless steels (SS), nickel-base superalloys, and titanium and titanium-base alloys can be attributed to the natural, protective oxide layer (passive film) that forms on the surfaces of these metals. This protective oxide film is subject to localized breakdown, yielding pitting, crevice corrosion, and/or intergranular corrosion of the underlying substrate. Sintered stainless steels, nickel-base superalloys, and titanium and titanium-base alloys also derive their corrosion resistance from protective surface oxide films. However, in the case of the sintered metals, inherent pores/crevices are part of the material. Depending on their dimensions, these pores can act as initiation sites for breakdown of the protective oxide leading to the establishment of crevice corrosion.

Pitting resistance, especially in wrought stainless alloys, is often increased by the addition of passivity-enhancing elements to the base alloy. For wrought stainless steels, passivity is typically enhanced through the addition of molybdenum, nickel, or more chromium. These same alloying additions also enhance the pitting resistance of P/M stainless steels. While passivity-enhancing alloying additions also increase crevice-corrosion resistance, they are often not completely effective, and significant alteration of crevice dimensions (increasing its width and/or decreasing its depth), or total elimination of the crevice, is needed to deter crevice corrosion. Another form of localized attack that corrosion-resistant alloys are susceptible to is intergranular corrosion. This form of degradation is commonly encountered in wrought stainless steels and is the result of microstructural differences in composition in the grain-boundary region of the alloy. These unwanted compositional differences result in what is called a sensitized microstructure, and they are usually the result of improper heat treating or welding of the alloy. Powder metallurgy alloys can acquire sensitized microstructures during welding or, for unwelded components, as a result of the sintering/cooling cycle used to produce the alloy.

Susceptibility to pitting, crevice corrosion, and intergranular corrosion is typically evaluated by exposure testing or through the use of one or more electrochemical test methods. Exposure tests provide information on the number of pit or crevice sites present on the specimen surface and the maximum pit or crevice depth or weight loss resulting from attack of sensitized

regions of a microstructure. Electrochemical test methods indicate how the passive characteristics of one alloy compare to those of another and provide insight into the mechanisms responsible for corrosion. Parameters that are frequently used to assess passive behavior include the pitting potential, the protection potential, and the passive current density.

Much of the corrosion literature for P/M alloys, including corrosion-resistant alloys, consists of simple immersion and salt-spray cabinet test results. Data from these tests can provide useful information for some simple systems and will be included in this article; however, the results of these tests are often not discriminating enough to separate similar types of alloys, and they do not provide information concerning the nature or mechanisms of corrosion in P/M alloys. In fact, the mechanism of degradation in an artificial environment, such as the salt-fog chamber, is often quite different than the operative mechanism in a natural environment. This difference in mechanism could lead to design decisions based on totally inappropriate data. Electrochemical test methods provide another means for evaluating corrosion resistance, and they can also be used to elucidate important mechanistic information. The corrosion of P/M alloys is often interpreted in simplistic terms; however, in reality the corrosion of sintered stainless steels, nickel-base superalloys, and titanium and titanium-base alloys is more likely the result of somewhat complicated electrochemical interactions. An understanding of these interactions and the mechanisms of corrosion is essential to the continued development of corrosion-resistant P/M alloys and exploitation of their inherent processing advantages. This understanding can only come from carefully planned and executed experiments.

In the following sections, the corrosion characteristics of P/M stainless steels, nickel-base superalloys, and titanium and titanium-base alloys are presented and discussed. Whenever possible, the corrosion data for P/M alloys are compared to that of their wrought counterparts, and a wide array of test results is presented. Sections of this article have been derived from Erhard Klar's article "Corrosion of Powder Metallurgy Materials," which appears in *Corrosion*, Volume 13 of the *ASM Handbook*. Readers are strongly encouraged to read his article for further information on the corrosion of P/M stainless steel alloys and superalloys.

Acknowledgements

As noted earlier, much of the data of Dr. Erhard Klar were used in this review and the author would like to acknowledge him and thank him for this contribution. The author would also like to thank Mr. Michael Baran, currently at Gamry Instruments, for the contribution of his work on ferritic stainless steels.

Corrosion-Resistant Powder Metallurgy Alloys

Barbara Shaw, Penn State University

Evaluating the Corrosion Resistance of P/M Alloys

A wide array of experimental techniques is currently being used to assess the corrosion resistance of P/M alloys. These tests range from simple laboratory exposure studies in open containers to more sophisticated electrochemical approaches aimed at gaining insight into the underlying mechanism(s) of P/M alloy corrosion. This section introduces several of the more commonly employed tests and provides specific examples of the use of these methods in evaluating the corrosion resistance of P/M stainless steels. More detailed information on corrosion testing, in general, is available in *Corrosion*, Volume 13 of the *ASM Handbook* and in Volume 3.02 of the ASTM standards.

Results from Exposure Testing

Exposure tests are commonly employed for ranking the performance of a group of related alloys and assessing quality control. Ideally, these tests should be conducted in actual service environments. Unfortunately, very few references in the literature cite service or environmental exposure test results for P/M materials; instead, much of the P/M literature cites results from immersion and salt-spray cabinet testing.

Immersion Test Results. Most immersion test results found in the P/M literature are for exposures in either acid or chloride environments. The concentration of the aggressive species (i.e., chloride or hydrogen ions) in these immersion tests

is typically greater than that expected during actual service. The increased concentration of the aggressive species serves to accelerate the test; however, the degree of acceleration is unknown and no real consensus exists on the best concentration to use. Several investigators have used a 5% NaCl solution for the chloride exposures. Immersion test results have been reported in a number of acid solutions including 1% HCl, 30% H₂SO₄, 10% HNO₃, 20% HNO₃, at both ambient and elevated temperatures. Unfortunately, no single acid electrolyte is used consistently.

Erroneous results can occur with some specimen preparation practices that are used on wrought specimens. Surface polishing prior to testing, for example, can produce erroneous results because polishing tends to distort or close off surface pores that might normally be present on the surface of the actual component. Cleaning and degreasing porous P/M materials prior to testing is another practice that needs to be considered carefully prior to testing. Degreasing, a practice that is routinely used for wrought specimens, can trap liquids in the pores of P/M specimens and care must be taken to remove this liquid prior to the initiation of a test. As with all corrosion exposure tests, it is advisable to test specimens under their anticipated service conditions.

Evaluation of P/M specimens after exposure testing is also a subject of some controversy; however, several studies have followed a visual rating system proposed by Klar (see "Corrosion of Powder Metallurgy Materials," in *Corrosion*, Volume 13 of the *ASM Handbook*). This rating system involves visually assessing the amount of surface staining or corrosion on a test coupon and categorizing its degradation in one of four ways: A, no attack of the surface, categorized as 0% attack; B, attack of 1% or less of the surface; C, attack of 1 to 25% of the surface, and D, attack of more than 25% of the surface. A photographic chart showing a series of stainless steel specimens after exposure to a 5% solution and characterization using the A through D rating system (Ref 1) is shown in Fig. 1. Another way of using the data acquired from such an inspection is illustrated in Fig. 2, which shows a plot of the percentage of replicate specimens holding a particular rating versus the log of the time of exposure (Ref 1). This plot reveals that the mean life of a 316L P/M specimen immersed in 5% NaCl solution, accepting no surface rust or staining, is approximately 80 h (the intersection of the 50% line with the 1% surface rust/stain curve). If 1% surface rust/stain is acceptable, then the mean life is extended to longer than 300 h. If 1 to 25% surface rust/stain is acceptable, the mean life is extended to more than 1000 h. Corrosion-resistance data for a few different stainless steels, in terms of the hours needed to attain up to 1% surface rust or stain ("B" rating on Klar's scale), is presented in Table 1 (Ref 2). Not surprisingly, the more highly alloyed stainless steels exhibited the best performance. Because strict adherence with the first category in Klar's rating scheme (no rust or rust stain) is difficult to achieve for P/M specimens, this category is often broadened to allow for the first spot of rust or stain on the specimen surface. Some researchers find it more convenient to use 0.1% rust or rust stain for this first category instead of no attack (Ref 3, 4, 5).

Measurement of weight loss following exposure or immersion in a corrosive media is a standard method used for assessing corrosion resistance. While weight-loss measurements are relatively straightforward and easy to apply to wrought metals, they can be more difficult to apply to P/M materials because of their inherent porosity. Porosity traps the test solution and the corrosion products within the pores, making it difficult to accurately record small weight losses, even when elaborate cleaning and drying procedures are employed. Most researchers have been successful in obtaining meaningful weight-loss values for porous P/M alloys after immersion testing in acid solutions, but weight losses in less aggressive solutions (such as 0.1 M NaCl or 5% NaCl) are not available. Figure 3 (Ref 6) shows weight loss data for P/M 316L stainless steel as a function of sintering atmosphere, after immersion in a 10% HNO₃ solution for 24 h. Following testing, the specimens in this study were rinsed three times in distilled water and dried in a box oven at a temperature less than 100 °C. The drying was continued until the point where no further water evaporation was detected in the weight-loss measurements. A more elaborate cleaning and drying procedure, employed after similar testing, is described in Ref 7 and is outlined in Table 2. Researchers occasionally report weight gains following corrosion testing; however, the utility of such values in assessing corrosion resistance is unknown and is, perhaps, not of much value.

Table 2 Procedure used to clean P/M specimens after acid exposure testing

Step No.	Procedure
1	Heat P/M samples to 70 °C.
2	Submit samples to a vacuum of (-100 kPa) to evaporate solution in the pores.
3	Repeat steps 1 and 2 two times.
4	Fill pores of the P/M samples with distilled water to wash out the pores.
5	Repeat steps 1 and 2 three times.
6	Impregnate samples with ethyl alcohol to absorb water.
7	Repeat steps 1 and 2 once.
8	Store in a dessicator.

Weight-loss data are commonly used to determine the corrosion rate of a material. The conversion of weight-loss data into corrosion penetration rates is accomplished via the relationship given by (provided that the density of the material, the exposed surface area, and the time of exposure are known):

$$\text{mm/yr} = 87.6 W/DAT \quad (\text{Eq 1})$$

where D is the density in g/cm^3 , W is the weight loss in mg , A is the surface area in cm^2 , and T is the time in hours.

Corrosion-penetration rates of less than 0.02 mm/yr are considered outstanding, while those of 0.1 to 0.5 mm/yr, 0.5 to 1 mm/yr, and 1-5 mm/yr are considered good, fair, and poor, respectively (Ref 8). Weight-loss data are sometimes reported in the units of $\text{mg/dm}^2\text{day}$ (mdd) or $\text{g/dm}^2\text{day}$ (gdd). Conversion between these two corrosion rate measures is accomplished via the following equations:

$$\begin{aligned} \text{mm/yr} &= 56.6 \text{ mdd/specific gravity} \\ \text{or } 0.0566 \text{ gdd/specific gravity} \end{aligned} \quad (\text{Eq 2})$$

An example of corrosion rate data for 304L and 316L wrought and P/M sintered stainless steel after immersion in 0.5 M H₂SO₄, as a function of immersion time and sintering conditions, is presented in Table 3 (Ref 9). The wrought alloys clearly exhibited the lowest corrosion rates, followed by the vacuum-sintered alloys.

Table 3 Properties and corrosion rates of sintered stainless steels AISI 304L and AISI 316L

Corrosion rates are given in g/dm² day after exposure to 0.5 M H₂SO₄ at a temperature of 25 °C. Wrought specimens are denoted with a W and sintered specimens are marked A, B, and C.

(a) (g/dm² × day) in 0.5 M H₂SO₄, T = 25 °C, of compact (W) and sintered samples.

Elevated temperature or boiling acid solutions are often used to assess susceptibility of wrought stainless steels to intergranular corrosion, and procedures for this type of testing are covered in ASTM methods A 262 and A 763. Because the solutions called for in these ASTM methods are quite aggressive to porous P/M specimens, a variety of modifications have been employed by investigators to reduce the aggressiveness of the specified solutions. These modifications include reducing the time of the test, reducing the concentration of the acid, and/or reducing the temperature of the solution. Unfortunately, no consensus on the appropriate approach for intergranular corrosion testing of P/M alloys has been reached. Weight-loss values for both P/M and wrought 434L and 409 stainless steels after testing according to ASTM method A 763 practice Z are presented in Table 4 (Ref 10). Practice Z of ASTM method A 763 calls for exposure of the test specimens in a boiling solution of 6 wt% CuSO₄ + 16 wt% H₂SO₄ for a period of 24 h. In this test, the specimens are embedded in copper shot that is poured into the bottom of the test flask. The standard practice Z calls for 180° bending of the tested specimen, because weight loss for wrought specimens is often not large enough to determine corrosion rates. In the case of P/M parts, however, weight loss was found to be effective in measuring corrosion rates and, while 180° bending of the P/M specimens was possible prior to testing, bend testing resulted in fracture after only a few degrees of bending. Examination of the specimens after intergranular corrosion testing, via ASTM A 763 practice Z, revealed uniform corrosion of the P/M alloys in addition to the anticipated grain-boundary attack, as Fig. 4(a) and 4(b) reveal for a P/M 434 alloy. After modifying this test method by reducing the concentration of sulfuric acid, as suggested in Ref 10, weight losses were reduced to the values reported in Table 5. Examination of the specimens after testing revealed that corrosion was predominantly along the grain boundaries, as the scanning electron micrograph in Fig. 5(a) and 5(b) reveal.

Table 4 Average intergranular corrosion rates via ASTM A 763 practice Z

Another means of quantifying the degree of corrosion of a metal is to measure the amount of corroded material that is in solution following immersion for a given period of time. A colorimetric method for evaluating the corrosion of P/M stainless steels, which utilizes a commercially available test kit, has been described in Ref 11. In this method, the iron concentration in solution is measured as a function of time using a commercial test kit containing self-filling ampoules, activator solutions, and a photometer. First, a sample of the test solution is placed in a sample cup and an activator, a solution containing a mixture of thioglycolic acid and ammonia, is added to the solution. The activator dissolves most forms of particulate iron and reduces ferrous (Fe^{3+}) ions within the solution to ferric (Fe^{2+}) ions. The partially evacuated ampoule containing an acidic, buffered solution of 1,10-phenanthroline is inserted into the test solution, and its tip is snapped allowing both solutions to mix and fill the ampoule. After mixing, the ampoule is then inserted into a calibrated photometer and the transmission of light is measured by percentage. Iron content in parts per million (ppm), within the range of 0.01 to 7.6 ppm is then calculated based on a conversion chart provided with the test kit. Examples of the average total iron concentration measured as a function of exposure time for a variety of sintered stainless alloys exposed to a 5 wt% NaCl solution are presented in Table 6 (Ref 11). In each case, specimens of identical dimensions were exposed to 400 mL of a 5 wt% NaCl solution in closed containers, and the values reported were the average of five readings. A nearly linear iron dissolution rate was observed for most of the alloys during the eight-day test, as Fig. 6 illustrates (Ref 11). Good correlation was noted between the results of the colorimetric test and salt-spray and 5% NaCl immersion tests (Ref 12), as Fig. 7 and 8 reveal.

Immersion testing can also be used in conjunction with other experimental methods, such as mechanical tests, to assess corrosion resistance. Table 7 illustrates the results from such a test conducted on sintered 316L stainless steel specimens (Ref 13). Prior to mechanical testing via a three-point loading transverse rupture test, the specimens in this study were immersed in a 5% NaCl solution at 20 °C. Three sintering atmospheres were evaluated, and some of the specimens were passivated in acid

solutions prior to chloride exposure. Under the sintering conditions used (laboratory alumina tube furnaces, no purification of the gaseous atmospheres, and dew points in the range of -40 to -60 °C upon entering the furnace), only the vacuum sintered specimens showed resistance to corrosion. These data also reveal that the two passivating treatments were detrimental to corrosion resistance. Strengths of specimens sintered in vacuum and in hydrogen were similar. A similar investigation using a 20% NaCl solution, in lieu of the 5% solution, found that the corrosion resistance of 316L stainless steel was the same (Ref 13).

Table 7 Corrosion tests on 316L sintered stainless steel specimens exposed to 5% NaCl solution at 20°C

Specimens were sintered in various atmospheres at 1150 °C for 1 h. Passivation 1 was carried out for 30 min at 80 °C in a 16 vol% HNO₃ nitric acid solution. Passivation 2 was carried out for 60 min at 70 °C in a 40 vol% HNO₃ solution.

(a) Specimen did not break.

Ferric Chloride and Ferroxyl Exposures. The ferric chloride test method, ASTM G 48, for characterizing the resistance of wrought stainless steels and related alloys to pitting and crevice corrosion is sometimes used for evaluating P/M materials. While this method may be useful in assessing the susceptibility of wrought materials to crevice corrosion, its use for evaluating crevice-corrosion susceptibility in sintered stainless steel alloys is questionable because these materials already contain inherent crevices. Applying a crevice former to a specimen that already contains a crevice may facilitate the initiation of crevice corrosion. Because crevice width and length are critical factors in establishing crevice corrosion, the application of one crevice on top of another seriously alters the intent and validity of the original test. However, if the ferric chloride solution is simply being used as an aggressive oxidizing solution and no crevice formers are used, such as the test described in method A, then the data for P/M specimens may be of value.

It should be noted that some researchers have found the exposures in the 6% FeCl₃ solution suggested in ASTM G 48 to be too aggressive for the characterization of sintered stainless steels. An alternative solution that has been used for exposure studies is a hexacyanoferrate solution (ferroxyl) that may or may not contain added chloride (Ref 14). A benefit of this solution, in addition to being an oxidizing agent, is that it can be used as an indicator of contamination by iron because the solution turns blue in the presence of ferrous ions. A typical test involves exposure to the hexacyanoferrate solution for 24 h and a visual inspection of the specimens using the following rating scale (Ref 14):

Category	Amount of attack	Visual inspection results
0	No attack	No blue spots
1	Light attack	Very weak blue spots without growth
2	Moderate attack	Blue spots with slow growth-- no needle growth or large accumulation of blue dye
3	Severe attack	Blue spots with growth--needle growth or accumulation of the corrosion product on the surface

An example of the results obtained on sintered 316L stainless steel (produced under different sintering conditions) and a few wrought stainless steels (which were tested with an artificial crevice formed by an O-ring) are provided in Table 8 (Ref 14).

Table 8 FerroxyI test results for P/M and wrought stainless steels

Salt Spray Cabinet Test Results. Despite the controversy that exists concerning the applicability of salt-spray cabinet exposure results compared to natural environments, the test remains a standard in many communities. In relation to other types of corrosion data for P/M materials, a substantial amount of salt-spray cabinet data exists. In fact, when conducted according to ASTM method B 117, the test is probably the most commonly used experiment for assessing corrosion in P/M metals and alloys. Examples of the times needed to notice 0.1% surface rust for a variety of stainless steels after salt-spray cabinet testing are presented in Table 9 (Ref 3). An inspection at 100 h revealed no attack of wrought 316L specimens. Similar data, obtained using the Klar rating system, for sintered 304L, regular 316L, special 316L alloys, and SS 100 alloys after ASTM B 117 testing for times in excess of 1000 h are presented in Fig. 9 (Ref 11).

Electrochemical Testing

As stated earlier, electrochemical methods of corrosion testing yield information concerning corrosion mechanisms as well as information on corrosion rates. Because of their inherent porosity, some special issues arise in the electrochemical testing of sintered P/M materials. These issues include alteration of surface porosity resulting from polishing, insufficient removal of degreasing solvents from pores prior to testing, unknown or unreported surface areas, and increased time needed to establish steady-state conditions. Irrespective of the particular electrochemical test being conducted, care should be exercised in addressing each of the aforementioned issues.

Open Circuit Potential versus Time. Prior to initiating an electrochemical test it is customary to monitor the open circuit or corrosion potential for a period of time. Monitoring of the potential should be conducted for a long enough period of time to ensure that steady-state conditions exist between the metal and its environment. The length of time needed to establish a steady-state open circuit potential can vary from a few minutes to several weeks, depending on the particular metal/environment combination. Important information concerning the nature of corrosion can sometimes be determined from open-circuit potential versus time behavior. Comparison of open circuit potential versus time behavior for wrought and P/M alloys of the same nominal composition typically reveals lower potentials for the P/M alloys--indicating a more active electrochemical state, as Fig. 10 reveals for porous 316L sintered stainless steel (Ref 15, 16). Open-circuit potential behavior can also provide an indication of the role that alloying additions play in altering corrosion resistance. The data in Fig. 11 show that the addition of either nickel, platinum, or palladium to sintered stainless steel increases the open-circuit potentials of the alloy, suggesting that these alloying additions enhance passivity, at least temporarily (Ref 17). In some cases, the initial open-circuit potential versus time behavior for P/M materials reveals significant instabilities, supposedly resulting from the infiltration of solution into the porous alloy, as shown in Fig. 12 (Ref 18). Instabilities such as these, despite their origin, are the reason that the open-circuit potentials are monitored prior to initiating electrochemical experiments that rely on steady-state behavior, such as polarization tests.

Polarization experiments are the most commonly used electrochemical methods for assessing corrosion behavior. Of specific interest in the study of corrosion-resistant P/M materials are the following polarization techniques: anodic polarization, cyclic polarization, polarization resistance, and electrochemical potentiokinetic reactivation. Prior to a discussion of electrochemical corrosion testing of P/M materials, it is necessary to briefly review some basic information concerning polarization curves and to define a few terms related to polarization behavior and passivity. The reader is encouraged to consult Ref 19 for more detailed information.

Figure 13 shows anodic polarization behavior for an active/passive metal (Ref 20). With regard to corrosion-resistant P/M alloys, anodic polarization curves provide useful information concerning the potential range over which a material is passive, the amount of protection afforded by the film, the susceptibility to pitting, and the ease with which passivity is obtained. Starting at the open-circuit potential and moving in the anodic direction, many metals undergo an initial period of active dissolution, prior to passive film formation, as the potential is scanned in the positive direction. The current density just prior to the onset of passive film formation is termed the "critical current density" and is often denoted by i_{crit} . The potential marking the onset of passivity is termed the primary passivation potential and it is denoted by E_{pp} . Passivity is observed in the region of the anodic polarization curve where the current density drops significantly. It is desirable for passivity to extend over a broad potential range and for the current density in this range, termed the passive current density (i_p), to be very low (typically, a few $\mu\text{A}/\text{cm}^2$ or less). If aggressive species, such as chloride ions, are not present, then the end of the passive region of the curve is determined by the onset of transpassive dissolution of the film or the initiation of another anodic reaction, such as oxygen evolution, on the specimen surface. The passive film is subject to pitting corrosion when chloride or another aggressive species is present. The onset of pitting is marked by a sudden increase in the current density--the potential where this increase occurs is called the pitting potential, E_p , or the breakdown potential, E_b . The higher the pitting potential, the less susceptible the material is to pitting. It should be noted that the pitting potential as measured in a potentiodynamic polarization experiment is a function of scan rate. As a result, care must be exercised in picking a scan rate to ensure that a slow enough scan rate is being used to maintain steady-state conditions at the metal electrolyte interface and to allow for the induction time needed for the onset of pitting. In a polarization curve, such as the one shown in Fig. 13, the potential provides the driving force for a reaction to occur and the current density (the current/surface area of the specimen) is a measure of the corrosion rate (Ref 20). For some metal/solution combinations, the protective passive film is present on the metal surface initially and polarization is not required for its formation. The term "self-passivating" is used to describe such metals, and their polarization behavior is illustrated in Fig. 14 (Ref 20).

Fig. 14 Anodic polarization curves for stainless steel in a neutral chloride solution showing self-passivating behavior (top curve, solid line) and active dissolution in a strong hydrochloric acid solution (bottom curve). Source: Ref 20

Anodic polarization curves for wrought and P/M 434L stainless steel in 0.1 M NaCl are presented in Fig. 15 (Ref 18). In this particular example, the current density was based on the apparent surface area of the specimen rather than the actual wetted surface area of the specimen. Measurement of the actual wetted surface area would be needed for precise determination of current-related polarization characteristics, such as the passive current density and critical current density. In addition, the actual wetted surface area is needed for an accurate determination of the corrosion rate. Unfortunately, much of the P/M electrochemical corrosion literature fails to measure and/or report actual surface areas. As a result, care must be taken when basing judgments on variations in current density (i_p , i_{crit} , or i_{corr}) of an order of magnitude or less, unless the actual surface area of the specimen was measured. Anodic polarization characteristics (i_p , i_{crit} , E_p , E_{corr}) are often summarized in tabular form, as shown in Table 10 for wrought and sintered 316L stainless steel (Ref 1).

Table 10 Data obtained from anodic polarization testing of sintered AISI 316L, raw 316L powder, and wrought 316 as a function of sintering conditions

Electrochemical properties were measured in 0.1% Cl⁻, pH 5, 30 °C, with a scan rate of 5 mV/min.

Because E_p is subject to scan rate effects and is a stochastic parameter, other more conservative parameters are often used to characterize the safe upper potential bounds for use of a passive metal. The most frequently used parameter in this category is the protection potential. A cyclic polarization experiment in which the potential scan direction is reversed after reaching a predetermined critical current or potential is used to determine the protection potential, as shown in Fig. 16 (Ref 21). Pourbaix originally defined the protection potential as the potential at which the current on the reverse scan returns to a low value. This low value is traditionally reported as the potential at which the reverse scan intersects the forward scan. Cyclic polarization experiments are frequently conducted on P/M materials, and an example of the difference in protection potential observed between wrought and porous 316L stainless steel is shown in Fig. 17 (Ref 15).

Fig. 17 Anodic potentiodynamic polarization curves for 316L stainless steel. A, P/M specimen; B, wrought specimen. Source: Ref 15

A few types of electrochemical measurements can be used to determine corrosion rates, as discussed in Ref 19. One of these methods, polarization resistance, involves polarizing the specimens a few millivolts above and below the open-circuit potential and measuring the current response. The data are plotted using linear scales and the slope of the potential versus

current density data at the open-circuit potential ($\Delta E/\Delta i$) is taken as illustrated in Fig. 18. This slope is called the polarization resistance, R_p , and it is inversely proportional to the corrosion current density:

$$i_{\text{corr}} = (1/2.3R_p)[(b_a + b_c)/(b_a + b_c)] \quad (\text{Eq 3})$$

where b_a is the anodic Tafel slope and b_c is the cathodic Tafel slope. This can be used for the corrosion rate:

$$\text{Corrosion rate} = (3.26 \times 10^{-3})(i_{\text{corr}})(EW)/d \quad (\text{Eq 4})$$

where EW is the equivalent weight of the metal or alloy in grams, d is the density of the metal or alloy in g/cm, and i_{corr} is the corrosion current density in mA/cm². A comparison of polarization resistance values for P/M and wrought 316 and 304 stainless steels is shown in Fig. 19 (Ref 9).

Fig. 18 Sample polarization resistance data showing determination of i_{corr} from R_p . The slope at E_{oc} is called the polarization resistance, R_p . The Tafel slopes, b_a and b_c , must be obtained from anodic and cathodic polarization experiments or estimated.

Fig. 19 Polarization resistance, R_p , values for wrought (W) and sintered (A, B, C). A, B, and C correspond to the same sintering conditions as shown in Table 3. Type 304L and 316L samples in 0.5 M H₂SO₄ solution at $T = 25$ °C.

A, B, and C correspond to the same sintering conditions as shown in Table 3 (Ref 9).

Sensitization in stainless steels can be evaluated by two electrochemical potentiokinetic reactivation methods (EPR): the single-loop method and the double-loop method. A more detailed description of intergranular corrosion testing is offered in Ref 22. The single-loop EPR method is a rather time-consuming test because, in addition to the electrochemical experiment, the grain-boundary area of the specimen must be determined. The double-loop EPR method was developed as a more rapid and reliable means of assessing susceptibility to intergranular corrosion. In the double-loop method, the potential is scanned (at a rate of 6 V/h) in the anodic direction from the open-circuit potential to +300 mV versus a saturated calomel electrode (mV SCE). At +300 mV, the direction of the scan is reversed and the potential is decreased (at the same scan rate) until the corrosion potential is reached. Susceptibility to sensitization is determined from the ratio of the maximum current on the reverse scan (I_r) to that measured on the forward scan (I_a), as illustrated in Fig. 20. The I_r / I_a ratios have been correlated with the step, dual, and ditch structures observed during oxalic acid etch screening of wrought stainless steels to identify sensitization. These three structures are presented in Fig. 21. Step structures (Fig. 21a) are free of grain-boundary attack resulting from sensitization. If the grain boundaries contain enough carbides to encircle the grain completely, then grains are undermined upon exposure to the etch and a ditch structure is observed (Fig. 21b). If the ditches do not completely encircle the grains (Fig. 21c), then a dual classification is used to describe the structure. Current ratios in the double-loop EPR test in the range of 0.0001 to 0.001 correspond to step structures, ratios of 0.001 to 0.05 correspond to dual structures, and ratios of 0.05 to 0.3 correspond to ditch structures. Double-loop EPR curves for P/M 316L stainless steels with and without sensitized microstructures are shown in Fig. 22 (Ref 14). In this example, the sensitized microstructures in curves in Fig. 22(b) and 22(c) resulted from high nitrogen contents and liquid phase sintering using a boron addition, topics that are discussed in more detail in subsequent sections of this article.

Corrosion-Resistant Powder Metallurgy Alloys

Barbara Shaw, Penn State University

P/M Stainless Steels

It was stated earlier that the corrosion resistance of the metals and alloys that are considered in this article is a result of the protective passive film that forms on their surfaces. This is certainly true for stainless steels, whose passive characteristics result from the alloying of iron with chromium. For wrought alloys, the influence of chromium concentration on the passivity of iron in a 2 N H₂SO₄ solution at 90 °C is shown in Fig. 23 (Ref 20). As the chromium content is increased, the primary passivation potential, E_{pp} , the critical current density, i_{crit} , and the passive current density, i_p , are reduced--extending the potential region over which the alloy is passive, reducing dissolution of the alloy, and enabling the alloy to become self-passivating, respectively. When chloride is present, chromium increases the pitting potential, as revealed in Fig. 24 (Ref 20).

Fig. 23 Effect of chromium content of FeNiCr alloys on their anodic polarization behavior in 2 *N* H₂SO₄ at 90 °C. The nickel content was in the range of 8.3 to 9.8%. Source: Ref 20

Fig. 24 Effect of chromium content in pitting potential of FeCr alloys in deaerated 0.1 *N* NaCl at 25 °C. Source: Ref 20

Figure 23 clearly shows that a significant improvement in passivity occurs as the chromium content approaches 12%. While there is some debate over the minimum chromium content needed to call an iron-base alloy a stainless steel, most consider that at least 12% is needed to enhance passivity and, thus, corrosion resistance significantly. Passivity results from the presence of a stable, protective oxide barrier on the alloy surface. For stainless steels, this protective barrier is largely composed of chromium oxide and significantly limits dissolution of the underlying metal. Corrosion resistance in stainless

steels is compromised when the chromium concentration of the alloy, or any part of its microstructure, falls below a threshold concentration of 10 to 12%.

The primary difference in the corrosion resistance of wrought and P/M stainless steels is due to the inherent porosity of the P/M materials. Of special concern with regard to the corrosion resistance of sintered stainless steels is their susceptibility to localized breakdown of the passive film in the form of crevice corrosion, pitting, intergranular corrosion, and stress-corrosion cracking. Development of corrosion-resistant sintered stainless steels depends on increasing one's understanding of how passivity is attained and sustained in porous metals.

Despite the fact that P/M stainless steel production accounted for only 2% of the overall U.S. stainless steel market in 1993, research on the corrosion resistance of these alloys has been increasing, and it is obvious that an enormous opportunity exists for their future development and utilization. To date, the compositions of commercial P/M stainless steels have been largely based on those of their wrought counterparts. A listing of the currently produced commercial, water-atomized P/M stainless steel alloys is presented in Table 11 (Ref 23). As stated earlier, applications for these P/M alloys are wide ranging with austenitic grades accounting for approximately two-thirds of the total usage. Table 12 summarizes a number of the current applications for the P/M stainless alloys identified in Table 11 (Ref 23). It should be noted that automotive applications, especially exhaust systems, are responsible for much of the recent, increased interest in and demand for corrosion-resistant P/M stainless steel alloys.

Early P/M stainless steel developmental efforts were aimed at improving powder atomization and compacting properties, while interest in enhanced corrosion resistance has been more recent. In fact, the understanding of the corrosion of P/M stainless steels and the concomitant development of corrosion-resistant P/M alloys (specifically, P/M alloys that have been especially developed for their corrosion resistance) is still rudimentary. Several factors are responsible for the differences between the corrosion resistance of P/M stainless steels and their wrought counterparts. Next to the properties of the powder itself (which needs to have carbon, oxygen, and nitrogen levels less than or equal to values 0.02%, 0.2%, and 0.03%, respectively), the chief factor governing the production of corrosion-resistant P/M alloys is the sintering process. Several sintering variables are of significant importance in the production of corrosion-resistant P/M alloys. Inadequate dissipation of lubricant results in the incorporation of unwanted carbides, and low sintering temperatures encourage chromium nitride formation; both conditions can deplete the alloy of the chromium needed to maintain passivity and aid in the establishment of microgalvanic cells in the microstructure. Low sintering temperatures encourage chromium nitride formation and deplete the alloy of the chromium needed to maintain passivity and establish microgalvanic cells within the microstructure. Insufficient cooling rates contribute to chromium carbide and chromium nitride formation. High dew points encourage oxide formation that has been associated with diminished corrosion resistance. Carbon and iron contamination from furnaces leads to carbide formation and iron incorporation in the alloy. Sintering atmospheres can either promote or degrade corrosion resistance; vacuum and hydrogen atmospheres typically yield the best results and dissociated ammonia usually produces the worst results. Unfortunately, a significant portion of the literature on the corrosion of P/M alloys, stainless steels included, lacks specific details concerning processing conditions, making performance comparisons among different alloy groups difficult or impossible.

Austenitic stainless steels owe their corrosion resistance to chromium, nickel, and other passivity enhancing alloying additions such as molybdenum. As stated earlier, chromium is the primary element responsible for the corrosion resistance of stainless steels. Nickel stabilizes the austenitic structure and promotes repassivation, especially in reducing environments. Molybdenum stabilizes the passive film, especially in combination with chromium, and improves pitting and crevice-corrosion resistance. Nitrogen enhances the strength and corrosion resistance of austenitic wrought stainless steels, but is linked to sensitization in stainless steels. These elements, and a few others, influence polarization behavior and enhance passivity in wrought alloys in the manner depicted in Fig. 25 (Ref 20).

Fig. 25 Summary of the effect of alloying elements in stainless steels on the anodic polarization behavior. Source: Ref 20

Intergranular corrosion of 300 series stainless steels has long been associated with sensitization resulting from welding or improper heat treating. If the alloys are held in the temperature range of 550 to 850 °C, carbides can form at the grain boundaries depleting the alloy adjacent to the grain boundary of chromium, as the chromium profile for a sensitized 304 stainless steel shown in Fig. 26 reveals (Ref 24). The region adjacent to the grain boundary with the lower chromium content has a lower corrosion resistance than either the precipitates at the grain boundary or the rest of the grain. These areas of dissimilar chromium concentration can result in the establishment of localized galvanic cells within the microstructure that lead to corrosion of the chromium-depleted regions adjacent to grain boundaries, as Fig. 27 illustrates (Ref 23). In P/M alloys, sensitization can occur during sintering as well as during welding operations. Stainless steel alloys with carbon and nitrogen contents that approach 0.03% have been shown to form chromium precipitates at the grain boundaries (Ref 24). In addition, sintering or cooling (especially from 870 to 425 °C, or 1600 to 800 °F) in an atmosphere that contains nitrogen can lead to the formation of chromium nitrides. When these chromium carbides and chromium nitrides form, they deplete the adjacent microstructure of chromium. Hence, a galvanic interaction ensues between the more corrosion-resistant, high-chromium concentration regions of the microstructure and the less-corrosion-resistant, chromium-depleted regions.

Fig. 26 Chromium concentration profile across a grain boundary between $M_{23}C_6$ carbides in type 304 (0.039% C) stainless steel heat treated for 10 h at 700 °C (Ref 24)

As revealed in Table 12 (Ref 23), the 300-series alloys account for the largest percentage of applications for stainless P/M alloys. Among wrought stainless steels, 304L is the most commonly used alloy because of its excellent corrosion resistance and lower cost compared to other austenitic stainless steels. To date, 316L is the most commonly used P/M stainless steel because of its improved corrosion resistance in comparison to sintered 304L stainless steel. Low-carbon-grade alloys are essential for P/M stainless components because of sensitization that can accompany the sintering process.

Corrosion data for 300 series P/M stainless steels is largely centered on the susceptibility of these alloys to pitting/crevice corrosion, intergranular corrosion, and processing-induced degradation. This last item is the subject of the next section of this article. It must be stated that while there is an expanding base of literature on the subject of corrosion of sintered stainless, a number of studies fail to mention important details related to either processing or testing of the alloys. Processing details such as dew-point temperatures, sintering and delubing times, and information related to cooling of the alloys are often missing. All of these items are critical to the production of corrosion-resistant stainless steels, and the lack of such information limits the utility of a number of the studies that have been conducted. Testing details that are sometimes neglected include surface area measurements (needed for determining corrosion rates), test specimen preparation and test cleaning procedures, and the

inclusion of wrought counterparts or control materials in test plans. This information is especially important because sintered alloys contain porosity. Corrosion resistances of a variety of austenitic stainless steel P/M alloys are shown in Tables 13 and 14 (Ref 1, 14).

Mechanical properties of 316L stainless steel as a function of some of the more important processing parameters are presented in Fig. 28, 29, and 30 (Ref 23). As these figures reveal, nitrogen-containing atmospheres result in the absorption of considerable amounts of nitrogen, which increases strength, decreases ductility, and, as is seen in the following paragraphs, influences P/M alloy corrosion resistance. Mechanical properties for a few P/M stainless steel alloys sintered in dissociated ammonia are presented in Table 13 (Ref 1).

Ferritic and Martensitic Stainless Steels. The 400 series alloys are typically less heavily alloyed than the austenitic grades and, as a result, they usually exhibit inferior corrosion resistance. In addition to the lower pitting and crevice-corrosion resistance resulting from lower concentrations of passivity enhancing elements, ferritic stainless steels are also more susceptible to sensitization and intergranular corrosion. Ferritic stainless steels exhibit a greater affinity for sensitization than austenitic stainless steels because the solubility limit of carbon in the austenite phase is greater than in the ferrite phase. Hence, the precipitation of carbides is more prevalent in ferritic microstructures (Ref 18).

Corrosion-Resistant Powder Metallurgy Alloys

Barbara Shaw, Penn State University

Influence of Processing Parameters on the Corrosion Resistance of P/M Stainless Steels

Influence of Iron or Steel Contamination on Corrosion Resistance. It should come as no surprise that the corrosion resistance of P/M stainless steels is seriously degraded if iron or steel particles become incorporated into the alloy. The potential difference between iron or steel and stainless steel is typically on the order of several hundred millivolts and easily results in the establishment of galvanic or dissimilar metal corrosion within the contaminated component. There are numerous possible contamination sources: contamination of the initial powder at the supplier; inadvertent introduction during mixing/blending, feeding, or pressing operations; incorporation of airborne particles during processing or storage; and inadequate furnace cleaning. Cleanliness is of the utmost importance and separate or dedicated equipment is often used for the production of stainless components. Figure 31 shows an example of the appearance of iron-contaminated sintered 316L stainless steel after exposure to a 5% NaCl solution. Rusting became apparent within minutes of exposure to the chloride-containing solution.

Fig. 31 Small circles of rust around iron particles embedded in the surface of sintered type 316L stainless steel after testing in 5% aqueous NaCl. 35×

Corrosion resulting from iron or steel contamination is perhaps the worst and, ironically, most avoidable corrosion problem encountered with P/M stainless steels. A concentrated copper sulfate solution can be used to easily detect iron, or an iron alloy, present in a stainless steel powder or on the surface of a sintered part. Dissolved copper from a copper sulfate solution readily plates out on the anodic (lower potential) iron sites, making them easy to see at low magnification.

Influence of Lubricant and Carbon. As Fig. 32 suggests (Ref 24), carbide formation (especially, chromium carbide formation) with concomitant sensitization is an issue when the carbon content of an austenitic stainless steel exceeds 0.03%. In order to resist intergranular corrosion, water-atomized stainless steel powders have carbon contents greater than 0.03%. Unfortunately, other sources of carbon are associated with processing sintered stainless steels. These sources include the carbon resulting from inadequate organic lubricant dissipation and carbon contamination (soot) from insufficiently cleaned furnaces. Microstructures from two sintered 316L stainless steels, one below and one above the critical 0.03% concentration, are shown in Fig. 33. Thin, undecorated grain boundaries are observed in the low-carbon stainless steel, whereas, heavily decorated grain boundaries are observed for the high-carbon stainless steel. In insufficiently cleaned furnaces, loose, adherent soot can fall onto the surface of stainless steel parts or moisture from the sintering atmosphere can react with soot and form carbon monoxide and carburize the stainless steel. If care is not taken to limit the uptake of carbon, sensitization of the microstructure can occur and severely compromise the overall corrosion resistance of the alloy. The influence of carbon content on the pitting potential for a number of different sintered stainless steels is shown in Fig. 34 (Ref 14). Sensitization can be minimized with proper lubricant dissipation, a clean furnace, and low initial carbon concentration in the powder. It should be noted that when optimal sintering conditions are used, differences in corrosion resistance have not been noted as a function of lubricant type, as Table 15 reveals (Ref 25).

Table 15 Effect of binder/lubricant on the corrosion resistance of sintered 316L stainless steel in deaerated 1000 ppm Cl buffered with acetate at 30 °C (pH=5)

The dew point of the gas atmospheres in the furnace was approximately -30 °C.

Carbon contents in excess of 0.03% can be of benefit when stainless steels are vacuum sintered. In vacuum sintering, the excessive carbon is used for the reduction of some oxides on the water-atomized stainless steel, improving strength, ductility, and corrosion resistance. Microstructures of vacuum-sintered 430L stainless steel with and without the addition of 0.2% graphite are shown in Fig. 35. The graphite-containing stainless steel exhibited clean grain boundaries, while the alloy without graphite had grain boundaries containing carbides.

grain boundaries (no graphite added)

Influence of Nitrogen and Sintering Atmosphere. Dissociated ammonia is a commonly used sintering atmosphere because it costs less than other sintering atmospheres. However, sintering in dissociated ammonia usually leads to the pickup of nitrogen by the stainless steel--a factor that can enhance susceptibility to corrosion in a manner analogous to that observed with chromium carbide formation. For wrought stainless steels, enhanced passivity is observed with increased nitrogen content. However, if chromium nitrides precipitate, the sensitized stainless steel is susceptible to intergranular corrosion. Equilibrium solubilities for nitrogen in austenitic stainless steels with different chromium contents are presented in Fig. 36 (Ref 23). The concentration of dissolved nitrogen depends on the amount of nitrogen in the atmosphere, the sintering temperature, and the cooling rate of the sintered alloy. An example of the influence of nitrogen concentration in the sintering atmosphere on the corrosion resistance of 316L stainless steel is shown in Table 16 (Ref 14). These results reveal that up to the point where supersaturation associated with sensitization occurs, no significant difference in corrosion behavior was noted. In addition, these results show that the EPR test is very sensitive to the identification of nitride formation. Reference 26 reported that chromium nitrides were not present in 316L when its nitrogen content was lower than 0.4 wt%. This point is supported by the weight loss data after exposure to 10% HNO₃ (as a function of absorbed nitrogen content) for sintered 316L stainless steel shown in Fig. 37 (Ref 3). The data presented in this figure were obtained using several sintering atmospheres. An example of the influence of temperature on dissolved nitrogen concentration is shown in Fig. 38 (Ref 13). The data in this figure were obtained by continuously measuring weight gain during heating in dry nitrogen (nitrogen containing 0.01% water and 1% water). In the 700 to 1000 °C temperature range a large absorption of nitrogen occurs. A maximum of 9 mg per gram of stainless steel was absorbed--24 mg/g would be required to convert all of the chromium in the alloy to Cr₂N (Ref 13). An example of the influence of cooling rate, and hence the dissolved nitrogen concentration, on the corrosion rate of 316L stainless steel is shown in Table 17 (Ref 13). While the rate of heating had no influence on corrosion of the alloy, cooling rates in excess of 100 °C/s inhibited or eliminated corrosion. Chromium nitride sensitization with concomitant loss of corrosion resistance is not limited to 316L stainless steel. Other stainless steels (both 300 and 400 series alloys) are subject to loss of corrosion resistance when nitrogen-containing sintering atmospheres are used. Table 2 showed weight-loss data for sintered 304L and 316L stainless steels as a function of sintering atmosphere and revealed that nitride formation lowered corrosion resistance (weight loss after 5% NaCl exposure).

Influence of Oxygen and Water Vapor/Dew Point on Corrosion Resistance. The influence of oxygen on the corrosion resistance of sintered stainless steels can, perhaps, best be understood by visualizing the structure of the as-sintered material. The as-received powders contain oxygen, much of which resides on the surface of the powder. Reduction of these oxides in industrial furnaces is not always complete, and the grain boundary oxides within the as-sintered structure provide paths for easier corrosion of the alloy. The role these grain-boundary oxides play in the corrosion of sintered metals is likely similar to the role that such oxides play in the degradation of thermal sprayed coatings (Ref 27, 28). Upon cooling, high oxygen affinity elements oxidize when they reach the metal-oxide equilibrium temperature, and the water content (dew point) of the atmosphere determines the stability of the oxides according to Fig. 39 (Ref 23). This figure reveals that the oxides are more easily formed at lower temperatures. The negative effect of high dew point on the corrosion resistance of sintered 316L stainless steel is further shown by the data in Table 18.

A number of investigators have observed decreased corrosion resistance with increasing oxygen content (Ref 14, 18, 25, 29). Figure 40 reveals that the pitting potential of P/M 316L stainless steel is found to decrease with increasing oxygen content (Ref 25). Immersion data in a 5% NaCl solution shows an identical trend, as seen in Fig. 41 (Ref 23). High dew points (greater than -34 °C) resulted in high oxygen concentrations within sintered alloys leading to a reduction in mechanical properties and corrosion resistance. This is not surprising in light of the type of microstructure that is attained in high dew point sintering atmospheres and illustrated in Fig. 42 (Ref 22). The P/M 316L stainless steel specimen shown in Fig. 42 exhibited a lack of interparticle bonding, resulting from the high grain boundary oxides, that lead to poor mechanical and corrosion properties. Immersion data for sintered 316L stainless steel in a 5% NaCl solution, as a function of water vapor content of the hydrogen sintering atmosphere, is shown in Table 19 (Ref 30). When the water vapor content was 45 ppm or lower, no corrosion was noted after eight days of exposure.

Table 19 Effect of water-vapor content on the corrosion resistance of stainless steel specimens sintered at 1150 °C in hydrogen

Influence of Sintering Temperature, Sintering Time, and Cooling Rate on Corrosion Resistance. Improved electrochemical corrosion resistance has been noted for sintered 316L stainless steel with increased sintering time, as Table 20 reveals (Ref 25). These improvements in corrosion resistance were attributed to the reduced nitrogen, oxygen, and carbon levels observed for the specimens after the longer sintering time. Carbon, oxygen, and CO, H₂O, and CH₄ concentrations in a hydrogen sintering gas as a function of time at temperature are presented in Fig. 43. Earlier, the significant influence of cooling rate on corrosion resistance is shown in Table 17. When there is sufficient water vapor to cause corrosion with slow cooling, it appears that a fast cooling rate (200 °C/min) retards corrosion, as shown in Table 21 (Ref 13).

Table 20 Effect of sintering temperature and time on the corrosion resistance of sintered 316L stainless steel

The materials were sintered in hydrogen with a dew point of -70 °C.

Influence of Porosity/Alloy Density. Sintered stainless steels are used in low-density forms (e.g., in filters) and in a wide variety of forms requiring higher-density alloys. The literature on P/M stainless steels in acid solutions reveals that corrosion resistance improves with increasing density, as Fig. 44 shows (Ref 31). In saline solutions the situation is not as clear--some researchers have reported that increasing density is beneficial, while others have reported it to be detrimental. These discrepancies are believed to be a result of differences, from study to study, in pore morphology and alloy density. This point is illustrated in Fig. 45, which shows the corrosion resistance of sintered 316L stainless steels as a function of density (Ref 1, 32). At low sintered densities, the network of pores, including boundary oxides and particle boundaries, is rather open and discourages the formation of the occluded cell environment associated with crevice-corrosion initiation in stainless steels. At relatively high sintered densities, this network is tighter and encourages both the establishment of an aggressive environment within the crevice and a high potential drop down the crevice. At very high sintered densities, crevice-corrosion susceptibility decreases as the porous network is closed off with increasing alloy density. Data showing the percentage of open pores as a function of sintered density and the resulting time to first rust during salt spray exposure are presented in Table 20 (Ref 25).

Fig. 44 Relationship between sintered density and weight loss of three austenitic stainless steels in 40% HNO_3 solution. Source: Ref 31

Fig. 45 Effect of sintered density upon corrosion resistance of sintered 316 type alloys. Source: Ref 1, 32

In the corrosion literature for wrought alloys, it is well recognized that the aspect ratio of a crevice (the ratio of its width to its length) is a critical parameter in the establishment of crevice corrosion. Figure 46 illustrates that for narrow crevice gaps, crevice corrosion initiates at shallow depths, whereas, for wider crevice gaps, attack initiates deeper within the crevice (Ref 24). As a result, narrow and/or long crevices are likely initiation sites for crevice corrosion. In sintered stainless steels the inherent porous nature of the material provides a narrow tortuous electrolyte path that both encourages crevice-corrosion initiation and sustains its propagation.

Fig. 46 Effect of crevice gap and depth on the initiation of crevice corrosion in various stainless steels and alloy 625. The gaps and depths below and to the right of the curve for each material define crevice geometries where initiation of crevice corrosion is predicted by the mathematical model of T.S. Lee and R.M. Kain, NACE Corrosion 83 Conference proceeding paper 69, 1983. Source: Ref 24

Several changes occur in the occluded cell environment of a crevice during the initiation stages of crevice corrosion: oxygen depletion within the crevice that establishes a separation of anodic and cathodic sites (where the cathode is largely outside the crevice and the anode is inside the crevice), a lowering of the pH of the solution within the crevice by hydrolysis reactions, and migration of chloride into the crevice to maintain charge neutrality. For some of the less heavily alloyed stainless steels, the reduction in E_p resulting from the increased chloride concentration is enough to initiate crevice corrosion, as the schematic polarization curve and mixed potential analysis in Fig. 47 reveal (Ref 33). The crossover point in the mixed potential analysis indicates dissolution of the metal within the crevice via a pitting type of attack. Changes in the anodic polarization behavior for the stainless steel within the crevice, resulting from acidification and increase in chloride ion concentration of the crevice solution, are illustrated in Fig. 48 (Ref 33). As the aggressive nature of the crevice solution increases, i_{crit} , E_{pp} , and i_p increase, while E_p decreases. A mixed potential analysis of crevice-corrosion initiation (using the cathodic polarization behavior for the stainless steel in the environment outside of the crevice and the anodic polarization behavior for the stainless steel in the environment inside the crevice) is depicted in Fig. 49 (Ref 33). This analysis reveals that when the potential drop associated with the tortuous electrolyte path of a crevice exceeds a certain value, IR^* in this illustration, crevice corrosion is initiated by active dissolution of the metal in the crevice. While the mechanisms just described were proposed for wrought materials containing intentional or unintentional crevice formers, such as O-rings or gaskets, they are equally applicable to P/M materials containing inherent porosity. In fact, the extremely tortuous path provided by the pores, oxides, and particle boundaries in a sintered stainless steel provide what could be viewed as the ultimate geometry for establishing and, perhaps, even studying crevice corrosion. Clearly, by gaining a better understanding

of the influence that processing parameters play in establishing pore morphologies susceptible to crevice corrosion, it will be possible to alter pore morphology to discourage crevice-corrosion initiation.

Fig. 47 Crevice-corrosion initiation resulting from lowering of E_p with increasing chloride concentration. Source: Ref 33

Fig. 48 Changes in anodic polarization behavior that occur as the environment in the crevice becomes increasingly aggressive. Source: Ref 33

Fig. 49 Crevice-corrosion initiation by an IR -induced mechanism. When the IR drop down the crevice exceeds IR^* , crevice corrosion initiates. Source: Ref 33

Another means of altering the susceptibility of sintered stainless steels to crevice attack is to alter alloy composition. By altering alloy composition the hydrolysis reactions responsible for lowering the pH within the crevice can be influenced, and these changes can be used to discourage crevice-corrosion initiation, as Fig. 50 reveals (Ref 32). The enhanced crevice-corrosion resistance of the 317L and SS100 alloys is attributed to their higher molybdenum concentrations. It should be noted that the addition of molybdenum does not make these alloys immune to crevice corrosion because it is possible to initiate crevice corrosion in neutral pH crevice environments without the presence of chloride when the aspect ratio of the crevice is severe enough; it simply makes initiation more difficult.

Fig. 50 Effect of density on corrosion resistance of sintered austenitic stainless steel. Source: Ref 32

Approaches Used to Improve the Corrosion Resistance of Sintered Stainless Steels. A variety of means have been employed to improve the corrosion resistance of sintered stainless steels--some of which simply alter the number of open pores, others are aimed at both reducing the number of open pores and enhancing passivity of the alloy. These approaches include the following finishing processes: tumbling, grinding and shot blasting, passivating treatments, liquid phase sintering, double pressing and sintering, and the addition of alloying elements, such as copper, tin, and noble metals (Ref 34).

One group of researchers evaluated the influence of several finishing processes on the anodic polarization behavior of P/M 316L stainless steel in a 0.1 *N* NaCl/0.4 *N* NaClO₄ solution (ASTM B 627). As shown in Fig. 51, the investigation revealed the following results: tumbling likely smears the pores and is ineffective at improving corrosion resistance; coining/sizing introduces residual stresses in the surface of the alloy that may increase corrosion; grinding, turning, and shot blasting can seal surface pores and improve corrosion resistance; and thermal and chemical passivation processes can alter the thickness and/or composition of the passive film, thus enhancing corrosion resistance (Ref 3). In another investigation, thermal passivation in the temperature range of 325 to 500 °C for 30 min also showed promise for enhancing passivity, and thus corrosion resistance, of sintered 316L stainless steel exposed to a 1 *N* H₂SO₄ solution, as Fig. 52 reveals (Ref 35).

Fig. 51 Anodic potentiodynamic polarization curves for 316L stainless in 0.1 *N* NaCl/0.4 *N* NaClO₄ as a function of surface finishing. Source: Ref 3

Fig. 52 Rest (open-circuit) potential measurements for sintered 316L thermally prepassivated at temperatures between 325 and 500 °C. Source: Ref 35

Closing of porosity through operations such as double pressing and double sintering (DPDS), while expensive, has been found to significantly reduce the amount of open porosity and yield anodic polarization behavior in aggressive acid solutions similar to that of wrought materials. Figure 53 shows anodic polarization data for wrought and hot pressed and hot sintered 316 stainless steel in 1 N H₂SO₄ (Ref 29). When a DPDS operation is used, a P/M 316 stainless steel alloy of nominal composition exhibits a degree of passivity almost identical to that of wrought 316 (Ref 36). Another, more thorough, means for reducing or eliminating open porosity in P/M materials is liquid phase sintering. Sintering additives such as boron, NiB, BN, and CrB have been found to be effective in producing dense microstructures with enhanced salt-spray corrosion resistance, as Table 22 reveals (Ref 14). Unfortunately, sensitized microstructures, as evidenced by the high I_r/I_a ratio listed in Table 22 are a by-product of liquid phase sintering (Ref 14). Careful development of liquid phase sintering additives for stainless steels will be needed in order to produce dense alloys that are not susceptible to intergranular corrosion. Injection molding also shows promise for producing dense P/M alloys with enhanced corrosion resistance. Figure 54 compares weight-loss values for injection-molded and wrought 14-4PH stainless steel as a function of exposure time in either full strength chlorine bleach or a 10% FeCl₃ solution (Ref 37). The injection-molded P/M compacts had densities of 96 to 97% of the wrought density and exhibited weight losses comparable to those of the wrought 17-4PH stainless steel.

Table 22 Corrosion properties of liquid phase sintered 316L steels with the addition of boron-base sintering additives

All stainless steels were sintered at 1250 °C for 60 to 120 min in pure hydrogen.

Additive	Density, g/cm ³	Open pores, %	$E_{stp}^{(a)}$ mV SCE	NSS1, h	NSS2	$I_r/I_a \times 10^3$

A number of alloying additions or infiltrants have been explored as means for enhancing passivity in P/M stainless steels. Among the most popular are copper and tin. Infiltration of P/M 316L and 304L alloys with either copper or bronze have been observed to increase corrosion resistance in boiling and room-temperature acid solutions (see Fig. 55). As this figure reveals, similar results were noted for the bronze and copper in the room-temperature acid, while the bronze infiltrant gave the best results in the boiling acid. Enhanced corrosion resistance was attributed to the elimination of open-connected porosity and the effect of the alloying. It should be noted that in both cases the infiltrants diffused either partially (bronze at all infiltration percentages and copper at the 6% infiltration level) or totally (copper at 4 and 6% infiltration levels) into the matrix. Table 1 illustrates the beneficial influence of copper alloying additions on the corrosion resistance of 316L stainless steel. Additional data supporting the beneficial influence of copper alloying additions on hot-pressed-and-sintered 316 stainless steel are provided in Fig. 38 (Ref 35). The improved passivity of the copper-containing alloys is attributed to its depolarizing influence on the oxygen reduction reaction. Depolarization of the cathodic, oxygen-reduction reaction enables the alloys to passivate more easily. Figure 56 shows the benefits of tin additions to the polarization behavior of 316 stainless steel (Ref 39). The addition of tin decreases the passive and critical current densities of the hot-pressed specimens by two orders of magnitude. Improvements in corrosion resistance, such as the ones just described, led to the development of copper- and tin-modified stainless steel powder chemistries, which are currently being marketed under the trademarks of Ultra 303L, Ultra 304, and

Ultra 316. The enhanced corrosion resistance of these alloys, when compared to those of nonmodified 303L, 304L, and 316L, is evident in Fig. 55 and 56. When both copper and tin are prealloyed into the powder, the alloys are marketed with an "LSC" designation. The improved corrosion resistance for 316LSC in comparison to that of nonmodified 316L is presented in Fig. 57 (Ref 23).

As this section has revealed, a number of processing variables exert a strong influence on the corrosion resistance of sintered stainless steels. A listing of the most important variables and their impact on corrosion performance is presented in Table 23 (Ref 23).

Table 23 Effect of iron, carbon, nitrogen, and oxygen on corrosion resistance of sintered austenitic stainless steels

Variable	Origin of problem	Effect on corrosion, resistance	Suggested solutions
Iron	Contamination of prealloyed powder with iron or iron-base powder at powder or parts producer's facility	Lowering of corrosion resistance by more than 99% due to galvanic corrosion	Utmost cleanliness at both powder and parts producer's manufacturing facilities, preferably separate and dedicated equipment and facilities
Carbon	Inadequate lubricant removal; carburizing sintering atmosphere soot in sintering furnace; high-carbon powder	Inferior resistance to intergranular corrosion	<ul style="list-style-type: none"> • Use L-grade designation of stainless steel powder. • Ensure adequate lubricant removal (before sintering). • Use clean soot-free sintering furnace and carbon-free sintering atmospheres; carbon content of sintered part should be $\leq 0.03\%$.
Nitrogen	Sintering in dissociated NH_3 or other nitrogen-containing atmosphere combined with slow cooling	Inferior resistance to intergranular corrosion	<ul style="list-style-type: none"> • Reduce percentage of nitrogen in sintering atmosphere. • Use fast cooling of parts preferably >150 to $200\text{ }^\circ\text{C/min}$ (>270 to $360\text{ }^\circ\text{F/min}$) through critical temperature range (700 to $1000\text{ }^\circ\text{C}$, or 1290 to $1830\text{ }^\circ\text{F}$). • Use higher sintering temperature. • Use intermediate dew points (-37 to $-45\text{ }^\circ\text{C}$, or -35 to $-50\text{ }^\circ\text{F}$) in cooling zone of furnace. • Use tin-modified stainless steel powders.
Oxygen	Excessive oxygen in powder; excessive dew point of sintering atmosphere; slow cooling after sintering	Inferior resistance to general corrosion	<ul style="list-style-type: none"> • Use low oxygen content powder, preferably $<2000\text{ ppm}$. • Control dew point within sintering furnace to ensure reducing conditions. • Fast cooling, preferably $>200\text{ }^\circ\text{C/min}$ ($360\text{ }^\circ\text{F/min}$) • For nitrogen-containing atmospheres, use dew point of -37 to $-45\text{ }^\circ\text{C}$ (-35 to $-50\text{ }^\circ\text{F}$) in cooling zone. • For sintering in H_2, ensure that water vapor content of atmosphere is below 50 ppm.
Density of	High sintered density	Inferior resistance to	Use lower density to increase pore size and circulation of

sintered part	crevice corrosion	corrodent. In acidic environments, corrosion resistance improves with increasing density due to a decrease of specific surface area.

Corrosion-Resistant Powder Metallurgy Alloys

Barbara Shaw, Penn State University

P/M Superalloys

Development of P/M superalloys began in the 1960s with the search by the aerospace industry (and later the electric power industry) for stronger high-temperature alloys in order to operate engines at higher temperatures and thus improve fuel efficiency.

Initially, lower production costs were a major objective in exploring the P/M approach. Later, specific advantages linked to the P/M approach, such as the use of more complex and greater volume fractions of dispersoids, reduced segregation, improved workability, and reducing the cost of consolidating superalloy powders, particularly of oxide-dispersion-strengthened (ODS) superalloys, through the development of suitable forging techniques (Ref 40). Efforts are also underway to exploit the advantages of microcrystallinity and extended solid solutions of rapid solidification technology.

Uses and State of Commercialization. Table 24 summarizes the uses of P/M superalloys in terms of components, engine use, and reasons for using P/M technology. Other uses of superalloys include nuclear reactors, heat exchangers, furnaces, sour gas well equipment and other high-temperature applications.

Table 24 Aerospace applications of P/M superalloys

Manufacturing of P/M Superalloys. An important prerequisite for making P/M superalloys that possess reliable dynamic properties is the use of clean powders. Years of intensive work were spent in identifying and controlling the problems related to unclean powders. Today, argon and vacuum (also known as soluble gas process) atomization, as well as atomization by the rotating electrode process, are known to be suitable for producing powders with the required low oxygen content and low degree of contamination. The so-called prior particle boundary (PPB) problem, that is, the presence of carbides segregated at PPBs, was solved through the development of low-carbon alloys. Special equipment is used for removing ceramic particles and particles containing entrapped argon. Some of these problems are minimized or avoided in ODS alloys made by mechanical alloying. In mechanical alloying, elemental and master alloy powders as well as refractory compounds are mechanically alloyed by high-energy milling (Ref 42, 43).

Two established powder consolidation techniques for P/M superalloys are hot isostatic pressing (HIP) and isothermal forging. Both P/M methods permit the manufacture of so-called near-net shape parts with attendant improved material use and reduced machining costs. Powder metallurgy forging exploits the improved forgeability deriving from the higher incipient melting temperature and reduced grain size of P/M material. Hot compaction by extrusion leads to very fine grain size, improved hot ductility, and superplasticity.

Depending on the application of a superalloy part, the powder consolidation process can be controlled in order to yield either a fine or a coarse grain size. Fine grain size is preferred for intermediate temperatures (up to about 700 °C, or 1290 °F) because of its higher strength and ductility at these temperatures. For high-temperature blade and vane applications, however, a large grain size (ASTM 1 to 2) provides superior creep strength due to reduced grain-boundary sliding. Grain coarsening of ODS alloys is achieved through special heat treatments after consolidation (Ref 40).

Compositions and Properties. Table 25 shows the compositions of the best known P/M superalloys. Many have the same compositions as cast alloys but are manufactured similarly to wrought alloys. The important P/M superalloys--IN-100, René 95, and Astroloy--were adapted in the P/M process by reducing their carbon content and by adding stable carbide formers to eliminate the problem of PPB carbides. To facilitate HIP, alloy compositions were modified to increase the temperature gap between the γ' solvus (above which HIP has to be carried out for increasing grain size) and the solidus temperature.

Oxidation. Nickel-, cobalt-, and iron-base superalloys use the selective oxidation of aluminum or chromium to develop oxidation resistance (Ref 44). These alloys are therefore often referred to as Al₂O₃ or Cr₂O₃ formers depending on the composition of the oxide scale that provides protection. Alloy composition, surface conditions, gas environment, and

cracking of the oxide scale affect the selective-oxidation process (Ref 44). Figure 58 shows the development of superalloys in terms of the progress achieved against high-temperature oxidation.

Fig. 58 Advancing steps in the protection of superalloys against oxidation of high temperatures showing life (in h) to 0.25 mm (10 mils) penetration of 980 °C (1800 °F). Source: Ref 45

Cyclic oxidation causes protective scales of Al₂O₃ and Cr₂O₃ to crack and spall. Regeneration of the scales will eventually result in the complete depletion of chromium and aluminum. The length of time for which superalloys are Al₂O₃ or Cr₂O₃ formers under given conditions is very important because of the subsequent appearance of less protective oxides. The importance of chromium for imparting oxidation resistance is demonstrated in Table 26, which lists fatigue crack growth rates for different alloys.

Table 26 Relative increase in fatigue crack growth rates after 15 min at 650 °C (1200 °F)

$\Delta K = 30 \text{ MPa}\sqrt{\text{m}}$ (27 ksi $\sqrt{\text{in.}}$)

Alloy	Relative increase in crack growth rates	Grain size, μm	Chromium content, %
René 95 after HIP + forge	242	50-70	12.8
IN-100	43.4	4-6	12.0
HIP-consolidated MERL 76	41.5	15-20	12.0

Figures 59 and 60 show comparisons of the oxidation resistances of superalloys with and without oxide dispersions. Many studies have confirmed the beneficial effect of dispersed oxides on oxidation resistance. The lower oxidation rates of ODS alloys have been attributed to the reduced time required to form a continuous Cr_2O_3 scale due to the presence of dispersed oxides, which act as nuclei for oxidation (Ref 47). Based on marker studies with platinum, one investigation attributed the beneficial effect of oxide dispersions to the predominant, inward diffusion of oxygen ion (O^{2-}) and a slowdown of the chromic ion (Cr^{3+}) diffusion (Ref 48). The latter may be caused by the blocking of the dispersions in the Cr_2O_3 scale. With the dispersed oxides becoming dissolved in the scale, it also appears possible that trivalent ions, such as yttrium (Y^{3+}) and lanthanum (L^{3+}), will reduce the number of vacant cation sites, thus lowering the diffusivity of Cr^{3+} .

Fig. 59 Comparison of the oxidation resistance of ODS alloys MA 956, MA 754, and MA 6000 with that of other superalloys. Testing conditions: 504 h at 1100 °C (2010 °F) in air containing 5% H_2O . Temperature was cycled between test temperature and room temperature every 24 h. Source: Ref 46

Fig. 60 Cyclic oxidation of ODS alloys MA 956, MA 8077, MA 953, and TD-NiCr compared to that of coated alloy MM 200. Testing conditions: held at 1100 °C (2010 °F) for 1 h and cooled by a 3 min air blast. Source: Ref 46

Dispersed oxides may also improve scale adhesion because of the thinner scale or because of increased porosity or smaller grain size in the oxide scale (Ref 46). It was reported that at 1300 °C (2370 °F) the outer regions of the Al₂O₃ film of MA 956 (Fe-20Cr-4.5Al-0.5Ti-0.5Y₂O₃) became enriched with titanium, giving rise to a continuous layer of titanium-rich oxide (Ref 49). Pegging of the oxide by titanium carbide particles and the irregular metal/oxide interface is said to contribute to the good spalling resistance of the alloy.

In oxidation tests in air and in an inert atmosphere at 1260 °C (2300 °F) for MA 754 (Ni-20Cr-0.5Ti-0.5Y₂O₃-0.3Al-0.05C), Ni-20Cr (cast/wrought), and an ODS nickel-chromium alloy, subsurface porosity was attributed to the oxidation of chromium and aluminum (Kirkendall porosity), and thermally induced porosity was excluded as a cause (Ref 50). This type of porosity decreases with improving oxidation resistance of the alloy.

Results of cyclic oxidation tests at 1100 °C (2010 °F) for MA 956, TD-NiCr, and Hastelloy X are given in Table 27. The superior resistance of MA 956 is attributed to a very stable Al₂O₃ film and parabolic oxidation for more than 500 h. Tables 28 and 29 list sulfidation and carburization resistance data for MA 956. As in the case of oxidation, the alloy shows marked superiority to the other alloys tested. Tables 30 and 31 provide similar data for alloy MA 6000E (Ni-15Cr-4.5Al-4W-2Mo-2Ta-2.5Ti-1.1Y₂O₃) (Ref 51). The functions of the various alloying elements are as follows:

- Aluminum, titanium, and tantalum for γ' hardening
- Y₂O₃ for high-temperature strength and stability
- Aluminum and chromium for oxidation resistance
- Titanium, tantalum, chromium, and tungsten for sulfidation resistance
- Tungsten and molybdenum for solid-solution strengthening

Hot Corrosion. The requirement of hot corrosion resistance of superalloys derives from the use of sodium- and sulfur-containing fuels and the presence of salt in the air necessary for combustion. Under such conditions, combustion gases often leave deposits of sulfates or chlorides with metallic constituents of sodium, calcium, magnesium, or potassium on the surfaces of superalloys. The resulting corrosion problems are particularly severe if these condensed phases are liquid. Hot corrosion may occur in gas turbines, boiler tubes, and incinerators. Typically (and similar to what happens in pure oxidation), hot corrosion of superalloys occurs in two stages: a slow rate initiation stage, followed by a propagation stage of rapid degradation. The difference, compared to oxidation, is that the conditions causing hot corrosion simply shorten the time in which superalloys form protective Al₂O₃ or Cr₂O₃ scales by selective oxidation (Ref 44). Factors affecting the length of the initiation stage (at the end of the initiation stage, the superalloy must be removed from service because of the start of excessive corrosion) include alloy composition, alloy fabrication conditions, gas composition and velocity, deposit composition and its physical state, amount of deposit, temperature, temperature cycles, erosion, and specimen geometry.

When a protective scale dissolves into a liquid deposit, so-called fluxing reactions can occur with the appearance of other basic or acidic nonprotective reaction products. Propagation may also be caused by components from the deposit that can accumulate in the deposit or the alloy and thus cause a nonprotective scale to form. Chlorine and sulfur produce such effects, and hot corrosion caused by the latter is known as sulfidation. Figure 61 shows the temperature ranges over which the various hot corrosion propagation modes are important.

Fig. 61 Schematic showing the temperature regimes over which different propagation modes are most prevalent.

Some superalloys corrode in several modes. For example, hot corrosion of IN-738 proceeds by alloy-induced acidic fluxing, but is preceded by other propagation modes, including a basic fluxing mode. The higher chromium content alloys IN-738 and IN-939 were developed to improve the hot corrosion resistance of land-based gas turbines. Carbide stabilization through tungsten and tantalum and delay of $M_{23}C_6$ formation in service were expected to allow the large chromium content to impart improved hot corrosion resistance. Increasing the chromium and decreasing the Al_2O_3 , however, lowered γ' solution temperatures and strength, which necessitated the use of coatings. The use of coatings led to the current use of enhanced aluminum, that is, carefully balanced coating alloys (based on nickel, iron, or cobalt with chromium, aluminum, and other active elements). Generally, all superalloy load-bearing parts used at very high temperatures under dynamic conditions are coated (Ref 45). Nevertheless, coatings generally last longer on more corrosion-resistant base materials.

In a model study, IN-738 was used to demonstrate the effect of grain size and Y_2O_3 dispersions on hot corrosion behavior (Ref 52). Under gas turbine simulated hot gas corrosion test conditions at 850 and 950 °C (1560 and 1740 °F) (Fig. 62), the presence of a Y_2O_3 dispersion lowered the corrosion rate. At 950 °C (1740 °F), a finer grain size further reduced the corrosion rate, which was thought to be mainly due to a higher diffusion rate of chromium and aluminum. The effect of the dispersion was predominant at 850 °C (1560 °F). Reduced sulfate formation at 850 °C (1560 °F) was attributed to the likely formation of yttrium oxysulfide.

Fig. 62 Comparison resistance of alloy IN-738LC in hot (850 °C, or 1560 °F) gases. A, IN-738LC; B, IN-738LC with Y_2O_3 dispersion, annealed at 1270 °C (2320 °F); C, IN-738LC with Y_2O_3 dispersion, annealed at 1100 °C (2010 °F). Source: Ref 40

In a study of the oxidation and hot corrosion resistance of P/M LC Astroloy and IN-100, isostatically pressed samples were found to be moderately attacked in a sulfate-chloride environment and heavily corroded by pure sodium sulfate (Na_2SO_4) (Ref 53). Heat treatment and the use of coarse powder (62 to 150 μm for Astroloy and 88 to 200 μm for IN-100) lowered the susceptibility to catastrophic corrosion. Additions of yttrium to IN-100 improved the corrosion resistance in pure sulfate, but were detrimental when NaCl was present. Therefore, yttrium additions to IN-100 cannot be recommended for marine turbines. It was concluded that in many cases impregnation coatings must be considered for components made of IN-100 alloys.

As a part of an evaluation of improved alloys for use in oil and gas drilling at depths of 6100 m (20,000 ft), HIP nickel-base alloy Inconel 625 was studied in a simulated deep, hot, sour cell environment (Ref 54). The alloy demonstrated resistance to pitting and crevice corrosion, sulfide stress cracking, chloride stress-corrosion cracking (SCC), and elevated-temperature anodic stress cracking. Hot isostatically pressed Inconel 625 exhibited essentially the same corrosion resistance as wrought Inconel 625.

Fatigue and Creep Crack Growth. Fatigue crack growth rates of nickel-base superalloys measured at frequencies above 0.1 Hz, at intermediate temperatures, and at an intermediate stress intensity range, ΔK , were found to be several times higher than those measured in inert atmospheres (Ref 55). The buildup of corrosion products with decreasing ΔK , however, was thought to enhance crack closure, thus reducing the effective stress intensity range and leading to fatigue thresholds higher than those in inert environments.

Table 32 shows creep crack growth rates of IN-750 with various grain-boundary carbide microstructures (Ref 46, 55). Aggressive environments (helium + 3% SO_2 and air) produce order of magnitude increases over the rates in inert gas. In general, the reaction of both oxide dispersoid-free P/M superalloys and cast and wrought superalloys to aggressive environments is similar. This suggests that crack growth is governed mainly by microstructure and alloy chemistry.

Table 32 Dependence on carbide microstructure of creep crack growth rates of alloy IN-750 in four environments

Grain-boundary carbide microstructure	Crack growth rate (da/dt), mm/min ^(a)			
	Helium	Air	Helium + 4% methane	Helium + 3% SO ₂
Blocky	7×10^{-4}	1.95×10^{-2}	7×10^{-4}	1.5×10^{-1}
Cellular	1.15×10^{-3}	2.6×10^{-3}	3.1×10^{-3}	1.3×10^{-1}
None	7×10^{-4}	6.3×10^{-2}	7×10^{-4}	1.6×10^{-1}

$$K = 35 \text{ MPa} \sqrt{\text{m}} \quad (32 \text{ ksi} \sqrt{\text{in.}}).$$

Oxide-Dispersion-Strengthened Alloys. Mechanical alloying has removed many constraints on the development of new superalloys. Many new ODS alloys were designed specifically for corrosion resistance because alloying requirements for precipitation strengthening can be greatly reduced. Superior creep, corrosion, and erosion resistance at high temperatures have been claimed to enable the use of lower-grade fuels (Ref 56). Figures 63, 64, 65, and 66 show the corrosion resistances of ODS alloys MA 956, MA 6000, and MA 754 compared to several conventional superalloys.

Fig. 63 Comparison of the corrosion resistance of MA 6000 and MA 956 with that of other superalloys. Tested in a burner rig for 312 h using a 30-to-1 air-to-fuel ratio. Fuel contained 0.3% S and 5 ppm seawater, and specimens were held at temperature for 58 min of each hour, then cooled 2 min an air blast. Source: Ref 46

Fig. 66 Hot corrosion of alloys MA 953, HDA 8077, and MA 956 compared to that of some non-ODS alloys. Test conditions: 900 °C (1650 °F), 1 h, followed by a 3 min air blast, 5 ppm sea salt. Source: Ref 46

Coatings for ODS Alloys. As mentioned above, for extended high-temperature service, superalloys require additional protection through coatings. The use of aluminide coatings appears to be unsatisfactory due to the development of subsurface Kirkendall porosity and early spalling of the protective scale. Kirkendall porosity decreases with increasing aluminum content of the substrate alloy as well as with decreasing grain size (Ref 56). Only limited information exists on the properties of Cr-Al-Y coatings (Ref 46) and on diffusion barrier coatings (Ref 57, 58, 59, 60).

Magnetic Materials and Properties for Powder Metallurgy Part Applications

Kenneth H. Moyer, Magna-Tech P/M Labs

Introduction

MAGNETIC POWDER METALLURGY PARTS are produced predominantly from "soft" (or temporary) magnetic materials, which generate a magnetic force only in the presence of an externally applied magnetic field. Commercial soft magnetic P/M alloys are commonly produced from high-purity iron or various ferrous alloy types such as Fe-2Ni, Fe-3Si, Fe-0.45P, Fe-0.6P, and 50Ni-50Fe. The use of P/M techniques to make magnetically soft components are effective for applications in which complicated magnetic parts would otherwise require considerable machining. In some applications, P/M fabrication eliminates all machining operations and saves a substantial amount of the total cost, compared to conventional manufacturing.

Powder metallurgy and metal injection molding (MIM) also have other advantages for fabrication of magnetic materials. One major advantage includes economical blending of small-lot specialty alloys. Powder metallurgy also has the advantage of processing materials that would be difficult for fabrication as wrought metal forms. For example, iron-phosphorus alloys cannot be made in wrought form because of "hot shortness," while Fe-P alloys can be processed effectively by P/M methods for soft magnetic applications. Powder metallurgy also is the method used for the relatively new permanent magnetic materials based on combinations of neodymium, iron, and boron (introduced in 1983). The high reactivity of neodymium or other rare earths and their alloys requires the suppression of contamination during alloy preparation and processing. In particular, oxidation by O₂ or H₂O or both must be kept to a minimum. Any oxidation of the alloy occurring during processing depletes the alloy of the rare-earth components. This usually results in the production of an alloy having unfavorable magnetic qualities. To obtain powder compacts with maximum magnetization, the powder is magnetically aligned and pressed.

Magnetic Materials and Properties for Powder Metallurgy Part Applications

Kenneth H. Moyer, Magna-Tech P/M Labs

Basic Magnetism

In simple terms, magnetism is a field force that can be produced either by permanent ("hard") magnetic materials or by an electric current generated in a coil of wire that surrounds a section of iron. The magnetic field is defined quantitatively in terms of the magnetic field strength (or the magnetizing force), designated as H , with the unit of oersteds (Oe) or amps/meter (A/m).

The magnetic response of a material is characterized by the induced magnetic field that is caused by an applied magnetic field, as shown in Fig. 1. The current in the primary winding produces an external magnetic field, which then induces a magnetic field in the toroid and the secondary circuit. This method characterizes the magnetic response in terms of magnetic induction (B) versus the applied field (H) as shown in Fig. 1(b). These basic characteristics of magnetic response are briefly summarized in this introductory section.

Fig. 1 Standard toroid test of magnetic response. (a) Test setup. (b) Hysteresis response. Source: Ref 1

Intensity of Magnetization and Magnetic Induction. The intensity of magnetization (I) is defined in terms of the number of unit north poles and south poles, m , within a given cross-sectional area. A rectangular bar of length l and cross-sectional area a with m unit north and south poles at each end would have an intensity of magnetization defined as $m/a = I$. The intensity of magnetization also can be likened to the flow of electrons through a wire where the concentration and direction of the electrons are known at any point.

In a magnetic field, flux lines pass from a magnetized material into the air at the north pole, re-enter at the south pole, and then pass through the material to the north pole to form a closed loop. The total number of lines crossing a given area at right angles is defined as the flux in the area. The flux per unit area is defined as the flux density or the magnetic induction, B . Both the magnetizing force or the applied field, H , and the intensity of magnetization, I , contribute to the lines of induction, but in magnetic materials, the intensity of magnetization, I , is generally much larger. The magnetic induction is therefore defined by the formula: $B = H + 4\pi I$. The cgs unit of magnetic induction is gauss (G), the SI unit is tesla (T). A tesla is equivalent to 10^4 G.

Magnetism and Permeability. When a piece of iron is brought near a permanent magnet or a magnetic field of an electrical current, the magnetization induced in the iron by the applied field is described by a magnetization curve obtained by plotting either the intensity of magnetization or the magnetic induction, B , as a function of the applied field, H . A typical magnetization curve is shown in Fig. 2(a). However, if the direction of magnetization is reversed, the magnetization curve does not retrace itself but has a property known as hysteresis. Owing to this hysteresis, a loop rather than a curve is generated (Fig. 2b). However, unless losses are realized, the magnetization curve should be reproduced repeatedly.

Fig. 2 Schematic of (a) magnetization curve (b) hysteresis loop. Source: Ref 1, 2

The behavior of any magnetic material can be defined by the hysteresis loop and the permeability. The ratio B/H is defined as the permeability, μ . This value indicates the relative increase in flux or magnetic induction caused by the presence of a magnetic material. Of the many useful permeabilities, the initial permeability, μ_0 , and the maximum permeability, μ_{\max} , are of most importance for P/M applications. The initial permeability, μ_0 , is simply the slope of the initial portion of the magnetization curve, say to 0.01 T (100 G). The maximum permeability, μ_{\max} , is the slope to the tangent of the magnetization curve (Fig. 2). After μ_{\max} is achieved, the permeability falls off rapidly and finally reaches a value of 1. At this point, the magnet is said to be saturated. In other words, even though the magnetization curve will continue to rise, the contribution to magnetization will derive only from the applied field. The magnetic induction at a permeability of 1 is defined as the saturation induction (B_{sat} or B_m in Fig. 2b). Each magnetic material at a temperature of 20 °C will have a specific constant value for the magnetic saturation. In the case of iron, the value is 2.15 T (21,500 G).

Hysteresis Loop. When the applied magnetic field (H) is cycled over time, the magnetic induction lags the applied field and defines a hysteresis loop (Fig. 2b). There are two magnetic properties of interest that occur as a result of the hysteresis. These properties include the remanence or residual induction, B_r , and the coercive field, H_c . The remanent

magnetization is the specific value of the magnetic induction when the applied field has been reduced to 0. In other words, the remanent magnetization is the magnetic induction at an applied field of 0, or the intercept of the B -axis. The coercive field, H_c , is the applied field required to reduce the magnetic induction to a value of 0. This value is the intercept of the H -axis. Both of these properties, including magnetic induction, are important to the performance of any magnetic material. These properties are identified in Fig. 2b as specific points on the hysteresis curve.

Demagnetizing Fields, Air Gaps. Most magnetic devices are not solid but contain discontinuities, such as air gaps. When a discontinuity or an air gap is present, it creates a magnetic field in a direction opposite to the applied field. The net effect is to reduce or subtract from the magnetic induction that results from the application of the applied field. Thus, the true applied field causing the magnetic induction is somewhat lower than the applied field, owing to any demagnetizing forces that are present, such as air gaps. The true applied field can therefore be expressed as follows: $H = H_a - \Delta H$. The demagnetizing field is therefore approximately proportional to the intensity of magnetization. In other words: $\Delta H = NI$, where N is defined as the demagnetizing factor, and where:

$$\Delta H = \frac{N(B - H)}{4\pi}$$

The effect of air gaps is to shear the magnetization curve. In other words, air gaps counteract the positive effects of purifying materials and growing grains (for example, by the use of high-temperature sintering during P/M processing).

Ferromagnetism and Factors Affecting Magnetic Quality. The magnetic properties of magnetic materials depend on the chemical composition, cold deformation, and heat treatment. There are essentially three elements and their respective alloys that are truly magnetic. These ferromagnetic materials are iron, nickel, and cobalt. Iron and cobalt have high magnetic saturations (Table 1). Because of the expense, scarcity, and difficulty of sintering, cobalt and its alloys are not generally selected, except for special applications. Iron, on the other hand, is inexpensive and quite common. Nickel has a magnetic saturation of only about 0.6 T (6 kG). Owing to its much lower magnetic saturation with respect to iron and its higher cost, nickel and its alloys are used mainly when quick response is required.

Table 1 Room-temperature magnetic properties of selected materials

Material/condition	Density, g/cm ³	Maximum induction, B_{\max}		Residual induction, B_r		Maximum permeability, μ_{\max}	Coercive force, H_c

- (a) Magnetic saturation (B_{sat}) values.
- (b) Samples sintered at 1250 °C (2280 °F), 45 min in dissociated ammonia.

In crystalline materials, the basis for ferromagnetism lies in the alignment of magnetic moments from noncompensated electron spins in the 3d shell of the transition series elements, such as iron, nickel, and cobalt (Table 2). In ferromagnetic materials that are below their Curie temperature, the magnetic moments of adjacent atoms are "coupled" parallel to each other. For a small volume of material, all of the individual magnetic moments are aligned in one direction. This small volume is magnetized to saturation and is known as a magnetic domain. An adjacent volume of material, also magnetized to saturation, can have the summation of its magnetic moments point in another direction. Where two such volumes meet with differing alignments, a domain boundary wall must exist. The total magnetization of a sample of material is the net vector summation of all the individual component domain magnetization vectors.

Table 2 Magnetic moments of neutral atoms of 3d transition elements

Unpaired 3d electrons	Atom	Number of electrons	Electronic 3d orbitals	configuration	a/D ratio ^(a)
3	V	23			2
5	Cr	24			1
5	Mn	25			2
4	Fe	26			2
3	Co	27			2
2	Ni	28			2
0	Cu	29			1

Source: Ref 4

- (a) The ratio of atomic spacing, a , and diameter, D , of the 3d orbitals determines the occurrence of positive exchange energy for ferromagnetism.

The parallel "coupling" of magnetic dipoles in iron, cobalt, and nickel occurs from an "isotropic exchange energy," which is the mechanism responsible for ferromagnetism that was a complete mystery until the advent of quantum mechanics by Heisenberg. In very simple terms, parallel "coupling" of magnetic dipoles in iron, cobalt, and nickel is due to a positive exchange energy that occurs when the ratio of atomic spacing (a) to the diameter (D) of the third orbital is between 1.4 and 4.7 (Ref 4). Thus iron, cobalt, and nickel are ferromagnetic, but manganese and chromium are not (Table 2).

Factors Affecting Permeability and Hysteresis Losses. Permeability, coercive field, and hysteresis loss are affected by impurities within the alloy, by cold deformation such as sizing, and by any heat treatment that is provided. Impurities that are most harmful to these alloys include carbon, nitrogen, oxygen, and sulfur. All P/M parts also contain a lubricant to facilitate compaction. If this lubricant is not properly removed during the presinter portion of the sintering cycle, the structure-sensitive properties (permeability, coercive field, and hysteresis loss) may be significantly degraded. Sintering furnace condition and choice of protective atmosphere are also important. Hydrogen or vacuum is preferred. However, hydrogen/nitrogen mixtures, exothermic gas, endothermic gas, and dissociated ammonia can be selected as the protective atmosphere. Any of the latter can cause nitriding or carburizing, which will degrade the structure-sensitive magnetic properties. Because most powders that are used are water atomized and therefore contain surface oxides, these surface oxides must be reduced during the sintering cycle or else degradation of structure-sensitive magnetic properties will occur.

Knowledge of phase diagrams is important to the development of alloys for magnetic applications. Alloys most commonly selected are single-phase alloys. For instance, more than 0.008 wt% C or more than 0.006 wt% N causes carbide or nitride formation in α -iron. The more carbon contamination or the more nitriding that occurs, the greater the degradation of the structure-sensitive magnetic properties. In phosphorus irons, additions of >1.5 wt% P result in formation of phosphorus iron intermetallics. In silicon irons, >3 wt% Si makes the alloys difficult to compact; however,

as much as 6 wt% Si has been added to P/M silicon iron alloys. Soft magnets should be processed from single-phase compositions of high purity.

If second phases form, the structure-sensitive magnetic properties can be affected over time from aging. At the elevated temperatures required to sinter the parts, iron can dissolve considerable carbon or nitrogen into the structure, which consists of austenite (γ -phase). After sintering and cooling, the structure-sensitive properties can appear to be unaffected. However, over time in service, the properties degrade as a result of the nitrogen or carbon precipitating from solution. Some carbon or nitrogen can also be trapped in the iron, or a reversible action can occur. The net result is a degradation of the structure-sensitive magnetic properties over a period of time (aging). If the alloy is cooled rapidly after sintering, the carbon or nitrogen is trapped in solution in the iron, which in turn strains the iron lattice, causing degradation of the structure-sensitive magnetic properties. This latter effect is small, but it occurs nonetheless.

Magnetic Materials and Properties for Powder Metallurgy Part Applications

Kenneth H. Moyer, Magna-Tech P/M Labs

Magnetic P/M Materials

Most P/M materials are designed for soft magnetic properties with little or no retentivity--that is, if they are magnetized in a magnetic field and then are removed from that field, they lose most, if not all, of the magnetism they exhibited while in the field. Magnetically soft materials that are produced in large quantities include high-purity iron, low-carbon steels, silicon steels, iron-nickel alloys, iron-cobalt alloys, and soft-magnetic ferrites.

In contrast, permanent magnets are normally used in a single magnetic state and have stable magnetic fields. Permanent magnet materials include a variety of metals, intermetallics, and ceramics. Commonly included are certain steels, Alnico, CuNiFe, Fe-Co alloys containing V or Mo, Pt-Co, hard ferrites, and cobalt-rare earth alloys. Only a few P/M alloys are useful as hard magnetic materials. In this regard, the major alloy is Fe-Nd-B rapidly solidified powders.

This section briefly describes the common soft magnetic P/M alloys including high-purity iron Fe-2Ni, Fe-3Si, Fe-0.45P, Fe-0.6P, and Fe-50Ni. Table 3 compares the typical magnetic properties of P/M compositions. Values in Table 3 are only typical as considerable variability occurs in these properties, especially the magnetic force needed to demagnetize an alloy. Part of this variation is due to differences in sintered density, but impurity control is also a major factor. Like strength, the magnetic characteristics are sensitive to contaminants.

Table 3 Typical Magnetic properties of P/M alloys

Alloy	Resistivity, $\mu\Omega \cdot \text{cm}$	Maximum magnetization (B_{max}), T	Remanence magnetization (B_r), T	Coercive force, Oe	Maximum permeability
410L	90	1.2	4.1	3.5	960

Except for 400 series stainless steels at approximately 6.9 g/cm^3 , all others are high-density products over 7.4 g/cm^3 . Source: Ref 1

Pure Iron. Iron powder can be produced in many forms. All are magnetic, some more so than others. In early applications, sponge iron was used to produce magnets. The magnetic properties of these early magnets were not as good as those of current magnets because the sponge iron magnets contained as much as 2 wt% insolubles, generally in the form of oxides. Besides being impure, the sponge iron powder was also harder and therefore could not be compacted to densities above 6.2 g/cm^3 . Therefore, magnetic induction was limited, owing to the low sintered density. The structure-sensitive properties--permeability and coercive field--were limited by the impurities. If improved magnetic properties were required, either carbonyl iron or electrolytic iron was selected, at a great increase in cost of the powder.

Today, inexpensive water-atomized iron powder is readily available. This powder has <1 wt% impurities present, normally as surface oxides. Because the powder is pure, the structure-sensitive magnetic properties are greatly enhanced. In fact, these properties are governed by the sintering conditions that are provided. Given a quality sinter, there is no reason why these structure-sensitive magnetic properties will not equal those of the highest-purity wrought iron magnets.

In addition to water-atomized iron being pure, it is also soft because there are no hard inclusions present, and it is annealed under optimal conditions. As a result, water-atomized iron powder can be compacted to green densities approximately 6.8 to 7.2 g/cm^3 . With a conventional sinter of 1120°C (2050°F) for 30 min, magnetic properties listed as typical in ASTM specification A 811 can be attained (Ref 3). These magnetic properties are listed in Table 1. Also, listed in Table 1 are magnetic properties of other selected materials. The properties that are presented are not limiting, but they are those values that are achieved in present commercial parts. However, if the P/M parts are forged to remove the pores, the saturation magnetism of iron of 2.15 T (21,500 G) will be realized. Similarly, if parts are sintered at high temperatures $>1260^\circ\text{C}$ ($>2300^\circ\text{F}$), and they are held at temperature for long periods of time, maximum permeabilities of 350,000 and coercive fields as low as 0.8 A/m (0.01 Oe) are possible. The control is dependent on both grain growth and impurities within the material.

Iron is selected to produce parts because of the dimensional control that is realized when iron is sintered at 1120°C (2050°F) in standard belt furnaces for 30 min. These parts do not have the best magnetic properties but are adequate as inexpensive flux paths for magnetic devices. In reality, the P/M iron parts serve as inexpensive replacements for carbon steel parts. Properties are limited at these sintering temperatures because grain growth and sintered densities are limited by the limited diffusion at these sintering temperatures.

Phosphorus Irons. Although the attributes of alloying iron with phosphorus formerly were well known, wrought products, when hot rolled, became embrittled when phosphorus was alloyed with the iron in significant amounts. However, because phosphorus is normally admixed with water-atomized iron powder as $\sim 10 \mu\text{m}$ Fe_2P or Fe_3P powder, P/M technology can take advantage of phosphorus additions to iron. When compacted, the compressibility of the soft iron is realized without loss of green density because the hard, small $10 \mu\text{m}$ Fe_2P or Fe_3P particles rearrange themselves among the larger iron particles as compaction occurs. When sintered, the phosphorus iron intermetallic compounds melt at a temperature of 1050°C (1920°F) and diffuse into the iron, forming a solid solution of phosphorus in iron (Fig. 3). The liquid phase enhances diffusion rates and assists in the rearrangement of the pores and particle boundaries, thereby further densifying the iron. If a normal belt furnace sinter of 1120°C (2050°F) for 30 min is used, then sintered densities as high as 7.2 g/cm^3 can be realized (Table 3). If the sintering temperature is increased to 1260°C (2300°F), and the parts are sintered for 1 h in a partial pressure of hydrogen, a sintered density as high as 7.6 g/cm^3 can be realized. Because magnetic induction is a linear function of the sintered density, the magnetic induction realized from the phosphorus iron alloys is higher than that realized from pure iron parts. However, the drawback to the use of phosphorus iron parts is that, owing to the liquid phase sintering that occurs, dimensional control is more difficult. When sintered at 1120°C (2050°F) in belt furnaces, dimensional control is not too difficult because the normal phosphorus addition of 0.45 wt% provides what is commonly known as a zero-growth part. However, if the phosphorus content is increased to 0.8 wt% or if high-temperature sintering is specified to improve density and structure-sensitive magnetic properties, shrinkage becomes

greater and dimensions are more difficult to control. The problems with dimensional control and added cost of high-temperature sintering generally cause a compromise to be made between achievable magnetic properties and commercial manufacturing practice.

Fig. 3 Iron-phosphorous phase diagram. Source: Ref 5

From the iron-phosphorus binary phase diagram in Fig. 3, it can be seen that the maximum solubility of phosphorus in iron is ~ 1.5 wt%. Theoretically, phosphorus can be alloyed to this wt%; however in P/M technology, phosphorus additions to 2 wt% have been investigated (Ref 6). Increased alloying of phosphorus in iron results in several advantages to improve magnetic properties.

Resistivity is one physical property that is improved by alloying phosphorus with iron. If 0.45 wt% P is alloyed, resistivity is approximately doubled. If 0.8 wt% P is alloyed, the resistivity is approximately $24 \text{ m}\Omega \cdot \text{cm}$. Higher resistivity is required to minimize eddy current losses at low levels so that heat generation will not destroy the magnetic device. The low resistivities of the phosphorus irons do not enable these alloys to be used for most alternating-current applications. However, if 0.8 wt% P is used, then the phosphorus irons can be considered for some pulsed direct-current applications.

It is therefore readily understandable that phosphorus irons have become the workhorse for specification of material for magnetic parts. Depending on impurity content, sintering conditions, and heat treatment, these alloys can compete with most other P/M magnetic materials for demanding devices that require improved performance for direct current, and for many devices that require a pulsed direct current for application. Owing to low resistivity and the inability to produce thin sheet for laminations, the alloys are not normally considered for alternating-current applications. Typical magnetic properties of the two phosphorus iron alloys considered for current commercial applications are shown in Table 4.

Table 4 Typical-direct-current magnetic properties of phosphorous iron alloys

Property	Compacting pressure					
	0.45% P compacted at pressures of:			0.80% P compacted at pressures of:		
	410 MPa (30 tsi)	550 MPa (40 tsi)	685 MPa (50 tsi)	410 MPa (30 tsi)	550 MPa (40 tsi)	685 MPa (50 tsi)

Source: Ref 3

It is possible to enhance structure-sensitive magnetic properties (permeability and coercive field). If a 0.8 wt% alloy is sintered at 1260 °C (2300 °F) for 1 h in a partial pressure of hydrogen, maximum permeabilities of 15,000 and coercive fields as low as 55 A/m (0.7 Oe), are possible (see Moyer, 1990 in "Selected References"). These values are comparable to those of commercial 3 wt% silicon iron. In reality, even more improved structure-sensitive properties are possible if impurity products, such as carbon, nitrogen, oxygen, and sulfur are maintained at low levels, and heat treatment is provided to grow grains. However, practical difficulties (cost, time, dimensional control) prevent industrial application.

Ferritic Stainless Steels. The automotive market consumes approximately three-fourths of the P/M parts that are fabricated today. This statement is also true for direct-current magnetic parts. As newer applications emerge, magnetic part applications can involve higher operating temperatures and require improved corrosion resistance. The optimal material selection for these applications are the ferritic stainless steels. Although corrosion resistance is enhanced by this selection, the magnetic properties are sacrificed at the expense of this requirement.

Four ferritic stainless steels (409L, 410L, 434L, and 430L), are commercially available for magnetic applications. The 410L powder nominally contains 12 wt% Cr as an alloying addition. The 434L powder contains nominally 17 wt% Cr and 2 wt% Mo. The latter alloy is more corrosion resistant but more expensive. In addition, because magnetic induction depends on the quantity of iron present in the alloy, the magnetic induction of the ferritic stainless steels is lower than that of either iron or the phosphorus irons.

Most stainless steel powders are generally water atomized, although gas-atomized powders are used for parts made by the MIM process. Because of the solid-solution strengthening of chromium in the iron matrix, the powder particles are harder than iron powder, which limits compressibility. Therefore, sintered densities >7.2 g/cm³ are not common. The lower densities also limit the magnetic induction of these alloys.

Present state-of-the-art production generally requires a high-temperature sinter for these alloys to attain their best level of performance magnetically. For highest magnetic properties, the sintering temperature is normally 1260 °C (2300 °F) or greater for at least 1 h in either vacuum or hydrogen (Table 5). This sintering temperature is required because chromium oxides present on the surfaces of these water-atomized powders do not readily reduce at temperatures lower than 1260 °C (2300 °F).

DA, dissociated ammonia. Source: Ref 6

High-temperature sintering presents some problems in addition to increased cost. If ferritic stainless steel parts are high-temperature sintered, shrinkage of at least 1% is realized. These high shrinkage rates again make dimensional control difficult. Some parts fabricators therefore elect to sinter at either 1205 °C (2200 °F) or at 1230 °C (2250 °F) to reduce the problem of dimensional control. More recently, parts fabricators supplying parts to the automotive industry have even used belt furnaces to sinter ferritic stainless steels at 1150 °C (2100 °F). In all cases, lower temperatures result in lower sintered densities and higher oxygen contamination of the parts. This being the case, magnetic properties and corrosion resistance are sacrificed.

In addition to compromises with respect to sintering temperature, many parts fabricators elect to sinter in dissociated ammonia, nitrogen/hydrogen gas mixtures, nitrogen, exothermic, or endothermic gas. These atmospheres are rich in nitrogen, carbon, or both. Chromium in the ferritic stainless steel readily reacts with the components of these atmospheres to form carbides or nitrides in grain boundaries, thereby depleting the chromium protective film. These carbides or nitrides lower structure-sensitive magnetic properties and corrosion resistance and also decrease ductility.

50 Nickel/50 Iron. Nickel irons are usually the alloys selected when exceptional structure-sensitive properties are required. The alloy composition generally selected is 50 wt% Ni combined in solid solution with 50 wt% Fe. Although this alloy is most predominantly selected, nickel/iron combinations of all ranges have been selected for magnetic applications. Nickel irons are the most expensive of all the commonly used magnetic alloys today. The nickel irons are selected when fast response is required in magnetic properties. Fe-50Ni has a high maximum permeability (Table 3).

Because structure-sensitive magnetic properties are generally required, these alloys are normally high-temperature sintered at 1260 °C (2300 °F) or higher, in either vacuum or hydrogen, for at least 1 h (Table 6). These more demanding sintering conditions are necessary to promote diffusion of the substitutional elements (iron, nickel) and to aid grain growth and purification (removal of carbon, nitrogen, oxygen, and sulfur). If the above conditions are met, relative maximum permeability as high as 10,000, and a coercive field as low as 15 A/m (0.2 Oe) are possible in the as-sintered condition.

These alloys, however, are sensitive to heat treatment. Generally, if annealing is required, the wrought practice of heating to a temperature of 1120 to 1175 °C (2050 to 2150 °F) in dry hydrogen for 4 h is employed. Using this practice, the relative maximum permeability can be increased to 21,000; however, the coercive field is not changed. It must be stressed at this point that further work on heat treatment is needed to improve the structure-sensitive magnetic properties of the P/M alloy and make them comparable to the wrought product. Typical magnetic properties of the 50 nickel/50 iron alloy are shown in Table 6.

Silicon Irons. Wrought silicon irons have been selected for magnetic applications since the 1940s. These alloys normally contain 1.5 to 3 wt% Si. They are used primarily for motors, generators, and relays. Alloys containing from 3 to 5 wt% have found service in high-efficiency motors and in transformers. Barrett, Brown, and Hadfield in 1900 published a paper which stated that 2 to 2.5 wt% Si decreased the coercive field of the alloy to half that of iron. Silicon steels were first produced in Germany for commercial applications in 1903. Commercial silicon iron was also produced in the United States in the same year. Its features included increased permeability, lower hysteresis loss, lower eddy current losses owing to higher resistivity, and no aging.

The solubility of silicon in ferrite extends to \cong 16 mol% (Fig. 4). Although the solubility is high, providing an advantage of high resistivity, most wrought alloys are limited to 3 wt% Si because of the difficulty of deforming alloys containing greater additions of silicon.

Fig. 4 Iron-silicon phase diagram. Source: Ref 5

Although P/M magnetic parts had been fabricated commercially from 3 wt% silicon iron since the 1950s, only a few parts fabricators considered producing these parts. First, the silicon irons are made by admixing hard intermetallic compounds with a soft base iron matrix. In the case of the silicon irons, sufficient master alloy is added to yield 3 wt% Si upon sintering. Master alloys containing 17% Si can cause significant die wear.

In addition to an increased die wear problem, problems in sintering these alloys are also encountered. Silicon is even more readily oxidized than chromium. Therefore, high-temperature sintering is a must. If sintering temperatures below 1205 °C (2200 °F) are employed, the oxide film encasing the silicon master alloy is not reduced, and the master alloy particles do not diffuse into the ferrite, but they remain as small spheres within the basic ferrite matrix (Ref 8). A liquid phase develops (Fig. 4) below 1260 °C (2300 °F); therefore if a hydrogen atmosphere is employed as the protective atmosphere, the oxide film is reduced, and a proper sinter can be provided between 1260 and 1315 °C (2300 and 2400 °F). Because there is a large concentration of the master alloy present in the parts, sintering is rapid, and there is a danger of melting occurring if the sintering temperature selected approaches 1315 °C (2400 °F). Owing to the large amount of liquid phase that occurs, dimensional control is also more difficult and sizing may be required.

Provided that the parts fabricator is aware of the practical difficulties of processing silicon irons, enhanced magnetic properties can be realized from these alloys at reasonable cost. In addition to the above-mentioned disadvantages, the magnetic saturation of the silicon irons is lower than that of iron. Iron has a saturation magnetization of 2.15 T (21,500 G)

compared to 1.95 T (19,500 G) for Fe-3 wt% Si. Therefore, iron or phosphorus iron is a better choice for applications such as flux paths. However, the resistivity of a 3 wt% silicon iron is $\approx 65 \mu\Omega\text{cm}$, which is five times that of pure iron. High resistivity lowers hysteresis and eddy current losses. Therefore, if a pulsed direct current or a 60 Hz application is specified, the 3 wt% silicon iron is a logical choice for this application, provided that the part is not too thick. The only commercial P/M material with better structure-sensitive magnetic properties is 50 nickel/50 iron, but this is much more expensive. Typical magnetic properties of the silicon-iron alloy are shown in Fig. 5. Work continues to develop alloys with increasing silicon content for commercial applications.

Fig. 5 Magnetic properties of Fe-3%Si as a function of sintering temperature in dissociated ammonia. Source: Ref 7

Metal Injection Molding

Metal injection molding (MIM) is a process that has recently been developed to produce parts with complex geometry. Gas-atomized powders are normally selected to fabricate these parts because they are purer and finer. Iron and nickel powders produced by the carbonyl process are also widely selected. Gas-atomized and carbonyl powders are considerably more expensive than water-atomized powder. To date, the expense has restricted parts made by the injection molding process to those of a size less than that of a golf ball. However, as developments in this technology progress, there should be less restriction on the size of parts that can be produced using MIM. One part already being developed using MIM technology is a stainless steel magnetic fuel injector.

There is no restriction of the materials that can be selected to be metal injection molded, provided they are magnetic (alloys containing as base iron, nickel, or cobalt). Therefore, parts for magnetic applications have been made from all of the alloy systems discussed above. In addition, there is no restriction that limits development of new alloy systems for magnetic applications.

Normally, magnetic parts are produced from fine (10 μm) pure gas-atomized powders. These fine powders are mixed with a system of polymers to form a mixture with the texture of toothpaste when heated. The feedstock is then heated and injected under pressure into a die cavity that is of the geometry of the desired part. The molded part is heated to remove the polymers and then sintered. Some processing techniques may use a solvent to extract the binder prior to sintering. Nonetheless, MIM is not an easy process, and more detailed information is contained in the article "Powder Injection Molding" in this Volume.

For magnetic parts, much is to be gained by selecting MIM as the processing technology, provided that the increased cost can be justified. Because fine, pure powders and high-temperature sintering are normally considered in conjunction with MIM processing, densities approaching theoretical density are possible. Therefore, magnetic inductions close to saturation magnetic induction are possible. This means that magnetic inductions equivalent to those of wrought alloys are possible for alloys of similar composition. In addition, new alloys can be developed to take advantage of additional alloying elements that cannot be considered using wrought fabrication technology.

Although metal injection molded parts shrink much more than conventional P/M parts, dimensional control becomes less of a problem because the shrinkage is more uniform. The uniform shrinkage results because the part has uniform stress after injection and, if binder removal is done correctly, rearrangement of the particles occurs. Coupled with enhanced diffusion across pure reduced particle surfaces, this rearrangement results in a high-density part of more uniform dimensions.

The purity of the fine gas-atomized powders that are employed is also helpful in maintaining improved structure-sensitive magnetic properties. If the binder is removed properly and if the parts are sintered correctly, the relative maximum permeability and coercive field should equal those of the best processed conventional P/M parts. An added benefit is the magnetic induction should be equivalent to that of wrought parts, because the part density is so high.

A sampling of magnetic properties that are possible from MIM technology is shown in Table 7.

Table 7 Magnetic data on metal injection molded alloys

Alloy	Density, kg/m ³	Maximum induction (B_m), T	Residual induction (B_r), T	Coercive field (H_c), A/m

Magnetic Materials and Properties for Powder Metallurgy Part Applications

Kenneth H. Moyer, Magna-Tech P/M Labs

Optimizing Magnetic Properties

Powders. Most magnetic parts are fabricated from water-atomized metal powders. The major exception to this is metal injection molded parts, where gas-atomized powders are selected, as a rule. Because purity is important, carbon, nitrogen, and sulfur are maintained at very low levels if structure-sensitive magnetic properties are to be optimized. The major contaminant in the powders is oxygen in the form of surface oxides. In the case of ferritic stainless steel powders, as much as 2000 ppm of oxygen is concentrated on the surface of the water-atomized powders. Base iron powder normally contains 1000 ppm or less of oxygen. Gas-atomized powders contain even less oxygen. Nevertheless, these surface oxides must be readily reduced to provide a good sinter of the part.

The water-atomized powders are generally classified as -100 mesh powders and have a normal distribution. The gas-atomized powders, or the admixed additions, are normally 10 μ m in size. All additions must also be as free as possible of carbon, nitrogen, oxygen, and sulfur. Ferritic stainless steels and the 50 nickel/50 iron powders are prealloyed. In the case of the phosphorus irons and the silicon steels, alloying is accomplished by admixing the alloying components. For the phosphorus irons, generally a 10 μ m Fe₃P powder is admixed with the base iron powder, although a Fe₂P powder can also be selected as the alloying addition. Some practitioners have found, however, that Fe₂P powder is more abrasive and contributes to increased die wear. For the silicon irons, a master alloy containing \cong 17 wt% Si is generally selected as the alloying addition.

Compaction. Generally, parts are compacted to the highest green density possible because the magnetic induction is dependent on the sintered density. This is a linear function; the higher the density, the higher the magnetic induction. For flux paths, the higher the magnetic induction, the greater the amount of flux that can be carried in a given cross section. The limitation that normally controls the green density that can be achieved is the compaction pressure. Normally, most parts fabricators do not wish to use compaction pressures ≥ 620 MPa (>45 tsi) because tool breakage becomes a problem. High compacting pressures (1000 MPa) do not improve the magnetic properties of Fe-Si alloys (Ref 9). For certain applications with Fe-Si alloys, it is recommended to combine low compacting pressures and long sintering time (24 h) or medium compacting pressures (600 MPa) and short sintering time (2 h) (Ref 10). The density of complex or long parts also can vary appreciably within the cross section of the part. It is therefore important that the parts fabricator and the user agree on the critical density of the section of the part that is to be fabricated. Generally, green densities of 6.8 to 7.2 g/cm³ are desired.

Sintering. Of all the variables to consider in selection of the sintering conditions, the selection and control of the sintering atmosphere is the most critical. For example, dissociated ammonia is often used instead of hydrogen for cost reasons. This may introduce a contamination problem from the nitrogen in dissociated ammonia. When parts are sintered in dissociated ammonia, structure-sensitive magnetic properties can be seriously degraded (Table 8). In this example, rings fabricated from 0.45 wt% phosphorus iron were sintered in hydrogen, and companion rings were sintered in dissociated ammonia, at 1120 °C (2050 °F). As can be seen, contamination levels of both sets of parts are equivalent, except for nitrogen and oxygen contamination. Note that the sintered density of the parts sintered in hydrogen was higher. As a result, the magnetic induction of the parts sintered in hydrogen was also higher. The major changes in properties are seen in the structure-sensitive magnetic properties, relative maximum permeability, and coercive field. The relative maximum permeability of the parts sintered in hydrogen was doubled, and the coercive field was significantly lower. Minimization of carbon, nitrogen, oxygen, and sulfur is a must if structure-sensitive magnetic properties are to be achieved. Even if the proper sintering temperature is selected, magnetic properties will be severely degraded if the sintering atmosphere selection is incorrect.

Table 8 Effect of sintering atmosphere on magnetic properties

Property	0.45 mol % phosphorus iron 2050 °F	
	75H ₂ /25N ₂	H ₂
Carbon, %	<0.01	<0.01
Nitrogen, %	0.012	<0.0010
Oxygen, %	0.070	0.054
Sulfur, %	0.009	0.004
Density, g/cm ³	7.31	7.37
Induction at 15 Oe, kG	13.1	13.7
Residual induction, kG	11.4	12.6
Maximum permeability	2900	5100

Many kinds of sintering atmospheres are available. In most cases, cost is the prime consideration in the selection of the sintering atmosphere. Sintering atmospheres that can be considered include exothermic gas, endothermic gas, nitrogen, mixtures of nitrogen and hydrogen, dissociated ammonia, hydrogen, vacuum, and inert gas, such as argon. Of these atmospheres, exothermic and endothermic gases contain both carbon and nitrogen. If magnetic parts are sintered in these gases, carbon and/or nitrogen contamination are possible. If either occurs, magnetic properties are severely degraded.

Nitrogen, mixtures of nitrogen, and dissociated ammonia all contain some concentration of nitrogen. Nitrogen contamination can be most severe in magnetic parts because the nitrogen can be in solution in the ferrite or precipitated as nitrides. If in solution, the user may mistakenly believe that the magnetic properties are acceptable, only to find that with time and temperature of operation, the nitrogen has precipitated from solution as nitrides, and magnetic performance is severely degraded.

If structure-sensitive magnetic properties are a requirement, the choice of sintering atmosphere becomes hydrogen, vacuum, or an inert gas like argon. Of these, hydrogen is particularly recommended because hydrogen reduces carbides, nitrides, and oxides. Therefore, if highest purity of the part is desired, hydrogen is the choice. Vacuum or an inert gas is acceptable; however, the atmosphere is neutral and therefore does not assist in reduction of carbides, nitrides, or oxides. It is hydrogen that should be selected if structure-sensitive magnetic properties are required.

Iron and phosphorus-iron parts are normally sintered in belt furnaces at 1120 °C (2050 °F). For optimal magnetic properties, however, a high-temperature sinter at about 1260 °C (2300 °F) should be used. When high-temperature sintering is selected, shrinkage becomes a problem, and often the sintered parts must be sized to bring them to required dimensions. If sizing is required, the part is mechanically cold worked. An anneal should then be provided, if magnetic properties are to be optimized. Normally, parts sintered in belt furnaces will have sintered densities that range from 6.8 to 7.2 g/cm³. Parts that are high-temperature sintered can have sintered densities as high as 7.6 g/cm³. Many parts fabricators also use what is referred to as repressing to densify parts that require high magnetic induction. If this process is selected, an anneal must be provided or else magnetic properties are degraded.

Other factors to be considered in selecting a parts fabricator are more subtle. Contamination again is the problem. Many parts fabricators elect to sinter all parts in a common furnace. Because magnetic parts are more demanding in performance, parts fabricators that produce magnetic parts usually dedicate a furnace or furnaces to sintering only magnetic and stainless steel parts. Dedication of the furnace restricts the magnetic parts from becoming contaminated with carbon from other structural steel parts that may have preceded the magnetic parts. In addition to segregation of furnaces, some parts fabricators are also segregating presses to compact stainless steel parts. If parts containing iron powder precede the compaction of the stainless steel parts, there is the possibility of stray iron particles being embedded in the stainless steel parts. If this embedding of iron particles occurs, the stainless steel parts will not appear to be corrosion resistant because rust spots will develop in the parts contaminated with iron.

High-temperature sintering must be used if optimal structure-sensitive magnetic properties are required. High-temperature sintering permits grain growth and also helps to reduce impurities in the parts. Both must be achieved if structure-sensitive magnetic properties are a requirement.

High-temperature sintering of ferritic stainless steels, 50 nickel/50 iron, and silicon irons is always necessary if magnetic properties are to be optimized. Ferritic stainless steels contain chromium as the major alloying element. The powders are almost always water atomized and therefore contain 2000 ppm O₂ as surface oxide. This oxide is a protective Cr₂O₃ film. Unless a temperature in excess of 1205 °C (2200 °F) is achieved, there is little likelihood that the oxide film will be reduced and that adequate sintering will occur. In the case of the silicon irons, an SiO₂ oxide is on the surface of the master alloy particles. This oxide is even more difficult to reduce than the Cr₂O₃. It is therefore imperative that the silicon irons be sintered at a temperature of at least 1260 °C (2300 °F). The 50 nickel/50 iron alloy also requires a sintering temperature of at least 1260 °C (2300 °F). The alloy is strongly structure sensitive, and unless grain growth occurs and the alloy is cooled properly, structure-sensitive properties will be degraded.

Magnetic Materials and Properties for Powder Metallurgy Part Applications

Kenneth H. Moyer, Magna-Tech P/M Labs

Effects on Magnetic Properties

Porosity and all kinds of impurities in the form of inclusions generate the same magnetic interactions as small-size air gaps inside ferromagnetic materials. Their effects include demagnetization and shifting of magnetic domain borders during magnetization. Residual stresses may also degrade the magnetization characteristic of the sintered part. These general factors are summarized here.

Alloying. As previously noted, cobalt, iron, and nickel are the base elements for any alloy in magnetic applications. Other elements can be included to provide special properties, but the addition of other elements reduces the saturation magnetization. The addition of 0.45 or 0.8 wt% P does little to reduce the saturation magnetization of iron. In general, phosphorus lowers the magnetic induction by about ~0.05 T (500 G) (Fig. 6). In contrast, an addition of 3 wt% Si lowers the saturation magnetization to 1.95 T (19,500 G).

Fig. 6 Magnetization curves for hot repressed iron-phosphorus alloys. Source: Ref 12

Effect of Porosity. Most magnetic parts that are manufactured contain some degree of porosity. If no pores were present in the material and a proper sinter were provided, the magnetic induction and the remanent magnetization should be equivalent to a wrought product of comparable composition. Pores are merely an absence of material that is available to be magnetized. Therefore, the magnetic induction and the remanent magnetization decrease linearly as the amount of porosity increases. This behavior is shown in Fig. 7(a) for iron sintered at 1260 °C (2300 °F) in hydrogen atmosphere for 1 h. The effect of density on magnetic properties of sintered iron is shown in Fig. 7(b) and 7(c).

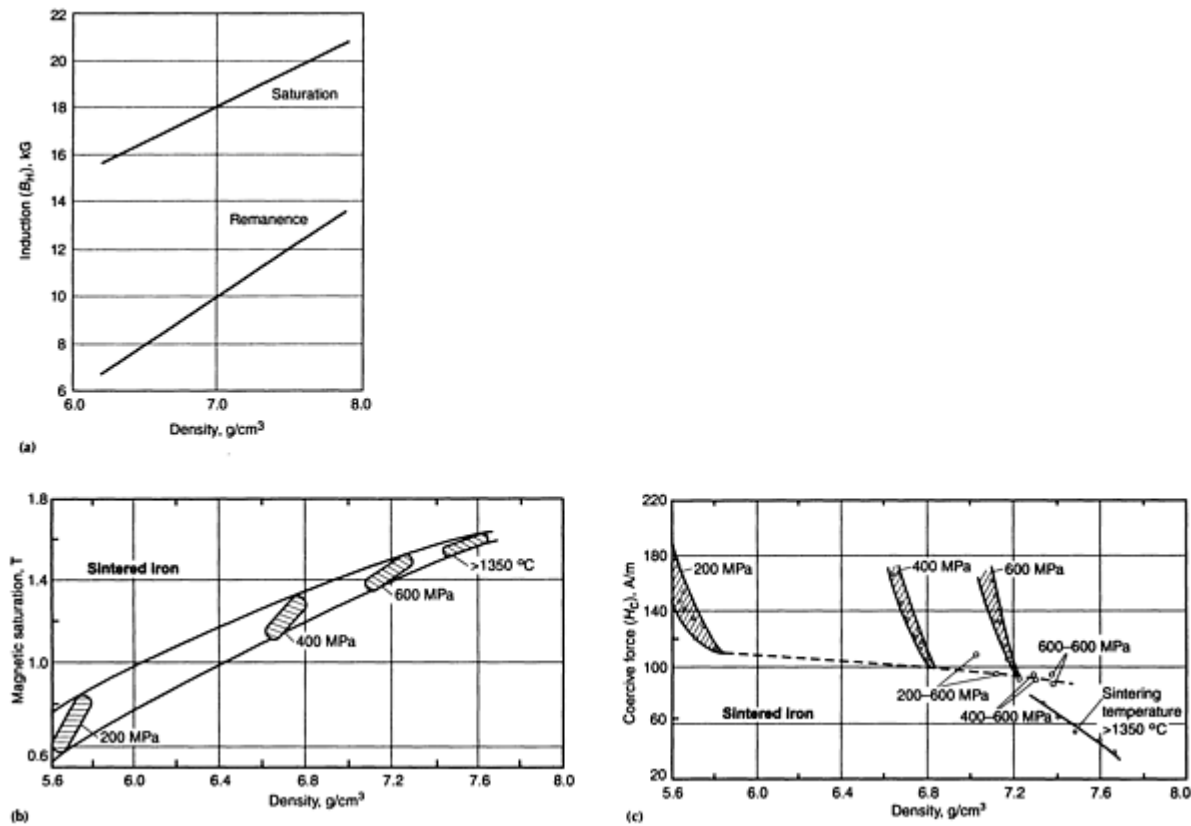

Fig. 7 Density effects on magnetic properties. (a) Effect on magnetic induction and remanent magnetization (1260 °C sinter/1h/H₂). (b) Magnetic saturation. (c) Coercive force of sintered iron as a function of density and sintering density (hatched areas indicate identical compaction but varying sintering times from 0.5 to 16 h and temperature from 1100 to 1300 °C). Source: Ref 10, 11

Purity. The major impurities in magnetic materials that degrade magnetic properties include carbon, nitrogen, oxygen, and sulfur. Small amounts of any of these impurities can severely degrade structure-sensitive magnetic properties. Most water-atomized powders, as well as sintering furnaces, are relatively free of sulfur contamination. Therefore, sulfur is not discussed in detail as a contaminant.

Oxygen is normally overlooked as a contaminant because oxygen is not a contaminant in wrought steels. However, powders are mainly water atomized and have large surface area. Oxygen then becomes a major problem in P/M alloy magnets. In iron and phosphorus iron, oxygen can be reduced to relatively low levels. To best accomplish this, hydrogen should be selected as the furnace atmosphere, and high-temperature sintering should be considered. The curve shown in Fig. 8 shows the effect of sintering temperature on oxygen reduction for parts that were sintered in hydrogen.

Fig. 8 Effect of sintering temperature on oxygen content. Source: Ref 12

Oxygen contamination in silicon irons and stainless steels is most troublesome. High-temperature sintering is mandatory if any reduction is to be achieved. Hydrogen as a furnace atmosphere is also a must, or else no reduction of oxygen will result. Unless oxygen is reduced, the customer has wasted his money paying for these two special-purpose alloys. In ferritic stainless steel, structure-sensitive magnetic properties equivalent to wrought ferritic stainless steels are possible through high-temperature sintering in hydrogen. However, corrosion resistance may not be adequate for some applications. For silicon irons, the SiO_2 film surrounding the master alloy particles are not reduced, and the silicon does not enter into solid solution in the ferrite.

Carbon is generally introduced into the part by improper burnoff of lubricant, furnace contamination, or choice of an exothermic or endothermic atmosphere. Most fabricators of magnetic parts use dedicated furnaces for sintering magnetic parts and select protective atmospheres that do not include carbon. However, most part fabricators burn off lubricant in the preheat section of the sintering furnace. If a belt furnace is employed, the belt speed is fixed by the length of the hot zone of the furnace. If large parts are sintered, the speed may be too fast to permit all of the lubricant to void from the part, resulting in carbon entrapment within the part. This entrapment of carbon is generally the reason for carbon

contamination in currently used parts. However, most parts fabricators that produce parts for magnetic applications are well aware of this and generally avoid contaminating parts with carbon.

Carbon contamination can occur when furnaces are not dedicated to sintering of parts that do not contain carbon. In addition, green parts contain lubricant. Unless this lubricant is completely voided from the parts, carbon contamination results.

Figures 9, 10, 11, and 12 demonstrate the effect that a small quantity of carbon can have on magnetic properties. The example is of a furnace that had previously been used to sinter parts containing carbon prior to sintering magnetic parts. The example can also serve for situations where small amounts of lubricant are trapped in the parts, owing to improper burnoff. The data are inclusive for both iron and phosphorus irons. Figure 10 shows that this small amount of contamination does not have a serious effect on the magnetic induction because the amount of iron available for magnetization controls. However, Fig. 10, 11, and 12 show the effect on structure-sensitive magnetic properties. As little as 0.03 wt% C seriously degrades these properties.

Fig. 9 Effect of carbon pickup on induction. Source: Ref 11

Fig. 10 Effect of carbon pickup on remanent magnetization. Source: Ref 11

Fig. 11 Effect of carbon pickup on permeability. Source: Ref 11

Fig. 12 Effect of carbon pickup on coercive force. Source: Ref 11

Nitrogen is another contaminant that damages structure-sensitive magnetic properties. As with carbon, the solubility of nitrogen is of the order of 0.006 wt%. Any amount greater than this causes nitrides to precipitate from solution. However, at common sintering temperatures, the amount of carbon and nitrogen that can be in solution in iron is greatly increased. On cooling, this amount of carbon or nitrogen cannot be maintained in solid solution, and therefore with time carbides or nitrides precipitate as a second phase. When this happens, structure-sensitive magnetic properties are severely degraded. Generally, selection of the protective sintering atmosphere is the main cause for nitrogen contamination. If structure-sensitive magnetic properties are required, nitrogen, nitrogen hydrogen mixtures, and dissociated ammonia should not be considered as the furnace protective atmosphere.

Nitrogen from these furnace atmospheres is the main cause of nitrogen contamination in iron, phosphorus irons, and ferritic stainless steels. It is to be remembered that nitrogen is not reducing like hydrogen. Therefore when nitrogen is selected, not only does nitrogen contamination result, but surface oxides are not reduced either (Fig. 13). The effect on iron-base alloys of nitrogen contamination resulting from nitrogen/ hydrogen mixtures is shown in Fig. 14.

Fig. 13 Effect of nitrogen base atmospheres on reduction of oxygen. Source: Ref 11

Fig. 14 Nitrogen content of compacts sintered in nitrogen-base atmospheres. Source: Ref 11

Aging Effects. Both carbon and nitrogen have an effect on magnetic properties after aging. Sometimes a part can behave like a high-purity part after sintering because, at elevated temperatures such as those selected to sinter iron or phosphorus iron parts, large concentrations of carbon or nitrogen can enter into solid solution in the austenite and form carbides or nitrides as the material cools. At room temperature, only 0.008 wt% C and only 0.006 wt% N can remain in solution in the ferrite. A slow cooling rate permits precipitation of the carbides or nitrides; magnetic properties are degraded, and the parts may be rejected. With a fast cooling rate, carbon or nitrogen can be retained in solution. In this case, the magnetic properties are not degraded, and the user can mistakenly believe that the part has acceptable magnetic properties. With time and temperature in service, the carbides and nitrides precipitate from solution, thereby degrading magnetic properties.

Two kinds of tests are employed to detect whether aging will occur in magnetic parts. An accelerated test heats the parts for 100 h at 150 °C, with a retest for magnetic properties. The alternative test heats the parts for 600 h at 100 °C and retest. Figures 15, 16, 17, and 18 show the effects on magnetic properties of aging times at 100, 150, and 200 °C for materials sintered in nitrogen/hydrogen mixtures. Contamination does not appreciably affect the magnetic induction and residual induction (Fig. 15, 16). However, structure-sensitive properties (relative maximum permeability, coercive field, and residual induction) are significantly affected if parts are contaminated with carbon or nitrogen (Fig. 17, 18).

Fig. 16 Effect of aging on the residual induction of iron compacts. Source: Ref 11

Fig. 17 Effect of aging on the maximum permeability of iron compacts. Source: Ref 11

Fig. 18 Effect of aging on the coercive force of iron compacts. Source: Ref 11

Effect of Residual Stresses. Secondary operations include any machining operation, sizing, and repressing. If any of these operations are required, mechanical stresses are induced into the alloy. Mechanical stresses degrade structure-sensitive magnetic properties. Therefore, an anneal is required to eliminate any mechanical stresses that may have been induced during secondary processing. Most parts fabricators have furnaces that are operating at the selected sintering temperatures. The parts fabricators simply reprocess the stressed parts a second time through the sintering furnace. For optimal magnetic properties, however, the protective atmosphere must be hydrogen.

Initially, when a part is evaluated for production, it is not produced to shape because dies are expensive. Rather, a slug similar in size to the part is compacted, sintered, and machined into the dimensions of the part. Machining induces mechanical stresses that degrade magnetic properties (Fig. 19). Unless the machined parts are annealed to remove the mechanical stresses, the measured magnetic properties will not be representative of the sintered part that will ultimately be produced. The misleading data can often result in extra expense owing to specification of excessive copper windings, weight, or permanent magnet requirements needed to activate the magnet.

Property	As machined	845 °C (1550 °F) annealed	1120 °C (2050 °F) annealed
Carbon	0.029	<0.01	<0.01
Nitrogen	0.017	0.0079	<0.0010
Oxygen	0.18	0.090	0.039
Sulfur	0.014	0.013	0.007
Magnetic saturation, kG	18.9
Induction at 15 Oe, kG	10.0	11.9	12.1
Remanent magnetization, kG · Oe	8.5	10.8	11.2
Maximum permeability, kG · Oe	0.8	2.5	3.6
Coercive force, Oe	5.0	2.3	1.5

Fig. 19 Magnetic properties of iron cores after annealing treatment. Source: Ref 11

Effect of Surface Treatment. Most ferrous magnetic parts are normally coated for corrosion resistance prior to service. Normally electroless nickel is used because nickel does not degrade magnetic properties. Prior to plating, the porous parts are infiltrated with a polymer to seal the porosity. Other elements can be used for plating as well, such as zinc. Because the plate is thin, magnetic properties are not degraded significantly. However, some parts fabricators prefer to steam treat, carburize, or nitride magnetic parts. In these instances, the surface of the part becomes contaminated and magnetic performance suffers.

Contrary to soft magnetic materials, permanent magnets cannot be easily demagnetized once they are magnetized. They provide a steady magnetic field and are unaffected by stray fields.

Permanent magnets are characterized by a high coercive force (H_c) and residual induction (B_r). These alloys are processed to provide the maximum energy product, which is the numerical value of $B_x \cdot H_x$ in the second quadrant (top left) of the hysteresis curve (Fig. 20). The energy product is measured by fitting the largest rectangle to the demagnetization curve, found in the second quadrant of the hysteresis loop (Fig. 20). It is normally expressed as the product $(B_d H_d)_{\max}$ and determines the quality of the permanent magnet. Higher contents of iron, cobalt, or nickel result in magnetization. Highest saturation is found in the iron cobalt alloys. The ability to resist demagnetization is of utmost importance. In this case, unlike soft magnets, precipitates, mechanical strain, material imperfections, and fine particles are all desirable in the microstructure.

Hard Ferrites. There are two kinds of ferrites: hard and soft. This section discusses only hard ferrites. Hard ferrites usually have a general formula of $MO \cdot 6Fe_2O_3$ and have a hexagonal structure. Two hard ferrites, barium ferrite ($BaO \cdot 6Fe_2O_3$) and strontium ferrite ($SrO \cdot 6Fe_2O_3$) are available. The latter is generally favored for current applications.

The ferrites are produced by blending Fe_2O_3 with SrCO_3 and other additives. The blend is then calcined to form a hexaferrite. The hexaferrite is wet milled and then either wet or dry pressed in a magnetic field. The green part is then

dried, fired in air, ground, and inspected. Even today almost 90% of permanent magnets are made from ferrites, because of their low cost.

Many ferrite applications require only polymer-bonded magnets. In this case, the magnetic powder is blended with various polymers. The mixture is then rolled into a sheet, cured, and slit or punched into a desired shape. If the polymer selected is a nitrile rubber, flexible magnets are produced.

Permanent hard ferrite magnets are selected mainly because of their low cost. Although they have only a moderate flux field, they have a high resistance to demagnetization. They are brittle and have moderate temperature stability. Hard ferrite magnets are used in loudspeakers, generators, relays, motors, telephone ringers, receivers, door closers, seals, and latches.

Alnicos. The Alnicos consist of a family of alloys containing aluminum, nickel, and cobalt. Next to the ferrites, these alloys are the most widely used today, again, owing to low cost. The alloys have a high-energy product, of the order of 39.8 to 71.6 kJ/m³ (5 to 9 MG · Oe), a high remanent magnetization of 0.7 to 1.35 T (7 to 13.5 kG), and a moderate coercivity of 40 to 160 kA/m (500 to 2010 Oe). The alloys are iron base with additions of aluminum, nickel, cobalt, and about 3 wt% Cu. Titanium is also alloyed with the high coercivity alloys.

In the case of the sintered alloys, the alloying elements are blended, compacted, delubed, sintered, heat treated, thermal aged, and surface finished. They can be compacted to very close tolerances and sintered to high strength. The alloys are extremely temperature stable, and magnetic orientation can be changed through a reheat treatment process.

Rare-Earth Alloys. Rare-earth magnets have maximum energy products up to 240 kJ/m³ (30 MG · Oe) and coercivities to 3200 kA/m (40 kOe). SmCo₅ single-phase magnets are widely used. The high coercivity of the rare earths is based on nucleation and pinning of domain walls at surfaces and at grain boundaries. Therefore, powders milled to particle sizes ranging from 1 to 10 μm are used for the alloy composition. The blended fine particles are compacted into a green part in a magnetic field, sintered, heat treated, machined to size, coated, and magnetized. Typical energy products range from 130 to 160 kJ/m³ (16 to 20 MG · Oe) with proper processing.

In precipitation-hardened Sm(Co, Cu)_{7.5}, copper is substituted for some of the cobalt. This produces a fine, coherent precipitate (~10 nm) when aged at 750 to 930 °F (400 to 500 °C). The coherent precipitates pin domain walls at the fine-precipitated particles. Again, a magnetic field can be employed in conjunction with the compacting cycle to align the magnetic field with the applied field. Additions of small amounts of iron and zirconium can further increase the coercivity.

Rare-earth magnets are used in medical devices, such as thin motors in implant pumps, valves, and in aiding eyelid motion. Rare-earth magnets are also used in electronic watches and traveling wave tubes. Direct-current and synchronous motors and generators include rare-earth magnets for size reduction. The reasons for usage include high flux density, high coercive field, high energy for size, and temperature stability.

Neodymium Iron Boron. Neodymium is also a rare-earth element. However, it is more abundant and less costly than other rare earths. An alloy close to the composition of Nd₁₅Fe₇₇B₈ is melted and then rapidly solidified by casting the molten stream on a cold rotating disk. This rapid solidification produces a thin, amorphous ribbon. The ribbon, in turn, is chopped and crushed into 200 μm particles. The finer particles, being less stable, can oxidize and create a fire hazard. The particles can be bonded with polyamides and injection molded to form magnets. The bonded magnets can have a maximum energy product of typically 95.5 kJ/m³ (12 MG · Oe), a residual induction of typically 0.76 T (7.6 kG), and a coercive field of typically 501 kA/m (6.3 kOe).

The crushed powder can also be formed into dense magnets by hot pressing. These magnets may have a maximum energy product as high as 60 MG · Oe. Disadvantages are that the alloy has a maximum operating temperature of only 170 °C, and the magnet must be coated for corrosion resistance.

Typical magnetic properties of the bonded and of the sintered magnets are shown in Fig. 21. Demagnetization curves are shown in Fig. 22. Uses for the bonded magnets are shown in Fig. 23. Automotive applications are listed in Table 9. Household applications of magnets include numerous devices for products such as air conditioners, electric shavers, garage door openers, lawn mowers, refrigerators, video cassette recorders, and washers and dryers.

Ferromagnetic Cores

Ferromagnetic cores are used for alternating-current applications where the frequency is high, generally within the kilohertz or the megahertz range. Iron, soft ferrites, or molybdenum Permalloy powder (B&D Industrial & Mining Services, Jasper, AL) have generally been used for these applications. Applications include power supply transformers, audio transformers, alternating current and radio-frequency filter inductors broadband RF transformers, narrow-band RF transformers and damping networks. Cores are generally produced in the form of rods, toroids, pot cores, and other forms.

The purpose of the core is to generate as high a magnetic flux as possible. Thus the induction B should be as high as possible, and the permeability should be high as well. Besides magnetic qualities, however, eddy current losses are also a critical concern at high frequencies. Therefore, particles should be as fine as possible, and insulation of particles is critical.

At high frequencies, eddy currents losses are a problem by the relation:

$$E \text{ (loss)} = \frac{k f^2 B^2 t^2}{\rho}$$

where f is frequency; B , flux density; t , thickness; ρ , resistivity; and k , a constant. Because thickness is also a squared term within the equation expressing the eddy current losses, it is imperative that fine particles be used for these applications and that each particle be adequately insulated. The other variable that can be controlled is the resistivity of the material. Because the resistivity is a reciprocal of eddy current losses, the resistivity should be as high as possible.

The form specified by the designer dictates the power level of the circuit in which the core is used, physical dimensions of the assembled transformer or inductor, and fabrication time. Generally, core assemblies use insulated bobbins to contain the windings for high-volume production. Pot cores, U cores, and I-E cores are generally used for these applications. Choice between core material is usually iron powder or ferrite. Because ferrites are easier to saturate, they are generally selected for direct-current to direct-current converters and magnetic amplifiers. The permeability of ferrites is also higher than that of iron, which permits an upper range of 90. With ferrite, it is possible to obtain a permeability as high as 5000. However, core temperature stability is also a requirement, and the greater the permeability, the more unstable the core will be at the higher frequencies. Stability is extremely important in circuits, such as narrow-band filters, narrow-band tuned transformers, and oscillators. Iron powder is a better choice for these applications because it offers a higher efficiency (Q factor), a low permeability, and therefore better stability over a wide range of flux levels and temperatures.

Iron powder cores consist of fine powders that are insulated from each other by a binder compound, such as a phosphate, which insulates the particles from each other. A lubricant can also be added to facilitate die compaction. The mix of coated particles is compacted into a desired shape at relatively high pressure to compact the core to the greatest density without disrupting the insulating coating. The core can then be baked to provide additional strength. The useful frequency range versus the Q of an inductor wound on the core is determined by the powder characteristics, size, and density. Extremely fine particles that distribute uniformly within the insulating coating permit application for very high frequency (VHF) applications and higher.

Recently, powder producers have modified the process by coating iron particles with a thin layer of an insulating thermoplastic. Coatings of the polymer are applied using fluid-bed technology. Hot powder compaction is then utilized to produce compacts with higher densities than cores made using prior technology. Strength for handling is also greatly enhanced by the new technology.

Typical magnetic properties of the warm compacted insulated powder are included in Table 10. Permeability, maximum induction, and resistivity vary as the amount of the insulating coating. At high frequencies, the polymer-insulated warm-compacted powder appears to have Q values and permeabilities that will provide competition for electronic circuits. Compared to laminations, however, the eddy current losses and the low induction for equivalent applied fields and frequencies limits the performance of these insulated powders in applications below 400 Hz.

Table 10 Magnetic performance data of plastic-coated iron powder

Material	Initial permeability	Maximum permeability	Coercive force, Oe	Induction at 40 Oe, G
SC120	120	425	4.7	11,200

Powder Metallurgy Electrical Contact Materials

Introduction

ELECTRICAL CONTACTS are metal devices that make and break electrical circuits. Contacts are made of either elemental metals, composites, or alloys that are made by the melt-cast method or manufactured by P/M processes. Powder metallurgy facilitates combinations of metals that ordinarily cannot be achieved by alloying.

A majority of contact applications in the electrical industry utilize silver-type contacts, which include the pure metal, alloys, and powder metal combinations. Other contact materials include copper, copper-base materials, platinum group metals, tungsten, molybdenum, and mercury.

This article describes the processing, properties, and performance of electrical contacts based on P/M or hybrid composite technologies with refractory metals and compounds. Copper-base P/M contact materials are described in the article "Copper Powder Metallurgy Alloys and Composites " in this Volume.

Powder Metallurgy Electrical Contact Materials

Tungsten and Molybdenum

Most tungsten and molybdenum contacts are made in the form of composites with silver or copper as the other principal component. Tungsten, which was one of the earliest metals other than copper and silver adopted for electrical contact applications, has the highest boiling point (5930 °C, or 10,700 °F) and melting point (3110 °C, or 5625 °F) of all metals; it also has very high hardness at both room and elevated temperatures. Therefore, as a contact material, it offers excellent resistance to mechanical wear and electrical erosion. Its main disadvantages are low corrosion resistance and high electrical resistance. After a short period of operation, an oxidized film will build up on tungsten contacts, resulting in very high contact resistance. Considerable force is required to break through the film, but high pressure and considerable impact cause little damage to the underlying metal because of its high hardness. Tungsten contacts are used in switching devices with closing forces of more than 20 N (4.5 lbf) and in circuits with high voltages and currents not more than 5 A, such as automotive ignitions, vibrators, horns, voltage regulators, magnetos, and electric razors. In low-voltage dc devices, tungsten is always used as the negative contact and is paired with a positive contact made of precious metal.

Tungsten rods or strips that are consolidated by swaging or rolling from sintered powder compacts have very poor ductility. They cannot be cold worked, in contrast to other contact materials. Tungsten disks are usually cut from rods or punched from strips and then brazed directly to functional parts such as breaker arms, brackets, or springs.

Properties such as grain size, grain configuration, and the degree of fibrous structure, which affect contact behavior, are controlled by using special swaging methods and annealing cycles. Tungsten disks usually are supplied with a ground finish, but they can also be electrochemically polished to obtain high-luster surfaces.

The high boiling and melting points of molybdenum--5560 °C (10,040 °F) and 2610 °C (4730 °F), respectively--are second only to those of tungsten and rhenium. Molybdenum is not used as widely as tungsten because it oxidizes more readily and erodes faster on arcing than tungsten. Nevertheless, because the density of molybdenum (10.2 Mg/m³, or 0.369 lb/in.³) is about half that of tungsten (19.3 Mg/m³, or 0.697 lb/in.³), use of molybdenum is advantageous where mass is important. Its cost by volume is also lower.

In addition to its use in make-break contacts, molybdenum is widely used for mercury switches because it is not attacked, but only wetted, by mercury.

Like tungsten, molybdenum strips and sheets are made by swaging or rolling sintered powder compacts. Disks made from rods or sheets are brazed to blanks of other structural components. Table 1 lists the properties of tungsten and molybdenum, and Fig. 1 and 2 show the effect of temperature or diameter on various properties.

Table 1 Typical properties of tungsten and molybdenum

Some of the physical properties of tungsten and molybdenum vary considerably with cross-sectional area and grain structure.

Tungsten	
Hardness, HRA (HV)	70 (385)
Modulus of elasticity, GPa (10^6 psi)	
At 20 °C (68 °F)	405 (59)
At 1000 °C (1830 °F)	325 (47)
Density, g/cm ³	19.3
Melting point, °C (°F)	3410 (6170)
Boiling point, °C (°F)	5900 (10650)
Specific heat, J/kg · K (Btu/lb · °F), at 20 °C (68 °F)	140 (0.033)
Thermal conductivity, W/m · K (Btu/ft · h · °F), at 20 °C (68 °F)	130 (75)
Coefficient of linear thermal expansion, μ m/m · K, at 20 °C (68 °F)	4.43
Specific resistance, n Ω · m, at 20 °C (68 °F)	5.5
Electrical conductivity, %IACS, at 20 °C (68 °F)	31
Molybdenum	
Hardness, HRA (HV)	58 (210)
Modulus of elasticity, GPa (10^6 psi)	
At 20 °C (68 °F)	325 (47)
At 1000 °C (1830 °F)	270 (39)
Density, g/cm ³	10.22
Melting point, °C (°F)	2622 (4750)
Boiling point, °C (°F)	4800 (8672)
Specific heat, J/kg · K (Btu/lb · °F), at 20 °C (68 °F)	270 (0.065)

Powder Metallurgy Electrical Contact Materials

Composite Materials

Composite electrical contacts are made from three categories of materials:

- Those that contain refractory constituents such as tungsten or molybdenum carbide
- Those that contain semirefractory constituents such as cadmium oxide, magnesium oxide, and tin oxide
- Those that contain elements (such as silver and nickel) that do not conventionally alloy, but which are formed by P/M processes to produce contact materials with unique properties

The various types of composite contact materials (Table 2) generally have a base material of silver, copper, or refractory metals and their carbides. The refractory-base and silver-base contacts are used in switching devices operated in air. Copper-base composite contacts are used in vacuum and oil-switching devices.

Table 2 presents the compositions and properties of various composite contact materials. Because manufacturing methods affect the properties of materials with the same composition, the manufacturing methods are also given in Table 2. The most common methods of producing composite electrical contact materials are described in the section "Composite Manufacturing Methods" in this article.

Data published by contact manufacturers usually include density, hardness, and electrical conductivity (Table 2). These data provide designers of electrical devices with the basic properties of a composite contact. Other properties, such as contact resistance, may depend on operational parameters such as force (Fig. 3).

Fig. 3 Contact resistance versus force for fine silver and Ag-CdO contacts. Unarced contacts were 12.7 mm ($\frac{1}{2}$ in.) in diameter with a 38 mm ($1\frac{1}{2}$ in.) spherical radius. Resistance measurements were made with ac current at 50 A and 60 Hz.

Characteristics that relate directly to failure modes such as arc erosion or material transfer are usually described in a qualitative manner. Very few quantitative data pertaining to these characteristics have been published because these properties depend on several test parameters. For instance, the arc erosion rate is affected by various mechanical factors:

- Opening force and opening speed
- Closing force and closing speed
- Bouncing of the movable contact
- Wiping distance
- Gap between opposing contacts

or electrical factors:

- Current--both amperage and whether ac or dc
- Voltage
- Power factor (inductive/capacitive)

Because each variable can greatly affect the arc erosion rate of a composite, it is virtually impossible to define a universal test to evaluate erosion rate.

Published data on erosion rate and welding frequency usually are collected under very specific conditions. They are valid only for qualitative description in a specific set of circumstances and cannot be extrapolated to suit other applications. The only means of learning how a composite will perform in a specific application is to test it extensively in the device in which it will be used. Examples of test data are given in Fig. 3, 4, 5, and 6.

Fig. 4 Contact erosion characteristics of silver and silver-tungsten contacts. Test conditions were 115 V, 60 Hz, and 1.0 power factor for 100,000 operations at 60 operations/min. Closing and opening speeds were 38 mm/s (1 $\frac{1}{2}$ in./s). Closing force was 980 mN (0.22 lbf) and opening force, 735 mN (0.165 lbf).

Fig. 5 Contact welding characteristics of silver and silver-tungsten contacts. Operation characteristics are the same as for Fig. 4.

Fig. 6 Results of short-circuit tests on silver-tungsten, silver-molybdenum, and silver tungsten carbide

Refractory Metal and Carbide-Base Composites

Refractory metals and their carbides are distinguished by high melting and boiling points and high hardness, but poor electrical and thermal conductivities and poor oxidation resistance. In pure elemental form, refractory metals perform well only under low-current conditions.

Forming a composite can compensate for these drawbacks. For example, the development of composite contact materials involving silver or copper with tungsten or molybdenum or their carbides has resulted in materials that can withstand higher currents and more arcing than other contact materials, without experiencing sticking or rapid erosion. The refractory metal content can vary from 10 to 90%, although 40 to 80% usually is used in air- and oil-immersed circuit breaker devices. Refractory metals offer good mechanical wear resistance and resistance to arcing. The silver and copper provide the good electrical and thermal conductivities.

Because silver and copper do not alloy with tungsten, molybdenum, or their carbides, P/M processes are required in fabrication. Depending on the composition, refractory metals containing silver or copper contact materials are made either by pressing and sintering or by the press-sinter-infiltrate method. When infiltration is used, either all refractory metal powder is compacted to shape, or a small amount of silver or copper powder is blended with the refractory metal, compacted, and sintered in a reducing atmosphere. The sintered compact is then returned to the furnace; silver or copper is added to act as the infiltrant.

Most infiltrated composite contacts use silver as the infiltrant because of its excellent thermal and electrical conductivities, as well as its superb oxidation resistance. Copper infiltrant, which costs less but has very poor corrosion resistance, is used for composites that operate in noncorrosive environments such as oil, vacuum, or inert atmospheres. At temperatures above the melting point of the infiltrant, the liquid metal penetrates and fills the interconnecting voids of the pressed-and-sintered compact. Densities of 96 to 99% of theoretical can be achieved by this process. Infiltrated contact materials find use as current-carrying contacts in air- and oil-immersed circuit breakers, heavy-duty relays, automotive starters, and switches. Lower properties can be obtained by pressing and sintering.

In a material made by infiltration, the function of the infiltrant (silver or copper) is twofold. First, because silver or copper does not alloy with tungsten, molybdenum, or carbides, the conductivity of the composite depends strictly on the volume percentage of infiltrant. Second, during arcing, the high temperature melts the infiltrant; consequently, the heat of fusion absorbs (quenches) a portion of the heat generated by the arc. Theoretically, the skeleton, which is made of a high-melting element, will not begin to melt until all the low-melting component evaporates. The refractory skeleton also prevents molten infiltrant from flowing by capillary action. Because of this, erosion loss of the contact is low. Properties (such as the erosion data in Fig. 4 and 6) of the contact vary with the composition of the composite. A composite with high skeletal composition has high hardness and better wear resistance, but lower current-carrying capacity. On the other hand, a high-silver composite possesses high electrical and thermal conductivities and undergoes lower temperature rise, but is softer.

Compositions of Refractory Component. There is a lower limit for the composition of the skeleton material. Generally, when the amount of refractory or carbide is less than about 30 vol%, it is difficult to form a sound and uniform skeleton to accommodate the amount of silver. For practical purposes, the skeleton material should amount to a minimum of 50 wt% for tungsten and molybdenum and 35 wt% for tungsten carbide. Any composite containing lesser amounts than these limits should be made by the press-sinter-re-press method and should be considered a silver-base composite in which the function of the refractory material is to reinforce the silver matrix. For compounds with 60% or less tungsten, the classical method of mixing the powders, pressing, sintering (generally below the copper melting point), and re-pressing might also be used. Materials with 60 to 80% W are generally produced by infiltration, either of loose tungsten powder or of a pressed-and-sintered tungsten compact.

Tungsten, tungsten carbide, and molybdenum powders are the most commonly used materials for making skeletons for infiltrated contacts. Composites with tungsten skeletons have the best arc-interrupting and arc-resisting characteristics and the best arc-erosion resistance. Their antiwelding properties are moderate (Fig. 5). High-energy devices usually use silver-infiltrated composites having a tungsten skeleton.

Composites with tungsten carbide skeletons have better resistance to welding, better anticorrosion properties, and more stable contact resistance compared with other infiltrated composites. Devices that handle switching arcs usually use composites based on tungsten carbide skeletons.

For a combination of properties, or sometimes for a special requirement, a skeleton made of a mixture of tungsten and tungsten carbide is used. The blended powder contains either the mixture of tungsten and tungsten carbide or a mixture of tungsten and graphite. In the latter case, the graphite and part of the tungsten react to form tungsten carbide during sintering.

Composites with molybdenum skeletons have relatively low contact resistance and behave well in circuit-interrupting devices. For the same current-carrying capacity, a molybdenum-base composite costs less than the other two, but the antiwelding and anticorrosion properties of molybdenum-base composites are inferior to those with tungsten or tungsten carbide skeletons. Figure 6 compares the erosion characteristics of a molybdenum composite with tungsten and tungsten carbide composites.

Silver-Base Composites

The main advantage of a silver composite over a silver alloy is that the bulk conductivity of a silver composite depends generally on the percentage of silver by volume. An alloying element in solution greatly decreases the conductivity of silver. For instance, the volume of silver in Ag-15CdO composite is less than that in Ag-15Cd alloy, yet the electrical conductivity of the former (65% IACS) is much greater than that of the latter (35% IACS).

In silver composites, the second phase forms discrete particles that are dispersed in the silver matrix. The dispersed phase improves the matrix in two ways. First, it increases the hardness of the composite material in a manner similar to dispersion hardening. Second, in the region where two mating contacts touch upon closure, the second phase particles reduce the surface area of silver-to-silver contact. This greatly reduces the tendency to stick or weld. In cases where the contacts do weld, the second-phase oxide particles (which are weaker and more brittle than silver) behave as slag inclusions and reduce the strength of the weld, allowing the device contact-separating force to pull the contacts apart.

Silver-base composites can be divided into two types: type 1 uses a pure element or carbide as the dispersed phase; type 2 uses oxides as the dispersed phase. In both types, the hardness increases and the conductivities decrease as the volume fraction of dispersed phase increases, and vice versa.

Silver-Base Composites with a Pure Element or Carbide. In type 1, the dispersed phase functions as a hardener and improves the mechanical properties of the silver matrix. The dispersed phase also promotes improved electrical performance such as antiwelding properties. Elements used include tungsten, tungsten carbide, molybdenum, nickel, iron, graphite, and mixtures of these materials.

Silver-Tungsten and Silver-Molybdenum Composites. Silver composites (made by the press-sinter-re-press method using tungsten, tungsten carbide, and molybdenum as the dispersed phases) show electrical conductivities similar to those of infiltrated composites of the same components. However, their mechanical properties are inferior because the dispersed phases do not form a refractory skeleton.

Silver-Nickel Composites. One of the elements typically combined with silver by P/M processes is nickel. Nickel is more effective as a hardening agent than copper; consequently, silver nickel is considerably harder than coin silver. At the same time, nickel does not increase contact resistance appreciably, particularly in combinations that include 15 wt% Ni or less. Silver nickel is combined in proportions ranging to about 40 wt%.

Composites with nickel as the dispersed phase resist mechanical deformation or peening under impact and possess good antiwelding properties. Silver-nickel composite contacts can be used as both members of a contact pair. Sometimes, a silver-nickel composite is used as the moving contact operating against a stationary contact of a different composite such as silver-graphite.

The combinations most widely used are 60Ag-40Ni and 85Ag-15Ni. These materials are very ductile and can be formed in all of the shapes in which silver contacts are used, including very thin sheets for facing large contact areas. This material is ideal for use under heavy sliding pressures. It does not gall like fine silver and coin silver, but instead takes on a smooth polish. It is therefore suitable for sliding contact purposes, as well as for make-break contacts. Silver nickel can handle much higher currents than fine silver before it begins to weld. It has a tendency to weld when operated against itself. Therefore, it is frequently used against silver graphite.

The 60Ag-40Ni composite is the hardest material in the silver-nickel series. It is the most suitable for sliding contact in which pressure is high. This alloy also has the lowest rate of wear under sliding action. It is less ductile than silver-nickel materials containing less nickel, but it is still sufficiently ductile for all conventional manufacturing processes.

The 85Ag-15Ni composite is the most widely used material in the silver-nickel series. Because of its ideal mechanical properties, 85Ag-15Ni is an ideal material for motor-starting contactors and is superior in this type of application to fine silver, coin silver, and copper. It is also suitable as a general-purpose contact for various types of relays and switches.

The contact resistance of clean 85Ag-15Ni contacts that have not operated under load tend to be slightly lower for fine silver. However, in make-break circuits, silver tends to gradually increase contact resistance. This increase is not necessarily permanent, as contact resistance varies with the effects of arcing on the contacts. Generally, average resistance is higher than the initial resistance before the contacts operate. The contact resistance of 85Ag-15Ni is similar, except that it usually varies within a narrower range. Exhibiting nearly constant contact resistance is more important than possessing low contact resistance.

85Ag-15Ni exhibits a lower contact resistance and is also harder than coin silver.

Another advantage of 85Ag-15Ni is its low flammability; that is, it makes a smaller arc than other materials. In testing of more than 40 contact materials, 85Ag-15Ni exhibited the lowest arc energy. Low arc energy is important in that the ability to break a circuit with as little flame as possible is desirable. This characteristic was primarily responsible for the adoption of 85Ag-15Ni for relays in aircraft electrical systems.

Silver-Graphite Composites. Graphite is also combined with silver by P/M techniques. Graphite in silver-base composites serves as a good lubricant, reducing the damage caused by frictional forces. Silver-graphite composites are used chiefly as sliding or brush contacts. These materials have high resistance to welding and are also used as make-break contacts. In circuit breakers, they are usually paired with silver-nickel composites.

The most frequently used composition is 95Ag-5C, although graphite compositions ranging from 0.25 to 90% with the remainder silver have been used. This material was developed as a circuit breaker contact material. The addition of graphite prevents welding. Frequently, 95Ag-5C is used in combination with silver-nickel or silver-tungsten contacts. It is also used in combination with pure nickel contacts and with fine silver contacts. Silver graphite is soft compared to other types of contact materials, and electrical and mechanical erosion is more rapid.

95Ag-5C has been widely used as a material for contacts in molded-case circuit breakers, sliding contacts, and contact brushes. This material is only moderately ductile and can be rolled into sheets and punched into contacts of various shapes. However, it cannot be headed to make solid rivets or bent to any great extent without cracking. It can be coined to a moderate extent. 95Ag-5C contacts can be individually molded. Depending on size, shape, and quantity, contacts of this material are either punched from rolled slabs, extruded, or individually molded from powders. Copper is combined with graphite as a substitute for silver in certain applications.

A modified form of silver graphite is silver-nickel-graphite. Typical compositions are 88Ag-10Ni-2C and 77Ag-20Ni-3C. These materials are substantially harder than 95Ag-5C and exhibit superior wear resistance, but offer less protection against welding. Like 95Ag-5C, they can be manufactured from slabs or by molding individually.

Composites of silver iron exhibit good antiwelding and good wear characteristics when used in creep-type thermostat devices. These materials have poor corrosion resistance.

Silver-Base Composites with Dispersed Oxides. Type 2 silver-base composites use semirefractory oxides as the dispersed phase. These silver-base composites are produced by a variety of methods such as internal oxidation, preoxidation, and conventional P/M processes (see the section "Composite Manufacturing Methods" in this article).

The semirefractory component of type 2 silver-base composites includes metal oxides such as CdO, SnO₂, or ZnO. In general, the semirefractory constituents promote nonsticking qualities or provide increased resistance to wear.

The Ag-CdO group of electrical contact materials is the most widely used of all the silver semirefractory contact materials. The addition of 5 to 15% CdO to silver imparts excellent nonsticking and arc quenching qualities.

Because of its resistance against arc erosion and its low contact resistance, which does not increase even after switching, Ag-CdO has proved to be a universally good contact material for many switching devices. Ag-CdO contact materials are well suited for contactors and motor starters, but are also used in circuit breakers, relays, and switches with medium to low currents.

Ag-CdO material has antiwelding and antierosion properties united with constant resistance, examples of its main advantage of well-combined properties. Another favorable quality is that it has good workability. It can be fabricated by either the internal oxidation (least costly), preoxidation, or P/M methods. The Ag-CdO material can also be cold reduced or rolled quite easily. For instance, Ag-15CdO material can endure more than 70% cold reduction.

Ag-SnO₂, which is used widely in Europe as a contact material, is a class of composite materials that has the potential to replace Ag-CdO composites in many electrical contact applications. However, general comparisons of Ag-SnO₂ contacts with Ag-CdO contacts are difficult because results may depend on the specific conditions of testing. Previous concerns on the toxicity of CdO, which was one of the motivations for using Ag-SnO₂ contacts, have also been relaxed in Japan and Europe. The toxicity of CdO must be distinguished from the highly toxic nature of cadmium.

Like Ag-CdO contacts, Ag-SnO₂ contacts can be produced by internal oxidation or P/M techniques. One drawback of the Ag-SnO₂ composite is that a third element (such as indium) must be added to achieve internal oxidation when the silver alloys contain more than 4% Sn. The oxidized material also does not allow a high level of cold reduction because of its brittleness. Therefore, a press-sinter-re-press method or extruded method is the most feasible way to fabricate Ag-SnO₂ although extruded products are more brittle than extruded Ag-CdO powder of similar compositions. For example, extended Ag-10SnO₂ can be subject to a maximum of 30% cold reduction compared to more than 60% for Ag-12CdO.

Another drawback is the higher-temperature rise of Ag-SnO₂ contacts (as compared to Ag-CdO) after arcing. This troublesome characteristic has, however, been eliminated with Ag-SnO₂ materials made by P/M methods.

Table 2 lists three grades of commercially available Ag-SnO₂ composite contact materials. Ag-SnO₂ contact materials cannot be easily brazed or welded. To be able to braze Ag-SnO₂ contacts, they are made with at least two layers, the contact layer and brazable or weldable fine silver layer. The brazing alloy can be applied separately in the shape of paste, wire, or foil, or it is already clad onto the semifinished product.

Ag-ZnO is another composite material that has been tested and marketed for contact applications. Ag-ZnO, like Ag-SnO₂ composite, cannot take high cold reduction because of the brittleness of the oxidized material. When internal oxidation is used, the maximum zinc content cannot exceed 6% for good oxidation. Typical applications of a commercially available Ag-ZnO composite are listed in Table 2.

Multiple-Component Composites. There is no ideal material to meet all conditions for contact applications. If required by manufacturers of switching devices, contact manufacturers can offer composite materials consisting of as many as four or five components. Most of these composites serve only special purposes. They are not universally accepted and generally cost more. Two common three-component composites are listed in Table 2.

Composite Manufacturing Methods

The methods used to manufacture composite contact materials can be classified into three major categories:

- Standard P/M processes, for producing composites from materials that cannot be conventionally alloyed
- Internal oxidation processes, for producing silver-base composites with dispersed oxides
- Hybrid consolidation, which is a combination of the internal oxidation and P/M consolidation processes

Powder Metallurgy Methods

Infiltration is used exclusively for making refractory metal and carbide-base composite contact materials. Metal powder or carbide powder is first blended to the desired composition with or without a small amount of binder to impart green strength, then is pressed and sintered into a skeleton of the required shape. Silver or copper is then infiltrated into the pores of the skeleton. This method produces the most densified composites, generally 97% or more of theoretical density. Complete densification is not possible because of the presence of some closed pores in the sintered skeleton. After infiltration, the contact is sometimes chemically or electrochemically etched so that only pure silver appears on the surface. The contact thus treated has better corrosion resistance and performs better in the early stages of use.

Press-Sinter. For small refractory metal contacts (not exceeding about 25 mm, or 1 in., in diameter), a high-density material can be obtained by pressing a blended powder of exact final composition into shape and then sintering it at the melting temperature of the low-melting-point component (liquid-phase sintering). In some cases, an activating agent such as nickel, cobalt, or iron is added to improve the sintering effect on the refractory metal particles. For this process, powders of much finer particle size are required so that more bonding surface exists. However, the skeleton formed by this process is weaker than that formed by the infiltration process. Formation of the skeleton usually shrinks the apparent volume of the refractory portion of the composition, thus bleeding out the molten component onto the surface of the finished contact.

Press-Sinter-Repress. The press-sinter-repress process is used for all categories of contact materials, especially those in the silver-base category. Blended powders of the correct composition are compacted to the required shape and then sintered. Afterward, the material is further densified by a second pressing (re-pressing). Sometimes the properties can be modified by a second sintering or annealing. The versatility of this process makes it applicable for contacts of any configuration and of any material. However, it is difficult to obtain material with as high a density as is obtained with other processes. Material thus produced also may have weak bonding between particles.

Press-Sinter-Extrude. Blended powder of final composition is pressed into an ingot and sintered. The ingot is then extruded into wires, slabs, or other desired shapes. The extruded material may be subsequently worked by rolling, swaging, or drawing. Material made by this method is usually fully dense.

The press-sinter-extrude process is used mostly for silver-base composites. Other processes used for manufacturing silver-base composite contacts are direct extrusion or direct rolling of loose powder. Although they appear to be uncommon, they are economically feasible if the equipment is properly designed and built.

Internal Oxidation

Silver-base composites with dispersed metal oxides can be produced by internal oxidation. In this process, a silver alloy (such as a silver-cadmium alloy) is first cast into ingots, which are rolled into strips or fabricated further into the finished product form. The silver alloy material is then heated in air or oxygen, so that the oxygen diffuses into the alloy and forms metal oxide particles (such as CdO in the case of a silver-cadmium alloy) dispersed in the silver matrix.

Internal oxidation is used in the production of a substantial portion of Ag-CdO composites. The initial silver-cadmium alloy can be internally oxidized either in strip or finished product form. The silver-cadmium alloy is heated between 800 to 900 °C (1470 to 1650 °F) in a furnace with air, oxygen-enriched air, or pressurized oxygen. Under this condition, the oxygen species diffuse into the silver-cadmium alloy and oxidize the cadmium species. Upon the completion of the

oxidation, the cross section of the material will display a microstructure of CdO particles embedded in a silver matrix. Contact parts are punched from the strip and then coined into required shapes.

The size of the CdO particles and the uniformity of their dispersion are dependent on the temperature and the partial pressure of oxygen. Reduced temperature decreases coalescence of cadmium prior to being oxidized and thereby causes a finer dispersion of CdO. Increasing the partial pressure of oxygen in the furnace increases the diffusion rate of oxygen into the silver. This also causes a finer CdO dispersion by reducing the time available for the cadmium to coalesce.

During the internal oxidation of a silver-cadmium alloy, the cadmium species become depleted in zones when the oxygen front moves into the silver-cadmium alloy. The cadmium atoms before the oxygen front immediately diffuse into the zone against the oxygen front. As the oxidation front moves from the surfaces of the strip toward the center, the concentration of the cadmium species becomes increasingly dilute as compared to the original composition. Hence, after the oxidation is completed, the cross section will display a significant oxide-deficient or oxide-depleted zone in the center of the contact body.

For some applications the presence of the depletion zone is detrimental, requiring its removal or displacement from the center. There are two common methods to achieve this result. In the first, an oxidation barrier, such as ceramic glaze, is applied to one surface so that the oxidation can proceed from only one side. The second method is to laminate two silver-cadmium sheets of the same size and to form a package by welding along the four edges. After oxidation, the sheets are separated. The oxide-deficient zone will appear on one side (the inner side of the package) of each sheet.

Package rolling is another technique for reducing the size of the depletion region. In this method, very thin silver-cadmium sheets are first oxidized. Then a number of sheets (for example, 16 sheets) are stacked together and hot-bond rolled into one slab. The cross section of the final product displays very thin depleted zones equal to the number of sheets.

Hybrid Consolidation

Various hybrid techniques use a combination of internal oxidation and P/M methods. These methods are used to produce a finer average oxide size and/or a more uniform distribution of cadmium oxides in the matrix of a Ag-CdO composite. Hybrid consolidation methods include preoxidized-press-sinter-extrude and coprecipitation. Table 3 compares Ag-CdO composites manufactured by different methods.

Table 3 Comparison of Ag-CdO material made by different methods

Properties	Press-sinter-re-press	Press-sinter-extrude	Internal oxidation	Preoxidize-press-sinter-extrude
Performance characteristics				
Resistance to arc erosion	3	2	1	1
Resistance to sticking and welding	1	1	2	2
Low contact resistance and temperature rise	1	1	1	1
Arc interruption	3	2	1	1
Resistance to corrosion	1	1	1	1
Material characteristics				
High mechanical properties	3	2	2	1
Resistance to annealing	3	2	2	1
Electrical and thermal conductivity	2	1	1	1
Flexibility of composition	2	2	2	1
Uniform cadmium oxide distribution	1	1	3	1

Note: 1 indicates that under most conditions this is the preferred material; 2 indicates that under most conditions the material is preferable to 3, but not as good as 1; 3 indicates that the material may be acceptable, but under typical operating conditions it is not as good as 1 or 2.

The preoxidized-press-sinter-extrude process combines the oxidation process and the press-sinter-extrude process. Commercially, it is called "preoxidized process." The purpose of this method is to redistribute the oxide-deficient center of Ag-CdO composites.

The preoxidized process is used exclusively for making Ag-CdO material. Alloys are reduced to small particles in the shape of flakes, slugs, or shredded foil. These particles are oxidized and then consolidated with the press-sinter-extrude process. Material made by this method is more uniform than the same material made by conventional internal oxidation. Mechanical properties are superior to those of the same material made by the press-sinter-re-press method.

The Ag-CdO particulates are made by one of four methods and then are pressed into ingots, sintered, and extruded according to standard metallurgical method. There are four processes to prepare the particulates:

- *Granulated wire:* Silver-cadmium alloy is first made into wire and oxidized. The oxidized wire is then chopped into granules with a length of about 3 mm ($\frac{1}{8}$ in.).
- *Low-pressure water atomization:* The molten silver-cadmium alloy is atomized by water at a pressure of 100 to 200 kPa (15 to 30 psi). The approximately quarter-inch particulates are in the form of thin twisted flakes. Then the flakes are oxidized for consolidation.
- *High-pressure water atomization:* The molten silver-cadmium alloy is atomized with high water pressure, usually higher than 2750 kPa (400 psi). The powder sizes range between 40 mesh (420 μ m) and 270 mesh (53 μ m). Then the alloy powders are oxidized before consolidation.

Coprecipitation. Conventional blending or mechanical mixing of silver and CdO powders begins by dissolving the proper amounts of silver and cadmium metals in nitric acid. Compounds of silver and cadmium coprecipitate from the solution when the pH value of the solution is changed by adding either hydroxide or carbonate solutions. During subsequent calcination at about 500 °C (930 °F), the compound mixture decomposes to form a mixture of silver and CdO. Alkali metal content can be controlled in the ppm range by adequate washing. Controlled amounts of sodium, potassium, and lithium may enhance electrical life. Excessive amounts of these elements can lead to rapid erosion, restrike, and generally poor electrical life. Depending on device design, the range may be from 10 to 300 ppm. Contacts are consolidated from this mixture by conventional P/M methods. The microstructure of contacts made by this method displays a finer particle size and a more uniformly dispersed CdO phase than material made by conventional blending.

Powder Metallurgy Electrical Contact Materials

Availability

Silver, gold, platinum, palladium, and most of their ductile alloys are available as stamped contacts. Except for material from which contact disks are produced, a variety of stock sizes are not maintained because, in general, no two applications are identical. For disks, material in strip form, varying in thickness from 0.25 mm to 1 mm (0.010 to 0.040 in.) is available.

Except for tungsten and molybdenum, contact materials are ductile enough so that they can be produced in all contact forms. Tungsten and molybdenum and some of the P/M materials have lower ductility and are available in fewer forms. The commercially available forms of common electrical contact materials are listed in Table 4.

Table 4 Commercially available forms of electrical contact materials

- (a) Contact disks attached to screws, rivets, blades, and bars.
- (b) Composite welding-type buttons produced for resistance welding attachment. Backings of nickel, Monel, and steel.
- (c) Clad materials including overlay, throughlay, edgelay, strip of precious metal on (or in) base metal

Silver, gold, platinum, palladium, and nearly all the alloys of these metals, as well as tungsten, molybdenum, and the various sintered products of silver and the refractory metals, can be used to produce steel-back contacts. Steel-back contacts have been made in the form of screws, rivets, or buttons for projection welding.

Powder metallurgy materials are available with final densities up to 99% of theoretical and with high-conductivity surfaces as inserts or overlays. Both P/M and wrought materials may be attached to appropriate carriers by brazing, welding, or diffusion bonding, even though they contain CdO. For percussion welding of Ag-CdO contacts, backing is not required. For resistance welding, a fine silver backing is needed.

Powder metallurgy contacts are available with a silver matrix for air and oil applications, and with a copper matrix for oil applications only. The second phase may be tungsten, molybdenum, graphite, tungsten carbide, CdO, or ZnO.

Materials with a high content of refractory metal (50% or more) are usually made by infiltration. In this process, the refractory metal powder is pressed into the desired size and shape with a controlled porosity. The compact is sintered at high temperature in a reducing atmosphere, and then molten silver or copper is infiltrated into the porous sintered compact.

Compositions of a lower refractory content are made by blending powders, pressing them to a desired size and shape, sintering the pressed compact at a high temperature, and re-pressing to size the parts and to increase the density of the compact.

Although parts usually are molded to final shape, they are sometimes finished by machining or grinding to obtain special shapes or unusually close tolerances. When only a few parts are needed, they may be machined from bars to save the cost of expensive dies for pressing a P/M compact.

Sintered materials are available in sizes ranging from rectangles or disks about 0.8 mm ($\frac{1}{32}$ in.) thick by 3 mm ($\frac{1}{8}$ in.) square or 3 mm ($\frac{1}{8}$ in.) in diameter to bars 200 mm (8 in.) long. Most are available in widths up to 75 mm (3 in.) and thicknesses up to 12.5 mm ($\frac{1}{2}$ in.). For some materials, these dimensions may be exceeded.

In small sizes (up to about 12.5 mm, or $\frac{1}{2}$ in., square), the higher refractory compositions are frequently made with serrated surfaces coated with excess silver or silver-base brazing alloy so that they can be attached easily to a backing by welding or by resistance brazing in a welding machine. Larger sizes are generally attached to backing by silver alloy brazing. The materials are often pretinned with silver-base brazing alloy in a controlled atmosphere for good wetting of the contact material.

Many of the low-refractory contact materials are fabricated as disks, rectangles, and special-contour facings that also are attached to backing by silver alloy brazing. Most materials with 90% or more silver are ductile enough to allow fabrication as rivets and to allow assembly by staking or spinning. Among silver-graphite materials, those containing more than 0.5% graphite cannot be satisfactorily cold headed into rivets.

Ag-CdO mixtures are available as round, rectangular, or special-shape facings, and also as rivets.

Porous Powder Metallurgy Technology

Mark Eisenmann, Mott Corporation

Introduction

THE TECHNOLOGY of fabricating lower density, porous P/M materials can fulfill a wide variety of applications. A rigid, permeable structure can be created using P/M technology by forming a network of sintered powder particles and interconnected pore channels. Using similar manufacturing equipment and technology as structural P/M components, porous P/M materials are normally sintered to densities between 25 and 85% of theoretical mean density (TMD). Structural P/M components are typically 85 to 99.9% of TMD. These unique engineered materials provide specialized products for applications such as filtration, fluid flow control, self-lubricating bearings, spargers, and battery electrodes.

Porous P/M materials are specified when special characteristics are required such as good mechanical properties, rigidity, corrosion resistance, uniform porosity, and controlled permeability. For example, porous bronze, stainless steel, or nickel alloys are often selected for service in elevated-temperature and pressure environments. Porous materials such as papers, synthetic fibers, and plastics are commonly selected for service in less severe conditions due to their lower cost (Ref 1). However, in applications where disposal costs are significant due to the nature of the service environment, renewable porous P/M materials offer excellent cleanability for economical reuse. Other porous metal materials made from sintered fibers, foam, perforated sheet, and screen may be selected as alternatives to porous P/M materials, depending on the application (Ref 2). Metal fiber/screen composites, foam/powder composites, screen/powder composites, and fiber/powder composites are also sintered to form porous media (Ref 3, 4, 5). Porous ceramics are utilized in applications

that require higher-temperature service or more extreme corrosion resistance than porous metals. However, porous ceramics are limited in their application because they have substantially lower mechanical properties than do metals and because of fabrication difficulties that result when joining to metal hardware (Ref 6).

Porous P/M materials accounted for about 2% of the overall P/M market based on market share by application. Approximately 70% of the overall P/M market is comprised of structural components for the automotive industry (Ref 7). Porous P/M materials are also estimated to account for less than 2% of the overall filtration and fluid control markets that are currently dominated by lower cost, disposable porous media. Despite the small market size currently served by porous P/M materials, this material science is an emerging technology driven by increased environmental concerns, improved product quality demands, and more complex processing of industrial products. The unique materials, characteristics, fabrication methods, and applications of porous P/M technology are summarized in this article.

Porous Powder Metallurgy Technology

Mark Eisenmann, Mott Corporation

Materials Selection

Materials can be selected from a wide variety of P/M materials, depending on the combination of application requirements and economics. The porosity is determined by the powder particle shape, the powder size distribution, the powder surface texture, and other powder characteristics that are dependent on the material processing method. Because the powder characteristics are one of the major factors in determining the porous material properties of the finished component, reproducible powder characteristics and manufacturing methods are critical to production of a consistent product.

The four most common porous P/M materials are bronze, stainless steel, nickel, and nickel-base alloys. Other materials such as titanium, aluminum, copper, platinum, gold, silver, iron, iron aluminide (Fe_3Al), niobium, tantalum, and zirconium are fabricated into porous materials from powder (Ref 8). The size distribution of the particles can be a direct result of the powder manufacturing process or can be altered by sieving or air classification techniques. The characteristics, sintering conditions, and commercial availability of a powder determine whether the desired material can be manufactured into a porous structure.

Bronze powders consisting of 89 to 90% Cu, 10 to 11% Sn, and 0.1 to 0.5% P are the most common material for porous bronze P/M components such as filters and self-lubricating bearings. Small amounts of phosphorous can be added to improve mechanical strength (Ref 9). Bearings can be produced from preblended elemental powder mixes or prealloyed powders. These 89/11 or 90/10 bronze powders are available from three main processes. Gas or air atomization of prealloyed bronze yields fine, spherical particles that can be processed to low densities by gravity sintering, as shown in Fig. 1. Spherical bronze particles can also be obtained by tin coating of gas-atomized copper powder. Rounded particles

are made from cutting tin-coated copper wire with a composition of 93 to 97% Cu and 3 to 7% Sn (Ref 10) as shown in Fig. 2. Bronze powder particle sizes range from 10 to 850 μm in diameter depending on the powder type.

Fig. 1 Bronze particles made by tin coating atomized copper powder with a size range of 45 to 100 μm that are gravity sintered to 64% dense in order to yield a 10 μm filter grade disk. 100 \times

Fig. 2 Bronze particles made from tin-coated, cut copper wire with a size range of 250 to 425 μm that are gravity sintered to 55% dense in order to yield a 40 μm filter grade disk. 100 \times

Stainless steel and nickel-base alloys are often specified for increased service life when more corrosion resistance, temperature resistance, or strength is required. Due to economic considerations, the most common stainless steel (SS) materials chosen are the extra-low-carbon, austenitic grade, type 316L, or from the nonstandard, 2 to 3% Si modified grade, known as 316B. The additional silicon serves as a sintering aid by lowering the sintering temperature and controlling the porosity and mechanical properties. Other austenitic, 300 series grades, such as 304L and 347, along with the ferritic grades such as 430 are used in a few specialized applications where the required corrosion resistance or mechanical properties are superior to 316L SS. Nickel-base alloys such as Hastelloy C22, Inconel 600, Monel 400, and Hastelloy X are utilized for extreme corrosion or thermal resistance.

Stainless steel and nickel-base alloy powders are produced by water or gas atomization (refer to Sections on production of stainless steel and high-alloy powders and production of nickel-base powders in this Volume). Water atomization produces powders with rounded, irregular shapes that can be processed by compaction and sintering, as shown in Fig. 3 and 4. These particles interlock when compacted to form a part with sufficient green strength for handling. The water-atomization process yields a wide variation in particle size distribution that must be separated into much narrower size ranges for subsequent processing into porous components. As the powder size decreases, the particle shape becomes more

rounded and higher compaction forces are required to produce components with adequate green strength. Some nickel-base alloys such as Hastelloy C22, tend to atomize into more rounded particles than similar size distributions of 316L SS and thus require increased compaction force to obtain similar green strength. Material characteristics such as hardness can also influence the compressibility of the powder. Water atomization typically produces particle sizes that range from as fine as 100 nm to as coarse as 1000 μm . The particles less than 10 μm in diameter are normally more spherical in shape and tend to have limited cold compaction green strength unless combined with an additive.

Fig. 3 Water-atomized, 316L SS powder particles with a size range of 300 to 600 μm that are compacted and sintered to 45% dense in order to yield a 40 μm filter grade sheet. 100 \times

Fig. 4 Water-atomized, 316L SS powder particles with a size range of 45 μm and less that are compacted and sintered to 75% dense in order to yield a 0.5 μm filter grade sheet. 100 \times

Stainless steel and nickel alloy powders are also produced by the gas-atomization process, which typically yields particles with spherical shapes. This powder cannot be readily compacted without additives. Components can be fabricated by vibratory filling of molds and gravity sintering. The mechanical properties of gravity sintered, spherical powders are normally much lower than other fabrication methods that use compaction. Therefore, gravity sintering is only used in special applications that require higher porosity or unique shapes. In addition, irregular-shaped powders, and powders with binders, can be processed using gravity sintering to obtain low-density products.

Carbonyl or water-atomized nickel powders are rapidly growing in acceptance for use as porous P/M products. The thermal decomposition of nickel carbonyl produces very fine (0.5 to 10 μm) particles attached in a filamentary chain-type structure. Very narrow particle size distributions are possible using this process, which can result in extremely uniform pore size materials after processing, as shown in Fig. 5. Although these powders do not flow well, components with higher porosity and finer pore sizes are made using very low compaction pressures less than 6.9 MPa (1000 psi) (Ref 11).

For nickel components with larger pore sizes, water-atomized, irregular-shaped particles with diameters greater than 20 μ m are normally selected instead of carbonyl nickel because the latter process produces more rounded particles as the particle size increases (Ref 12).

Fig. 5 Carbonyl nickel powder particles with a size range of 2 to 4 μ m that are compacted and sintered to 35% dense in order to yield a 0.1 μ m filter grade cup. 2000 \times

The atomization process can be varied to produce particles with other shapes designed to optimize porosity and permeability. Potato-shaped powders consist of elongated, rounded particles with smooth surfaces. Coarser grades of potato-shaped powders can be compacted directly to form shaped parts while finer grades are normally combined with a binder to achieve adequate green strength. Other processes have compacted and sintered mixtures of irregular-shaped particles with up to 25% spherical particles. The smoother surface and packing characteristics of potato-shaped powders and spherical powders can result in significant permeability increases, especially in the coarser filter grades (Ref 13).

The characteristics of the four most commonly used porous metal powder materials are briefly summarized to illustrate the different powder particle characteristics available to create porous structures. Characteristics of P/M materials are more completely described in previous sections of this Volume and other references (Ref 14, 15).

Processing Methods

After the material is selected, the P/M processing method is critical for determining the final mechanical properties and porous characteristics of the porous component. Selection of the fabrication method is dependent on the powder characteristics and the type of porosity required by the application. The preparation of the powders, the use of additives, the compaction methods, and the sintering conditions must be carefully controlled to produce uniform and repeatable porous characteristics. Secondary operations are normally required to enhance metallurgical properties and to allow easier adaptation to the intended application.

Powder preparation begins with the separation of the powder particles in the desired size distribution. Depending on the amount of secondary processing, commercial powders are available with either wide or narrow particle size distributions. For example, a wide particle size distribution such as $-150\text{ }\mu\text{m}$ (-100 mesh screen) can be generated depending on the powder manufacturing process. However, secondary sieving or screening can classify a much narrower particle size distribution such as between 75 and $150\text{ }\mu\text{m}$ ($-100/+200$ mesh). Screening must be carefully monitored because there are significant variations in the screen openings or because the screen openings are blocked with fine particles. Therefore, significant amounts of particles that fall outside of the desired particle size range are not removed by screening. The porous part manufacturers process the commercially available powders into even narrower size distributions by removing oversize and undersize particles or by adding another screen to produce a tighter cut, such as between 106 and $150\text{ }\mu\text{m}$ ($-100/+140$ mesh). Vibratory or ultrasonic screening methods are normally used for particles greater than $20\text{ }\mu\text{m}$ (600 mesh screen) and other separation methods such as air classification are used for particles less than $20\text{ }\mu\text{m}$. Porous P/M components manufactured from narrow particle size distributions have excellent reproducibility and uniformity of the final porosity.

Once the desired particle size distribution is obtained, the powder must be properly blended prior to use in order to avoid segregation and to maximize uniformity. The apparent and tap densities of the powder cuts are normally measured to meet tight specifications because these characteristics control further processing steps such as powder flow and die filling. Excessive blending can change the powder characteristics by generating additional fine powder particles or by changing the particle surface. Additives such as lubricants, pore formers, or binders are precisely mixed with the powder if required by the processing method (Ref 16, 17). Significant amounts of powder with controlled particle size distributions are used as loose pack beds for applications such as polymer filtration. However, most applications require further processing to develop a more rigid porous structure. The powder cleanliness and chemical analysis must also be carefully monitored to maintain the chemistry requirements of the material and to avoid contamination with other materials being processed. Because these materials are often used in aggressive environments, contamination from iron, carbon, aluminum, sulfur, and other elements could cause significant reduction in mechanical properties or corrosion resistance. Dedicated powder processing equipment and manufacturing facilities are the best defense against contamination. Other trace impurities such as oxygen, alumina, silica, and nitrogen levels from the powder manufacturing process can also affect the final mechanical properties.

Compaction methods and sintering are normally required to produce porous materials from stainless steel, nickel-base alloys, and nickel materials in order to achieve the best combination of mechanical strength, metallurgical properties, and porosity. Lower-density, higher-permeability parts from these alloys can also result from using a gravity-sintering process without compaction of the powder when the application does not require higher strength levels of compacted and sintered parts. Die compaction, isostatic pressing, and roll compaction increase the green strength of the part by cold welding of the particle to particle contact areas due to plastic deformation. As compaction force is increased, the density and green strength of the porous part increases, which results in finer porosity and lower permeability than methods that do not use compaction prior to sintering.

However, when compared to compacted structural P/M parts, the lower density and green strength limit the shape complexity of a porous component. For porous materials, uniform density is critical to the function of the parts because the largest porosity and greatest permeability are in the lowest-density region. Density variations of more than $\pm 2.5\%$ within the same component cause significant differences in performance.

Die compaction and sintering are the most common methods of improving mechanical properties for porous parts with length-to-diameter ratios of less than 5 to 1. Disks, cups, bushings, and other shapes can be readily compacted by filling the powder into dies and using hydraulic or mechanical P/M presses. Typically, porous materials are manufactured to achieve the lowest-density part in order to maximize porosity and permeability.

Minimum green handling strength can be obtained by using lower compaction forces in the range of 700 to 2100 kg/cm² (5 to 15 tons/in.²). By comparison, higher-density structural P/M components require compaction pressures of 4200 to 8400 kg/cm² (30 to 60 tons/in.²) (Ref 18). Porous parts with 20 to 50% green densities usually have minimal green strength and require careful handling; they often have to be manually picked off the press and placed in a sintering tray. Higher-green-density parts in the 50 to 80% range have sufficient green strength to allow the press feed shoe to eject the part off the die table and into a container. For low-density parts made from coarse powders, press rates can be less than 5 parts/min and part handling is critical to final yield rates. With proper sintering, die compaction can hold dimensional tolerances within $\pm 1\%$.

Die compaction with lower tooling forces can be accomplished with die-wall lubrication or adding less than 0.5% lubricant to the powder. In the case of coarser water-atomized stainless steel powders, only 0.1 to 0.3% lubricant addition to the powder is generally used. Because smaller particle sizes of this same material are generally more rounded and have better particle packing (smaller pores), slightly higher pressing forces and lubricant additions are required for adequate green strength. Waxes and stearates are commonly added to the powder to reduce die-wall friction and tool wear. However, because increasing the lubricant percentage also reduces green strength, minimizing lubricant additions is often a better alternative than obtaining maximum tool life service. Tooling must be kept in a highly polished condition with tight tolerances to avoid smearing of the part surface during ejection. If smearing or galling of the part surface occurs, significant reductions in the final surface porosity size and in the overall part permeability occur. Improper monitoring of lubricant additions and tooling conditions can lead to problems with the uniformity and the reproducibility of the porosity.

Isostatic compaction is a common method of compaction for producing components such as tubes that have a length-to-diameter ratio greater than 3 to 1. Isostatic compaction can produce porous components with more uniform density than can die compaction (Ref 19). The wet bag cold isostatic pressing (CIP) process uses a hydraulic fluid to apply pressure ranging from 3.5 to 550 MPa (500 to 80,000 psi) to the tooling, which is sealed after powder filling. As the hydraulic fluid is gradually pressurized, the soft polyurethane outer liner compresses the powder against the metal core rod to obtain sufficient green strength. This "outside-in" pressing process results in a green part with a smooth inner surface and a rougher outer surface. If the pressing direction is reversed by using an expandable polyurethane inner bladder to compress the powder against a metal outer sleeve, a tube with a smooth outer surface can be obtained. Other near-net shapes such as cones, funnels, and tubes with splines can be manufactured using the CIP process (Ref 20). For example, a 25 mm (1 in.) outside diameter (OD) by 19 mm ($\frac{3}{4}$ in.) inside diameter (ID) by 76 mm (3 in.) long tube would have uniform density along the entire length, whereas a similar-sized, die-compacted bushing would have high-density ends and a lower-density center. Hot isostatic pressing (HIP) combines the advantages of CIP and sintering into one process and is utilized in applications where complex shapes are needed or when a material has low green strength for handling.

Roll compaction of porous nickel sheet materials have been commonly used in the production of battery materials (Ref 21, 22). Nickel and other powders are rolled to a thickness ranging from 0.13 to 3.8 mm (0.005 to 0.150 in.) and widths up to 1 m (39.37 in.), depending on the green strength and requirements of the application. Controlling the powder feed is critical to the process to obtain the best uniformity of the final product. Attempting to roll sheet with larger cross-sectional thickness can lead to delamination or low-density center regions that cause poor mechanical properties. Thin cross sections or powders with low green strength limit the handling of the porous sheet prior to sintering. The rolled sheet can be directly fed into a sintering furnace to minimize handling problems in certain high-volume applications. Roll compaction is used to produce an economical, uniform density material with good mechanical properties and tight dimensional tolerances ($\pm 2\%$ on thickness). Width and length tolerances are determined by secondary machining, cutting, or shearing operations. Shapes or patterns can often be designed into the rolls, or parts can be stamped from the finished porous sheet.

Other forming methods used to manufacture porous metal components include centrifugal slurry casting (Ref 23, 24), blow molding (Ref 25), metal injection molding (Ref 25), extrusion (Ref 26), and gravity filling of shaped molds. Sheet materials can also be made using other processes such as a liquid lay-down method, which uses a powder and binder slurry (Ref 27). Complicated shapes and lower-density components are formed using additives or pore formers such as water and/or thermoplastic binders that allow sufficient handling strength. Removal of the additives prior to sintering is normally accomplished in the preheat zone of the furnace or in a separate controlled bake-out process. Metal

spraying (Ref 28) can create a controlled porous structure with or without additives by spraying molten metal onto a base material to combine compaction and sintering into one process.

Sintering of porous metal is a critical balance between maximizing material properties and maximizing the open porosity and permeability. However, because permeability and material properties such as strength and ductility are generally inversely related, the desired balance of these characteristics normally occurs in a very small processing window (Ref 29, 30).

Sintering requires the proper compromise of temperature, time at temperature, and atmosphere to arrive at the desired porosity characteristics. Porous components that are not adequately sintered exhibit poor mechanical properties due to lower density and insufficient interparticle neck growth. Porous components that are exposed to excessive sintering conditions have lower permeability and higher densities than desired.

The preheat and cooling portions of the sintering cycle must also be closely controlled to achieve the proper metallurgical properties. Controlling the preheat conditions ensures adequate burnoff of additives and lubricants as well as minimizing the distortion of the parts. The cooling conditions must be designed to provide maximum corrosion resistance and to avoid oxidation.

Sintering temperature must be selected by considering the material, the powder shape, and the powder particle size distribution. Sintering is normally accomplished at 70 to 90% of the material melting temperature. Finer powder particles require a lower sintering temperature because the surface energy driving force to initiate bond growth is much higher than for a coarser particle. Sintering at too high a temperature also causes the formation of very large pores and nonuniform porosity just prior to melting. Controlling the furnace temperature within $\pm 1\%$ of the optimal sintering temperature achieves the best porosity uniformity and reproducible properties. Furnace design, furnace loading, and furnace hot-zone uniformity are critical to the production of porous metal components. Even slight lot-to-lot variations due to differences in the powder shape or the powder particle size distribution can often require adjustment of the sintering temperature to maintain the balance of properties and permeability.

Sintering time must be monitored to allow for a minimum exposure time at the desired sintering temperature. Sintering for at least 30 to 60 min at the maximum sintering temperature is recommended for most materials for sufficient bond formation and growth. Inadequate sintering time can lead to large variations in part shrinkage and final density, causing porosity and permeability variations. The sintering time at temperature must allow for the temperature of the furnace load to stabilize at the desired temperature, especially when batch size and furnace recovery can widely vary. Furnace profiles and recovery rates for various load sizes for each furnace must be considered when determining appropriate sintering time. Shrinkage and density measurements can be used to control sintering time and temperature if the furnace atmosphere is consistent. Excessive sintering unnecessarily reduces permeability due to pore size reduction and pore closure without significantly improving mechanical properties.

Sintering atmosphere selection is critical for determining the metallurgical properties of the porous metal product. Because porous materials have much higher surface area than a similar-size structural part, the atmosphere has more contact with surfaces throughout the part rather than just near the surface. Porous parts also contain relatively large amounts of trapped air in the pores that must be removed by purging or good atmosphere circulation in the furnace. Often, higher flow rates of an atmosphere or longer vacuum pump down times are required to displace the air prior to sintering. The sintering cycle can be subdivided into three main processes: preheating, sintering, and cooling. Each process of the sintering cycle has unique atmosphere requirements that provide the optimal properties of the porous metal product just as with structural P/M components (Ref 31, 32).

The preheating cycle must remove any lubricants or binders from the green compact and normally requires an oxidizing atmosphere. A separate furnace is often used to burn off these additives in order to avoid contamination of the sintering furnace. Preheating in the same furnace with a reducing atmosphere is often sufficient to remove low levels of additives because the open porous network allows more complete removal of the thermal decomposition products than does a structural part. Specifically, mechanical strength and corrosion resistance properties are highly dependent on the interaction with the sintering atmosphere. Porous materials are commonly sintered either in reducing atmospheres such as nitrogen-hydrogen mixtures, hydrogen, dissociated ammonia, or vacuum. Inert atmospheres such as dry argon can be used to sinter some of the specialty porous materials such as aluminum, refractory metals, and precious metals. Reactive materials such as titanium and zirconium require good vacuum sintering with a high-purity, inert backfill gas. Nitrogen-containing atmospheres can have a nitriding effect on some materials such as porous stainless steels. Series 300 stainless steels can benefit from increased tensile strength with slightly lower ductility in a reactive nitrogen-sintering atmosphere such as dissociated ammonia. However, reduced corrosion resistance may result unless the cooling rate is carefully

controlled to minimize the formation of chromium nitrides (Ref 33). A hydrogen atmosphere with a low dew point or vacuum sintering with a hydrogen backfill during cooling produces the best combination of corrosion resistance and mechanical properties for porous stainless steels. The cooling process cycle usually requires a reducing or oxygen-free, inert gas atmosphere for best metallurgical properties. When heavy oxidation or nitriding is prevented during cooling, a protective passive surface layer will form and good mechanical properties will result. Carbon-containing atmospheres are not normally utilized in processing porous materials because higher carbon levels are usually detrimental to corrosion resistance.

Gravity sintering refers to one of the simplest methods of sintering to improve the mechanical properties of a porous component. Diffusion or liquid-phase bonds form between the particles when loose (noncompacted) powders are heated to a temperature near the solidus temperature (Ref 34). Localized melting of the particle surfaces form necks between the powder particle contact surfaces, and the amount of shrinkage during sintering controls the characteristics of the interconnected porosity. As an example, spherical porous bronze powders are poured and vibrated into a graphite or an oxidized stainless steel mold without compaction. The bronze or tin-coated copper powder is then sintered at 800 to 1000 °C (1472 to 1832 °F) for 20 min in a reducing atmosphere to form a liquid phase between the particles (Ref 9). Upon cooling, a strong metallurgical bond is formed at the contact points between the powder particles. Disks, cups, bushings, or other simple shapes can be produced using this method. Typically, parts have a 1° draft angle to facilitate part release from the mold and have dimensional tolerances of $\pm 3\%$.

Secondary operations are widely used to modify the part shape, the porosity, and the surface characteristics of a porous part. Porous parts can often be formed to net shapes for use without secondary operations. However, the lower green strength and density of porous parts can limit the complexity of the green part and subsequent handling prior to sintering. The part shape complexity can be enhanced by sizing, machining, and forming. Secondary sizing processes can improve the roundness, flatness, and other dimensional tolerances that cannot be held during sintering. Porous P/M materials must not be overstressed during sizing because cracking or closure of the pores will occur. Sizing operations increase the density of the part and reduce the surface porosity in the tool contact areas.

Secondary machining operations are used to produce features such as threads or tighter dimensional tolerances that cannot be readily controlled during compaction. Conventional machining of porous materials closes off the majority of the surface porosity by metal smearing. Machining can be utilized to blind off the porosity and fluid flow in selected areas, depending on the application. Controlled chemical etching of a machined surface can restore the surface porosity and still retain the tighter dimensional tolerances produced by machining. Care must be taken to avoid contamination of the porous material during machining or chemical reactivating. Machining methods without coolants and special cleaning processes are often used to remove the contamination after processing. Other machining methods such as electrical discharge machining (EDM) are also used to avoid closing off the surface porosity. However, removal of any machining fluids again requires special cleaning methods. Conventional machining, EDM, and laser methods are used to cut porous parts from larger parts or sheets.

Forming of porous materials by cold working using dies or calendering rolls is used to change the part shape. Flat sheet can be formed into tubes and seam welded. Cold working during forming increases the density, hardness, and tensile strength of the porous material, with a corresponding decrease in ductility. Forming is also used to make special shapes and assemblies. Light sizing and swaging operations alter the surface layer to produce parts with tighter dimensional tolerances than as-pressed components. The surface porosity is flattened during forming, and the permeability and the surface pore size are decreased. However, porous P/M materials are difficult to straighten or flatten because of their elastic properties, which result in significant "spring back" behavior just prior to crack initiation.

Joining methods such as brazing, welding, gluing, sinterbonding, and mechanical interlocking are used to create porous metal assemblies. The conditions for joining lower-density materials to other porous materials or to solid materials are very different from joining solid materials. For example, brazing materials and processing conditions must be selected to avoid wicking of the braze material away from the joint area. Often a braze material is selected to form a higher melting point eutectic upon alloying with the porous base material in order to solidify the braze material in the joint area.

Welding of porous materials to other porous materials or to solid materials becomes much more complex than welding solid materials. The addition of filler metal, the reduction of weld heat input and the use of special welding gases are required to overcome welding problems associated with higher porosity and gases trapped in the pores. Good weld joint design allow proper heat distribution to prevent leaks and large holes. Weld purge gases and material cleanliness are important to avoid contamination and to provide good corrosion resistance. Tungsten inert gas, electron beam, and laser welding processes are used to obtain full penetration of weld joints with relatively narrow heat-affected zones. Postweld heat treatment processes such as annealing or stress relieving are recommended for good metallurgical properties.

Heat treatment or thermal cycles in reducing atmospheres can also be used for sinterbonding porous parts by processing at 10 to 65 °C (50 to 150 °F) below the sintering temperature in order to maintain the porosity and permeability. Sinterbonding is a thermal processing method used to form a metallurgical diffusion bond between two parts such as between a porous part and assembly hardware. The hardware is generally the same material as the porous component and allows the sinterbonded assembly to be more easily adapted to the application than if only a porous part was used. The diffusion bonds formed are significantly lower than welded or brazed joints because the sinterbonds are only formed at the local contact points. However, the sinterbonds are significantly stronger than just an interference fit alone and can ensure that the porous component cannot be easily removed. Sinterbonding can be accomplished during a sintering cycle if proper allowances for shrinkage are considered. The sintered porous part must have adequate strength to allow for a press-fit assembly without developing cracks. The press-fit interference for parts less than 25.4 mm (1 in.) OD is between 0.025 and 0.1 mm (0.001 and 0.004 in.). The hardware surface should have at least a 0.4 μm (16 $\mu\text{in.}$) surface finish so that the assembly interface does not have any gaps that may form openings larger than the pores in the porous metal component. The assemblies are normally checked for joint integrity after sinterbonding.

Thermal processing can also be used for removal of oxidation, burnoff of certain contaminants introduced by secondary operations, and for passivation of the metal surfaces. Oxidation color from the heat-affected zone of welds or from the heat of a cutting operation must often be removed by heat treatment in a reducing atmosphere for corrosion resistance or aesthetic reasons. Organic contaminants that are captured in the pores from prior processing steps or improper handling can be vaporized and removed from the pores by thermal processing. Heat treatment in a reducing atmosphere can also restore a uniform oxide layer upon cooling that forms a passive surface on the porous metal in order to increase corrosion resistance.

Porous sintered metals can be coated with a material such as silicone to alter the surface characteristics. Silicone treatment of the pores changes the hydrophilic nature of the surfaces to a hydrophobic surface that still maintains some permeability. Metal oxide coatings have been successfully formed on the porous surfaces to increase corrosion resistance or to decrease the pore size by applying a thin layer of submicron particles of a metal oxide such as silica, titanium dioxide, or alumina (Ref 35, 36). These fine metal oxide particles can be bonded to a coarser porous metal substrate to produce a dual-porosity structure with good permeability and excellent corrosion resistance.

Porous Powder Metallurgy Technology

Mark Eisenmann, Mott Corporation

Porous Material Characteristics

Design engineering information is readily available for many of the porous material characteristics such as density, pore size and distribution, bubble point, permeability, and mechanical properties (Ref 8, 10, 17). However, many of the unique characteristics of porous P/M materials such as elevated service temperature and corrosion resistance properties in specialized environments require additional design engineering considerations. The density, pore size, pore size distribution, and permeability determine the overall performance of a porous material in an application. The interrelationship of these four characteristics often allows the design engineer to specify only one or two of these factors. For example, testing has shown that the permeability of a porous part can be accurately predicted if the density and the initial powder particle characteristics are known for a particular processing method (Ref 37). The initial powder particle size controls the pore size and distribution when sintered to a specified density. The permeability is related to the pore size and pore distribution. Other porous material characteristics can be estimated from wrought (or full-density P/M) products because higher-density products have more extensive test data available in the literature. Limited availability of design engineering data for porous materials often results in the need for actual testing in the intended application prior to use.

Material density is an important characteristic for predicting mechanical properties and permeability. As the density decreases (and porosity increases), the mechanical properties are reduced and the permeability is increased. Porosity consists of interconnected channels and isolated pores. Isolated pores that are either closed or dead-end channels do not contribute to the overall permeability, and the percentage of isolated pores must be considered if density comparisons are used to specify a component. Nearly all of the porosity in a component with an overall density less than 75% of TMD is interconnected to the surface pores and is usable for filtration and fluid-flow paths (Ref 38). As the overall density increases from 75 to 92% of TMD, the percentage of isolated pores increases rapidly and the functional interconnected porosity is depleted.

Density measurement methods for porous materials are described by International Organization for Standardization (ISO) Document 2738 (Ref 39), which includes the use of Archimedes principle. The porosity must be fully sealed prior to immersion in water using this method. Overall density can be estimated by weighing and volume calculation for simple part geometry. Density can also be measured by optical analysis of carefully prepared surfaces. The cutting, polishing, and etching techniques during metallographic preparation must be monitored to avoid smearing or excessive removal of the surface porosity. Density uniformity throughout a porous product must be considered when measuring overall density because the forming process may introduce large variations. For example, a coaxial pressed cup could have a density variation of more than 5 to 10% when comparing the lower-density side walls versus the higher-density end cap.

Pore characteristics such as size, shape, and distribution can be determined using many different measurement techniques. A comparison of the various pore characterization methods reveals that while the test method is usually consistent to show relative differences between various porous material grades, the test methods do not always agree (Ref 40). Because it is normally possible to correlate the various test methods, technical information regarding pore characteristics must be carefully compared to determine if the pore characteristics are equivalent.

One of the most common pore size characterization methods is a "bubble-point" test, which measures the pressure required to release the first bubble from the surface of a porous material submerged in a liquid and pressurized from one side as shown in Fig. 6. The liquid selected for this testing must have good wetting characteristics with relatively low viscosity and surface tension, such as isopropyl alcohol. Several standard test methods, such as ASTM E 128 (Ref 41) and ISO 4003 (Ref 42), have been developed to measure the pressure at which the first bubbles form and break away from one area. The maximum interconnected pore diameter can be estimated using Poiseuille's capillary law and an additional pore shape correction factor for noncylindrical pores:

$$d = 4KR \cos B/P$$

where d is the pore diameter, K is the shape correction factor, R is the surface tension of the wetting liquid, B is the contact angle of liquid and porous material, and P is the pressure at first bubble point (Ref 43). The shape correction factor, K , is largely dependent on the shape of the pores and the porous material. The shape correction factor can vary from about 0.2 for more spherical pores (e.g., bronze) to 0.4 for more irregular-shaped pores (e.g., 316L SS). Therefore, the bubble-point test is not a highly accurate measurement of pore size, but serves only as a reproducible, nondestructive test for ranking porous material grades by the largest pore size. The maximum pore size of the porous media calculated from the bubble-point test is not a direct indication of filtration performance, but the results can be correlated to more complex filter-retention testing. The filter industry often refers to the diameter of the largest pore determined by the bubble-point method as a micron rating. This terminology should not be confused with the diameter of a particle retained by a filter or the absolute filtration rating. The bubble-point test is not a good indicator of the gas or liquid filtration rating because filtration is dependent on many other variables, such as the uniformity and distribution of the pores, the media thickness, and the type of solids being filtered. The bubble-point method is also an excellent integrity test of a material that has been subjected to secondary operations such as welding or forming in order to determine if any larger pores were created.

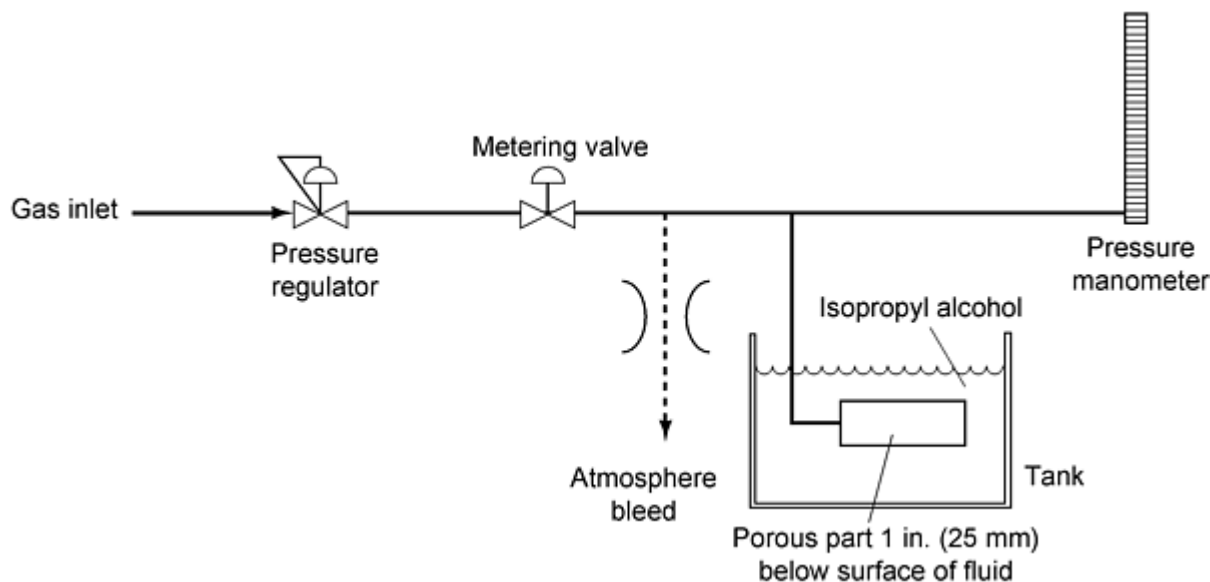

Fig. 6 Bubble-point testing apparatus

Mercury porosimetry and a mean flow pore size distribution measurement technique developed by Wenman and Miller use the Washburn Equation to calculate the pore diameter as the pressure is gradually increased (Ref 44, 45). Mercury porosimetry calculates the interconnected pore size and pore distribution of material by measuring the pressure required to force mercury into the pores and the volume of mercury in the pores. The other method determines the pore size

distribution using a fluid that fully prewets the porous sample and then measures the pressure differential as the air flow is gradually increased. As the pressure increases, the fluid is forced from the larger pores first, and the air flow permeability begins to increase until the sample is dried. A comparison of the wet and dry permeability curves allows the calculation of the pore size and distribution. ASTM F 316 (Ref 46) details the test method for determining the maximum pore size by bubble-point testing and the pore size distribution by mean flow pore testing. The capillary action of the porosity is dependent on pore size and is an important property for applications that require fluid wicking and storage.

Permeability is a measure of the flow resistance through a porous material and is one of the most important characteristics for design engineers specifying porous materials. The fluid flow through a porous material is normally expressed as a volumetric flow rate at a specified pressure differential for a given surface area (e.g., standard liters per minute per square centimeter at $dP = 1000 \text{ kg/cm}^2$ of nitrogen). The nature of the fluid flow can be characterized as diffusional, laminar, or turbulent depending on flow velocity. For very low flow rates and small pores or low absolute pressures, diffusional flow is the predominant mechanism and is not dependent on the fluid viscosity because the mean free path of the molecular collisions is larger than the pores. Fluid flow that is unidirectional along parallel flow paths with uniform velocity is considered laminar or viscous flow. Turbulent flow occurs when flow is high enough to cause irregular, random flow paths. Other types of flow mechanisms termed slip and inertial flow occur in the transition regions among diffusion, viscous, and turbulent flow (Ref 47). For example, inertial flow mechanisms must be considered to account for the energy losses and increased flow resistance of the gas at higher flow rates as it changes direction in the tortuous pore network flow path. For laminar flow of liquids, the volumetric flow rate, Q , can be predicted by Darcy's Law:

$$Q = dPAC_v/tV$$

where dP is the differential pressure, A is the surface area, C_v is the coefficient of viscous permeability, t is the material thickness, and V is the dynamic viscosity of the fluid. In the case of compressible gases, Darcy's law is modified to allow for the gas volume change with pressure as shown below:

$$Q = AC_v(P_1^2 - P_2^2)/2P_2tV$$

where P_1 is the upstream pressure and P_2 is the downstream pressure (Ref 48). For higher pressures and gas velocities, the flow rate through a porous material can be predicted by a modified version of Darcy's law, which includes correction factors for inertial and slip flow (Ref 48). Although the permeability can often be accurately modeled, the complex gas flow physics of the porous structures limits the accuracy of the theoretical calculation of fluid flow, especially in the extreme low- and high-flow regions. As the gas density increases due to an increase in pressure or a decrease in temperature, the permeability decreases. As the viscosity of a gas increases due to an increase in pressure or temperature, the permeability also decreases. Pressure increases result in only a slight increase in the gas viscosity, but significantly increase the gas density. Temperature increases typically result in an increase in the gas viscosity and a reduction in the gas density. When comparing different porous materials, the accuracy of theoretical calculations is often reduced due to the interactions of these variables along with the various flow mechanisms operating in the microchannels of the porous structure.

As shown above, the flow rate is also dependent on the surface area and the thickness of a porous structure. As surface area is increased, the differential pressure required to produce the same flow rate is decreased. Also, as the thickness of a material is decreased, the pressure differential is reduced to obtain the same flow rate. When comparing two porous materials, higher permeability indicates that a lower pressure differential was required to produce the same flow. Therefore, less surface area of a material with a higher permeability is required to produce the same fluid flow rate as a porous material with lower permeability. The economics become more favorable as the porous material surface area is reduced to meet the desired flow rate. The pressure differential and permeability are important design characteristics for determining overall flow rates for applications such as filter systems.

Permeability testing is one of the best methods for specifying the characteristics of a porous material by measuring the fluid flow rate and pressure drop. Permeability is a function of the gas or liquid testing fluid and requires close control of the fluid test conditions. Gas permeability is dependent on many variables such as density, viscosity, temperature, and pressure conditions. Many references have investigated gas-flow dynamics and have proposed models for predicting flow rates as conditions are varied (Ref 30, 48, 49, 50). The permeability of a fluid through a rigid porous material can be determined by standard test methods as described by ISO 4022 (Ref 51) and ASTM 128 (Ref 41). A typical gas permeability test schematic diagram is shown in Fig. 7. The flow path position of the volumetric flow measuring device is

critical in order to avoid inaccurate measurements if an excessive back pressure or vacuum is created. The flow rate is measured by controlling the pressure differential and correcting the measured flow to standard temperature and pressure conditions using the ideal gas law to correct for gas volume changes. The atmospheric pressure and gas temperature can be measured in order to correct the measured gas flow rate back to standard temperature (21.1 °C, 70 °F, or 294.1 K) and pressure (760 mm Hg, or 29.92 in. Hg). Accurate flow rate comparisons can then be made between porous parts tested with nonstandard conditions. A general formula that accounts for volume changes and corrects the measured gas flow rate back to standard conditions is given below:

$$Q_s = Q_m(P_m/P_s)(T_s/T_m)$$

where Q_s is the standard flow rate, Q_m is the measured flow rate, P_m is the measured pressure in mm Hg, P_s is the standard pressure, T_m is the measured temperature, and T_s is the standard temperature. Corrections to standard conditions are significant because a small pressure change of 25.4 mm Hg (1 in. Hg) or a small temperature change of 2 °C (4 °F) can result in approximately, a 1% difference in the flow rate.

Fig. 7 Schematic of gas permeability testing apparatus

Additional correction factors can further improve the accuracy of permeability testing by accounting for changes in the gas viscosity and the interactions of the gas with the pore structure as temperature and pressure are varied. As temperature increases, the gas viscosity increases and the gas density decreases, which in turn increases the measured gas flow rate relative to standard conditions as shown in Fig. 8. Also, as the gas contracts to enter or expands to exit the pore structure, energy losses occur to reduce the flow (Ref 49). When measuring the flow of one gas and calculating the flow rate equivalent of a different gas, the flow rate is adjusted for differences in gas viscosity or specific gravity. Gas flow conversions are important when testing of the actual gas is not practical due to safety or handling reasons. For example, the flow rate of nitrogen is often measured and used to estimate the actual flow rate of a toxic or corrosive gas at the same temperature and pressure conditions.

Fig. 8 Typical gas flow versus pressure drop through porous sintered metal restrictors

The volumetric flow rate can also be calculated by dividing the mass flow rate by the fluid density. The mass flow rate of gases can be measured with an accuracy of about $\pm 2\%$ by devices that correlate the gas flow rate to the cooling rate of the gas as it flows past a hot wire. These devices are based on calculating the gas flow rate by measuring the amount of energy required to keep the wire at a reference temperature and knowing the thermal conductivity of the gas. Mass flow rates do not need to be corrected back to standard conditions. Volumetric flow rates that are corrected back to standard conditions can achieve an accuracy of better than $\pm 1\%$ by collecting the fluid in a known volume as a function of time. Volumetric flow rate devices such as positive displacement piston meters are highly accurate primary standards. Mass flow rate devices are slightly less accurate and are secondary standard devices.

Liquid permeability is also sensitive to variations in temperature, pressure, viscosity, and density. Liquids flowing through porous materials are highly dependent on the viscosity and the ability of the fluid to wet the pore structure. Liquid flow rates are often difficult to reproduce if the fluid does not have consistent wetting properties. For example, isopropyl alcohol is preferred for liquid flow testing of porous metal materials, whereas water does not wet well. Water can also have large differences in the mineral content depending on the source, and these quality differences can make flow rate comparisons difficult, especially for tighter porous structures. The permeability of gases and liquids through a rigid porous material can be determined by specialized testing as described by ISO 4022 (Ref 51) and ASTM E 128 (Ref 41).

Mechanical properties such as ductility, tensile strength, shear strength, collapse strength, burst strength, and fatigue life of porous materials are highly dependent on the porosity and the processing method (Ref 52, 53). Table 1 illustrates typical values for tensile strength, elongation, and shear strength of 90% Cu/10% tin bronze discs and 316L stainless steel sheet as a function of density and filter grade as rated by the bubble-point method (Ref 8, 10, 54). Mechanical properties increase significantly as the pore size and the percentage of porosity decreases (Ref 54, 56, 57, 58). Alternatively, permeability decreases as the pore size and the percentage of porosity decreases. Therefore, an optimal balance of mechanical properties and permeability must be achieved to meet the application. Processing methods and materials can usually be selected to create a porous P/M material that meets the minimum mechanical properties and provides the maximum permeability. In some more severe applications involving high-pressure differentials, corrosive environments, and/or high-temperature service, mechanical properties are maximized at the expense of permeability in order to

maximize service life. Enhanced mechanical properties also extend the number of cleaning and reuse cycles in some applications.

Table 1 Typical mechanical properties of bronze and 316L SS filters

Material ^(a)	Filter grade ^(b) μm	Density, %	Minimum ultimate tensile strength		Elongation, %	Shear strength ^(c)	
			MPa	ksi		MPa	ksi
Bronze	10	75	48	7	8	130	18.8
	20	68	41	6	6	110	15.9
	40	62	35	5	4	100	14.5
	90	57	28	4	3	75	10.9
	150	54	21	3	2	40	5.8
	250	52	14	2	2	30	4.3
316L SS	0.2	80	180	26	6	250	36.2
	0.5	75	159	23	6	230	33.3
	2	65	117	17	5	190	27.5
	5	62	90	13	5	160	23.2
	10	60	69	10	4	130	18.8
	20	55	48	7	3	100	14.5
	40	50	31	4.5	2	80	11.6

- (a) For comparison purposes, wrought bronze (90% Cu/10% Sn) has a theoretical mean density of 8.8 g/cm^3 with a minimum UTS of 300 MPa (43 ksi) and 20% elongation. 316L SS bar stock (cold finished and annealed per ASTM A 276) has a theoretical mean density of 8.0 g/cm^3 with a minimum UTS of 482 MPa (70 ksi) and 30% elongation. Data are for commercial bronze filter disks and 316L SS sheet.
- (b) Filter grades in micrometers as estimated by bubble-point test method.
- (c) Shear strength is the punching force divided by the sheared edge area per DIN standard V 30910 (Ref 55).

Other material properties such as thermal conductivity, thermal expansion, fatigue, electrical conductivity, and magnetic properties are also highly dependent on porosity and generally decrease as porosity increases (Ref 59, 60). For example, thermal expansion can be directly related to the porosity by the equation (Ref 59):

$$C_t = C_o D_f^{1/3}$$

where C_t is the effective thermal expansion of the porous material, C_o is the bulk thermal expansion of the wrought material, and D_f is the fractional density. Other theoretical relationships have been proposed to cover the mechanical properties over a broad range of porous materials and porosity levels, but actual testing is recommended to determine the properties because slight variations in porosity and processing methods can produce significant changes (Ref 61, 62).

Elevated-temperature and corrosion properties are often important criteria for selection of porous P/M materials versus other porous materials such as plastics and papers. The maximum service temperatures for several P/M materials are listed in Table 2. The application environment is also critical to obtaining maximum service life because the atmosphere may be oxidizing, reducing, or inert in nature. Mechanical properties at an elevated temperature may be significantly reduced by accelerated corrosion reactions in atmospheres that contain ammonia, carbon, chlorine, fluorine, hydrogen, moisture, sulfur, or other reactive materials. For example, catastrophic oxidation of 316L SS can occur at a lower temperature than expected due to the formation of low-melting-point eutectic such as vanadium pentaoxide if vanadium is used as a reaction catalyst. The presence of lead and molybdenum can also result in catastrophic oxidation (Ref 63). The corrosion resistance of 316L SS is also reduced in ammonia service at 540°C (1004°F) due to the formation of a brittle nitride layer and in the presence of sulfur due the formation of iron and nickel sulfides. Temperature fluctuations and localized hot spots can cause accelerated oxidation due to spalling or cracking of the passive layer.

Table 2 Elevated temperature service for selected porous filter materials

Material	Maximizing temperature oxidizing atmosphere		Maximum temperature reducing atmosphere	
	°C	°F	°C	°F
Bronze	150	304	400	750
316L SS	400	750	538	1000
Inconel 600	593	1100	815	1500

Corrosion resistance of porous P/M materials is a very complex subject due to the large number of variables that change the material behavior (Ref 64). Material variables include composition, porosity characteristics (density, pore size, pore distribution, and pore surface condition), and the effect of interstitial elements (carbon, nitrogen, and oxygen). Processing variables include delube conditions, sintering conditions (time, temperature, atmosphere composition, dew point, and cooling rate), and secondary operations (cold work, machining, welding, and heat treatment (Ref 65). Environmental variables include fluid composition, velocity, aeration, temperature, process cycle, and exposure conditions. Corrosion failure of porous materials is normally due to localized attack of the sinterbonds due to intergranular corrosion, crevice corrosion, stress-corrosion cracking, and pitting mechanisms (Ref 66, 67). There is limited design engineering data that predict the corrosion rates of porous materials in various environments. In general, porous materials have significantly higher corrosion rates due to their larger surface area than the comparable wrought material. In order to predict the service life of porous materials without actual testing, corrosion handbooks (e.g., Ref 68) for solid materials offer a reference point. As a general rule, avoid selecting a porous material for an environment that rates the corrosion resistance of the solid material as excellent. Even a very low corrosion rate for a solid material at the specified conditions can often still be too high for a porous material that obtains its mechanical properties from the very small bonds at the particle contact points. The corrosion resistance of a solid is often rated using a low fluid velocity in contact with the surface layer. Increased fluid velocity in the pore structure and aeration of the fluid may decrease the corrosion resistance of a porous material if the passive layer on each powder particle is disturbed. Also, pitting- and crevice-corrosion mechanisms can occur in porous materials that have dead-end pore channels. Pitting corrosion can also occur if a corrosive liquid remains in the pores to create a localized concentration cell. Inadequate cleaning or prolonged storage without drying after removal from service can cause pitting failure.

There are many methods to enhance the corrosion resistance of porous materials. Proper alloy selection results in the best protection against corrosion although the economic considerations of the more expensive alloys may be prohibitive. One advantage of the P/M process is that special alloys or custom blends can be made. For example, more nickel, chromium, and manganese can be added to improve corrosion resistance of a 300 series stainless steel rather than being limited to standard alloys. Bronze filters can be plated with nickel or tin to improve corrosion resistance. While it is difficult to predict actual service life in a particular application, common corrosion tests can give some indication of corrosion reactions. Evaluating corrosion resistance using standard immersion (weight-loss) testing and salt-spray tests can often predict the behavior of porous materials (Ref 69). One of the best indicators of corrosion resistance uses porous tensile bar samples suspended in the actual solution. While the fluid-flow velocity effects are not considered in this test, mechanical testing and optical analysis can detect the effects of corrosion. Electrochemical testing can also be used to indicate the potential of a sample to exhibit passive behavior in a solution (Ref 66, 69). For stainless steels, indicator tests to determine the presence of unalloyed iron or carbide precipitation at grain boundaries determines proper processing. Sensitization of 316L SS due to slow cooling in nitrogen-containing atmospheres during sintering or carbide precipitation during welding can lead to intergranular corrosion (Ref 70). Welding should be followed by an annealing or stress relieving heat treatment to increase corrosion resistance and mechanical properties. Proper handling to minimize contamination and corrosion initiation sites (e.g., fingerprints, scratches, dents, foreign material) can also improve corrosion resistance.

Filtration properties are dependent on the porous material characteristics, the surface area available for filtration, and the process conditions of the application. Filtration and separation are intricate technologies that can be classified into six general areas: gas-solid, liquid-solid, gas-liquid, gas-gas, solid-solid, and liquid-liquid separation. Porous P/M parts are normally used for solid particle separation from a process stream, but have significantly different filtration properties in gas or liquid service (Ref 71). The filter efficiency or filter rating in a gas stream is higher than in liquids. There are additional gas-liquid separations possible with porous P/M parts such as bronze filters, which separate water from air due to surface tension differences. Filters are specified and compared by their desired performance characteristics, which include high permeability, low-pressure drop, retention efficiency of specified particle sizes, particle-loading capacity and resistance to blinding. The desire to have high permeability must be balanced with the minimum mechanical properties

required for filtration. As the porosity is reduced, the density of a filter increases, resulting in higher strength and lower permeability. Predicting filter performance in an application is difficult because there are many process variables such as the nature of the particles (size, shape, compressibility, and composition), particle concentration, fluid flow rate, viscosity, vibration, service temperature, and pressure.

Surface- and depth-type filter mechanisms perform the separation of solids from a process stream with porous P/M media. Surface filtration is characterized by the formation of a layer of particles (cake filtration) on the upstream surface of porous media due to sieving, direct interception, and bridging of the particles. As the filter cake forms, the layer of particles begins to filter the process stream, and the porous media act more as a support. Wire mesh screens are examples of surface-type filters that are generally used to retain coarser particles ($>140\text{ }\mu\text{m}$). Finer filtration retention can be accomplished with screens, but the higher pressures required to drive the fluid often pushes the finer particles into the screen openings to cause blinding. Thin layers of fiber metal bonded to the surface of a screen can provide even finer levels of filtration with improved permeability (Ref 72). Surface filters can be easily cleaned by reversing the flow direction if properly sized. Depth filtration is a more complex form of filtration than surface filtration because it is characterized by the retention of particles within the interconnected pore structure. Particles are retained by a variety of mechanisms including direct interception, inertial impaction, diffusion, adsorption, electrostatic attraction, and gravitational settling (Ref 73). In gas-solid separation, depth filtration depends primarily on capturing particles by interception, diffusion, electrostatic deposition, and impaction mechanisms (Ref 74). These mechanisms are less important in liquid-solid separation because the electrostatic repulsion and the hydrodynamic fluid flow forces allow certain particle sizes to navigate the pore channels and not be captured. Hydrophobic and electrostatic adsorption can also be important in liquid filters, depending on the nature of the electrical charge interactions of the filter media, the contaminants, and the liquid. Sieving mechanisms also occur in depth filters depending on the size and distribution of the contaminants.

Porous P/M materials offer a combination of surface and depth filtration for filtration requirements less than $140\text{ }\mu\text{m}$. Porous P/M materials are fabricated in relatively thin cross sections as low as 0.12 mm (0.005 in.) for use as surface filters. Typically, thicker wall cross sections are fabricated to obtain a strong, rigid media that can withstand the higher operating pressures associated with depth-type filters. The permeability decreases, and the corresponding drop in pressure across the filter increases as the thickness of the media is increased. Filtration ratings can be determined from standardized testing under tightly controlled conditions in order to compare various filter grades and materials. Standardized filter efficiency tests using monosized glass beads, test dusts, or polydisperse salt particles are used to more accurately determine filter ratings (Ref 58, 75, 76, 77). Other common industrial tests such as the Beta Rating Test use a known contaminant in a multipass filter challenge method (Ref 78). Filter challenge testing eliminates some of the confusion when filters are described by absolute, nominal, or mean filter ratings based on a correlation of the pore size determined by the bubble-point test. These descriptions can only offer a reference point for the actual filter efficiency at a given particle size because a "10 micron" rated filter may retain anywhere from 50 to 99.9999999% of $10\text{ }\mu\text{m}$ particles, depending on the application and test method. In addition, this filter rating does not indicate the filtration efficiency of the most penetrating particle (Ref 74). Particles that are smaller or larger than $10\text{ }\mu\text{m}$ can be more difficult to retain, depending on the test conditions and filter media. Testing the filter in the application is recommended to determine the actual performance and efficiency by measuring the downstream contaminants.

Cleaning and subsequent reuse of porous P/M materials is a major advantage over disposable media that generally have low strength, limited temperature capability, and corrosion resistance and cannot be cleaned practically. The economic justification for using porous metals often depends on extending the service life with numerous cleaning cycles. Regeneration of porous metal media with blocked porosity can be accomplished with a variety of cleaning techniques and solutions depending on the nature of the foulant. Cleaning methods include thermal removal, ultrasonic immersion, reverse flow methods, high-velocity waterjets, and chemical processing with soaking and rinsing baths. Cleaning solutions can range from mild detergents to harsher caustic solutions or diluted acids, depending on the type of blockage. The cleaning solution and technique must be selected to avoid damage or corrosion of the base metal. Combinations of methods and solutions can be selected for optimal cleaning. Some of the reverse flow, gas, and liquid blowback methods can be performed in situ while other methods such as furnace cleaning, salt baths, and ultrasonic baths require removal of the porous part. Cleaning service organizations determine the best method to clean the part without damage based on testing and experience. After cleaning the part, the cleaning solutions must be thoroughly flushed and dried. Visual inspection, bubble-point testing, and permeability testing are performed to determine the effectiveness of the cleaning method to return the porous part to the original manufacturer specifications. Measuring the weight before and after cleaning can also be used to evaluate cleaning performance as long as corrosion is not an issue. Gathering data on each serialized part prior to service provides a baseline for measuring cleaning effectiveness. Mechanical cleaning methods such as wire brushing, scraping, sand blasting, or glass bead blasting must be avoided to prevent pore smearing and

further entrapment of the contaminants. The porous part cannot always be fully cleaned without damaging the base material, but the part can be sufficiently cleaned to be returned to service.

Porous Powder Metallurgy Technology

Mark Eisenmann, Mott Corporation

Applications

A summary of the major applications of porous P/M materials are listed below. Filtration, flow control, battery electrodes, and self-lubricating bearings are the largest commercial applications. Many specialized applications have been developed to take advantage of the unique characteristics of porous materials, as shown in Table 3.

Table 3 Major application areas of porous P/M materials

Filtration/separation technology

- Polymer processing
 - Caustic/sizing recovery
 - Nylon and polyester fibers
 - Gel shearing
- Power generation
 - Condensate water polishing
 - Fossil-fuel waste streams
 - Radioactive material refining
- Semiconductor
 - Particle removal process gas
 - Bulk gas delivery systems
 - Purifier media retainers
- Analysis instruments
 - Gas/liquid chromatography
 - Gas sampling
 - Sensor protection
- Chemical processing
 - Catalyst recovery
 - Process gases and liquids
 - Fluid-bed reactor products
- Mineral processing
 - Coal, silica, metal oxides
 - Calciner and incinerator off-gas
 - Catalyst manufacturing
- Fluid power
 - Protect hydraulic valves
 - Pneumatic equipment

- Water removal in air lines

- Food and beverage

- Removal of yeast from beer
- Juice/sugar clarification
- Cooking oil, corn syrup

- Petrochemical

- Fluid cracking catalysts
- Slurry oils
- Flue gases

- Pharmaceutical

- Process steam
- Oxygen filters
- Autoclave vent filters

- Chemicals

- Acids, solvents, and inks
- Adhesives and greases
- Precipitates, salts, and carbon

- Other filter areas

- Oil burners
- Aircraft and marine fuel
- Paper and pulp

-

Flow-control devices and flow restrictors

- Flow restrictors
- Vents and breathers
- Calibrated leaks
- Gas and liquid metering
- Flow-rate timing devices
- Fuses, Vacuum delay valves

Surface area devices

- Batteries
- Electrodes
- Fuel cells
- Biomedical implant/prostheses
- Ionizers
- Cathode dispensers

Reservoirs and capillary attraction

- Self-lubricating bearings
- Heat exchangers
- Transpiration cooling
- Die-wall lubrication
- Liquid wicks, evaporation
- Printer ink reservoirs
- Heat sinks
- Applicators
- Atomizers

Dampening

- Sound attenuation
- Exhaust silencers/mufflers
- Hearing aids
- Telephone transmitters
- Flame arrestors/quenching

Filtration and separation technology applications (Ref 2, 8, 77, 78, 79, 80) are the largest market for porous P/M materials. Many industrial applications require the fine filtration capability, superior mechanical properties, and corrosion resistance of porous metals, especially at higher temperature and pressures. Particle retention, media uniformity, absence of particle shedding, and cleanability are critical to the filter system operation. Porous metals can also be used to support finer filter membranes or used as filter septum when they are coated with ion-exchange resins.

Laminar flow control devices utilizing porous P/M flow restrictors (Ref 2, 8, 80, 81, 82) are more accurate and reliable than other volumetric-flow-limiting products such as orifices and micrometering valves that operate at higher fluid velocities. Orifice technology normally relies on controlling gas flow in the choked flow regime by requiring that the inlet pressure be at least double the outlet pressure. Porous P/M materials are more resistant to contamination and plugging because there are hundreds of small flow paths available instead of a single orifice. Flow restrictors are used to provide a constant flow for a given set of conditions (pressure, temperature, and fluid) and are mechanically strong devices that do not have mechanical or electrical components that can wear or require calibration.

A few applications of porous P/M materials rely on the extremely high internal surface area and porosity available (Ref 2, 22, 83). For example, the conductivity of the electrodes for alkaline batteries and for fuel cells can be significantly increased by large contact area with the reaction fluid. Biomedical implants use the large surface area to allow tissue growth into the porous structure to allow good joint attachment.

Reservoirs and capillary-attraction devices are other major application areas (Ref 2, 8, 81, 83). Self-lubricating bearings that store lubricants in the pores and protect the surface from wear are one of the oldest commercial applications of porous P/M materials. Heat removal devices for microelectronics packaging and for cooling devices used in satellites are some of the newest application areas.

Sound, pressure, and vibration dampening components are also common industrial applications (Ref 2, 80, 81, 82). Porosity acts as an acoustical impedance and dampens certain sound frequencies while others pass through. A pressure surge in a fluid delivery line is also dampened by reducing the fluid velocity as it passes through the small interconnected channels. Many pressure gages have porous metal pressure snubbers to dampen the vibration or pressure change rate and to provide smoother operation of the indicating needle.

Boundary layer control devices such as air flotation bars and vacuum hold-down plates are highly specialized applications (Ref 2, 8, 81, 82, 84). A boundary layer of air for noncontact turning of thin films, tapes, or webs can be formed on the outside diameter of a fine-porosity tube when the inside cavity is pressurized.

In gas-liquid contacting applications (Ref 84, 85), flowing gas through a fine-grade, porous P/M material with high surface area produces small bubbles that result in high-efficiency transfer contact of the gas to the liquid. Finer pore size materials are used to prevent the liquid from penetrating back into the pores at lower internal pressures. Conventional drilled pipe spargers produce larger bubbles that do not dissolve and react as well as the finer bubbles generated by porous metals.

Overall, the application of porous P/M technology is rapidly emerging as a cost-effective, renewable, industrial resource that offers diverse solutions to engineering challenges.

Metallic Foams

J. Banhart, J. Baumeister, and M. Weber, Fraunhofer-Institute for Applied Materials Research, Bremen

Introduction

CELLULAR MATERIALS find widespread use in everyday life for cushioning, insulating, damping, constructing, and filtering purposes and in many other applications. Highly porous materials are known to have a high stiffness combined with a very low specific weight. For this reason, cellular materials frequently occur in nature as constructional materials.

Even pure metals and metallic alloys can be produced as cellular solids or metal foams. In the past, metal foams were prepared by adding a foaming agent to a molten metal after properly adjusting the viscosity of the melt (Ref 1, 2). The foaming agent is usually a powdered metal hydride, for example, TiH_2 , which releases hydrogen gas when heated to temperatures above approximately 400 °C. As soon as the foaming agent comes into contact with the molten metal, it decomposes such that there is little time to achieve a homogeneous distribution of the gas-releasing powder. Because this process is difficult to control, more widespread application could not be achieved with this technology.

A new P/M process for production of metal foams has been developed at the Fraunhofer-Institute for Applied Materials Research (Bremen, Germany) (Ref 3, 4). This enlarges the application range of cellular materials with the advantageous mechanical and thermal properties of metal foams and fewer ecological problems in comparison to polymer foams. The process has been developed for aluminum foams and is currently being extended to other metals and alloys such as tin- and zinc-base foams (Fig. 1). These nonferrous foams are the subject of this article.

Fig. 1 Optical micrographs of (a) aluminum (4 to 1), zinc (6 to 1), and lead (4 to 1) foams

For the production of steel foams, the type of foaming agent must be changed to prevent excessive oxidation. The foaming process for steel also has to take place in an inert atmosphere or in a vacuum. Using steel foams, the applicable temperature range could be extended. As an example, the exhaust manifold of car engines could be manufactured from this material. Due to the strongly reduced thermal conductivity of the manifold, it would require less time to reach the normal operating temperature of the exhaust catalyst, leading to a reduction in emissions.

Production Methods

The P/M process for production of nonferrous foams uses conventional foaming agents with compacted metal powders. Commercially available powders (such as aluminum, zinc, tin, or lead) are mixed with a foaming agent by conventional means, such as a tumbler mixer. In this simple manner, a very homogeneous distribution of the gas-releasing powder is obtained without the necessity of agitating a pool of molten metal. Subsequent to mixing, the powder blend is compacted to give a dense, virtually nonporous, solid semifinished product. Several compaction methods can be employed that range from uniaxial pressing to powder extrusion and even to roll compaction. The result of the densification step is a foamable material that, upon heating to temperatures within the range of the melting point, expands into a highly porous cellular solid with a closed-pore structure. This means that each particle of the foaming agent is embedded in a gas-tight metallic matrix so that, when decomposition of the foaming agent begins, the released gas cannot escape via some interconnected residual porosity.

Numerous shapes can be produced by this method (Ref 3, 5). The semifinished form can be processed by conventional techniques such as rolling, swaging, or extrusion to provide rods, sheets, profiles, and so forth, if desired. Merely heating this material to the melting point initiates the foaming process so that it is also possible to obtain complex-shaped foamed articles. Arbitrarily shaped hollow molds are filled with the foamable material and subsequently heated to effect foaming. It was found that thin-walled molds are particularly advantageous because they allow for a close temperature control of the foaming process.

Using appropriate heating methods, it is possible to selectively expand metallic foams. This means that certain regions of the material can be kept at a high density that facilitates joining to other materials.

Sandwich-type structures also can be produced via several methods. The simplest one is to glue sheets of conventional materials to a sheet of foamed metal. However, due to the low thermal stability of the resins, a metallic bonding of the sheets might be preferred. For example, this can be achieved by using a roll-cladding process.

Foaming agents are chosen to have a decomposition temperature that matches the melting point of the metal or alloy. Various foaming agents have been shown to yield good results for the metals in consideration (aluminum, zinc, lead). Among the foaming agents used are metal hydrides such as titanium, zirconium, and magnesium hydride, which have decomposition temperatures between 280 and 600 °C. Figure 1 shows typical cross sections of aluminum, zinc, and lead foams obtained.

Foaming Kinetics. Metal foam parts are usually produced by heating up a piece of foamable precursor material in a hollow mold and allowing the expanding melt to fill the volume. Foaming times and temperatures can be varied, and their influence on the foam properties studied. This procedure, however, does not yield any direct information about the foaming kinetics, that is, the time dependence of the volume of the expanding metallic melt and the corresponding temperatures. Therefore, an experiment was designed (Ref 6) that allows for measurement of such data. The device consists of a metal tube with a lid on one side and a movable piston on the other side. The position of the piston is measured with a magnetic detector and read out into a computer. Moreover, a thermocouple measures the temperature inside the tube. For an expansion experiment, a piece of foamable material is placed into the tube, which is then closed by the piston. The entire device is heated up at a selected heating rate. The expanding melt causes a displacement of the piston that, together with the temperature reading, generates a pair of functions $V(t)$ (volume) and $T(t)$ (temperature) that characterizes the expansion kinetics.

The expansion behavior of metal foams has been investigated for a variety of metals and alloys. Three examples are shown here: the foaming of an Al-12Si alloy, the expansion of Zn-4Cu, and the expansion of pure lead.

The expansion of Al-12Si is depicted in Fig. 2. As can be seen, the volume expansion takes place in four stages: first, before the melting temperature of the alloy (577 °C) is reached, the expansion is small, resembling the volume increase also found for samples without foaming agent. The actual expansion starts when the metal starts to melt and softens and the released gas can inflate the pores. In this stage II the volume increases to 2.5 times the initial volume. The expansion

even accelerates as the liquidus temperature is exceeded, and the now rising temperature releases more and more gas (stage III). After the maximum expansion has been achieved, the foam collapses (stage IV) due to the now-decreasing pressure in the cells as the foaming agent is exhausting.

Fig. 2 Expansion characteristics of Al-12Si (heating rate: 10 K/min).

The expansion of the zinc-copper foam is shown in Fig. 3. Here, the expansion takes place in just two stages: expansion (I) and collapse (II). There is hardly any sign of an expansion below the melting temperature, and the main expansion is not separated into two stages. The reason for this can be seen in the much higher heating rate that was applied in this case. One sees that the expansion is time controlled and that foaming is ruled by a complex interplay between melting and decomposition processes. Note that the temperature shows a kink at the melting temperature in Fig. 3. This can be attributed to an alloying process between zinc and copper, which were contained in the powder mixture as elementary powders. For lead foams, the expansion takes place in three stages (Fig. 4): first there is a slight expansion after the melting point has been reached (I), then the expansion accelerates as the temperature increases after all the metal has become molten (II) and, finally, the foam collapses (III). The reason for the slight decrease of volume between stages I and II is not yet clear and is being investigated.

Fig. 3 Expansion characteristics of Zn-4Cu (heating rate: 100 K/min)

Fig. 4 Expansion characteristics of lead (heating rate: 100 K/min)

Influence of Foaming Agent Content. It is important to know how much of the foaming agent is necessary to obtain the desired density of the foamed metal and how low the achievable densities are. In order to get this information, foamable precursor material was prepared with various contents of foaming agent for two different alloys. The content of the foaming agent was varied between 0 and 3%, the alloys chosen were pure aluminum (99.5% Al) and eutectic (Al-12Si). Each piece of precursor material was expanded to its maximum volume at the same temperature, and each measurement was repeated three times. The averaged results are shown in Fig. 5. The samples without any foaming agent exhibit the lowest expansion rate, which is about 15%. This expansion comes from the P/M preparation of the precursor material, which produces a high content of oxides, hydroxides, and gas in the powder compact that are then released upon heating. Already a small content of 0.1% TiH_2 causes an expansion of more than 50% in volume, producing a structure that justifies the name "foam." The maximum expansion is obtained for foaming agent contents of more than 0.7% and is independent of the foaming agent content up to 3%. Therefore, in practical applications foaming agent contents up to 1% are chosen. The maximum porosities that can be achieved are 80% for aluminum and 85% for Al-12Si. Higher porosities can be produced by changing the alloy composition or by adding reinforcement particles, but not by increasing the content of the foaming agent.

Fig. 5 Maximum porosity achieved when foaming aluminum alloys with various contents of foaming agent. Solid circles, Al-12Si; open circles, aluminum

Metallic Foams

J. Banhart, J. Baumeister, and M. Weber, Fraunhofer-Institute for Applied Materials Research, Bremen

Properties of Metal Foams

Like any other cellular solid, metal foams are characterized by a very low specific weight. Using the P/M technological approach described above, density values ranging between 0.5 and 1 g/cm³ are usually obtained with aluminum foams, although values down to 0.2 g/cm³ and up to 2 g/cm³ can even be achieved. Due to its closed porosity, aluminum foam floats upon water.

Mechanical properties of foams are usually determined by compression testing. To show the superior strength of metal foams, a polyethylene foam (density, 0.12 g/cm³) is compared to an Al foam (Al-4Cu alloy: density 0.45 g/cm³) in Fig. 6. In both materials, the initial porosity is about 83 to 87%. For better comparison, the strength scale of the PE foam was enlarged by a factor of 30. The curves show a behavior that is typical for highly porous cellular solids: an initial, approximately linear regime is followed by an extended plastic collapse plateau, truncated by a densification response at high strains during which the stress again increases steeply. Due to this special form of the compressive stress-strain curve, foamed materials have a high capacity to absorb great amounts of energy at a relatively low strength level.

Fig. 6 Stress-strain curve of an Al-4Cu foam (solid line, left scale) and of a polyethylene (PE) foam (broken line, right scale)

To characterize the energy absorption behavior of foamed materials, it is convenient to determine that efficiency η . For a given strain, this parameter is defined as the ratio of the actual absorbed energy to the energy that would be absorbed by an ideal absorber. Because an ideal cushioning material would exhibit a "rectangular" stress-strain curve, a real absorber can only approximate this behavior, giving rise to values below 1, or 100%, for the efficiency.

Compression Strength. Foamed materials show a universal compression behavior that makes them valuable for energy absorption applications: when loaded they first deform elastically until at a certain stress plastic deformation of the cell walls starts. This deformation typically takes place at nearly constant stress until the entire structure is densified. The stress that marks the beginning of the foam collapse is called the compression strength and can be extracted from the stress-strain diagram. Stress-strain curves were measured on specimens of metal foams with various densities (Ref 7).

The compression strength of a series of Al-12Si and Zn-4Cu alloys of various densities are shown as a function of foam density in Fig. 7. Simple theory based on cubic cells predicts a dependence of compression strength from density for an open-pore foam of the form (Ref 8):

$$\sigma_f = 0.3 \cdot \sigma_{ys} \left(\frac{\rho_f}{\rho_s} \right)^n$$

where ρ_f and ρ_s are the densities of the foamed and the massive material, respectively, and σ_{ys} is the yield strength of the matrix material. For closed pores, the formula is more complicated, but experience shows that the mechanical properties are determined by the thick cell edges and not by the thin membranes so that the equation for the open porosity works well. In order to allow for a direct reading of the exponent n , the data were plotted logarithmically in Fig. 7; the value of n can then be obtained by fitting the experimental data to a straight line, thus yielding:

Alloy	Exponent, n	Yield strength (σ_{ys}), MPa
Al-12Si	1.78	660
Zn-4Cu	2.00	990

The value for the exponent is in fairly good agreement with the value derived from the cubic model (1.5), whereas the value for σ_{ys} is much too high in both cases. One should keep in mind that the determination of the parameters n and σ_{ys} is not very accurate because of the considerable scatter especially for Al-12Si. As the pore structure of the Zn-4Cu foams is rather homogeneous, the relation between the foam density and its compression strength can be established in a more reliable way for these alloys. The results indicate that the cubic model gives a good description of the relative variation of compression strengths as the density is varied, but is not able to predict the absolute value of such strengths. This finding is compatible with earlier measurements on aluminum-base foams, where exponents between 1.5 and 3 were found, but the parameter σ_{ys} was always too high.

Fig. 7 Compression strength of a series of Al-12Si (open circles) and Zn-4Cu (solid circles) alloys. Test specimens were 30 by 30 by 40 mm. Testing was performed at 5 mm/min. As the transition from the initial linear increase of stress to the plateau regime is not defined unambiguously, the stress at 10% (Zn) or 20% (Al) deformation was taken as the compression strength (σ_f).

Elastic Modulus. The determination of the elastic modulus of foamed metals should not be carried out the convenient way, that is, by evaluation of the slope in the elastic portion of the stress-strain curve. Even in this early stage of loading

there are some plastic contributions that result from setting of the specimen, heterogeneities of the pore structure, and other defects. It is therefore preferable to apply elastic loading of the samples, for example, by means of vibrational testing (as described below) or ultrasonic methods.

The elastic modulus of foamed Al-12Si was investigated using vibrational bending tests. The resonance frequency (first order) of rectangular specimen 250 by 10 by 5 mm³ in size was determined, and the resulting storage modulus calculated. Because the values are independent of frequency, it can be concluded that the results represent the static modulus.

Considering the simplified nature of the cubic model, it is surprising that the predictions from this model describe the elastic modulus to a quite reasonable degree. The equation for the elastic modulus states that (Ref 8):

$$E_f + E_s \left[\left(\phi \frac{\rho_f}{\rho_s} \right) + (1 - \phi) \left(\frac{\rho_f}{\rho_s} \right)^2 \right]$$

where E_f is the modulus of foamed material, E_s is the modulus of the massive material, and ϕ describes the contribution of material in the cell edges, and where $(1 - \phi)$ is the contribution from cell faces. A straight line with a slope of 2 would be expected in a double-log plot of the foam modulus versus density. From Fig. 8, it can be seen that this type of correlation has actually been observed (solid line in Fig. 8). An even better approximation of measured values is obtained by taking $\phi = 0.88$ (dashed line). This means that most of the material in the aluminum foams investigated is concentrated in the cell edges rather than in the cell faces.

Fig. 8 Elastic modulus of Al-12Si foams as a function of the apparent density

Mechanical Damping. Measuring loss factors of metallic materials is a nontrivial task due to the relatively low level of damping and variables affecting the loss factor. Such variables are the friction between sample and bearings and air friction. Damping also depends on strain amplitude. Reproducible results without these contributions can be obtained by using flat strips of metal foam, which have an attached head. The whole structure is made of one block of foam. The head is used to clamp the sample with a considerable force and to reduce the slip of the sample relative to the mount to a minimum.

The sample was forced into vibrations by magnetic excitation. The resonance amplitude was monitored with a capacitive detector. By sweeping the applied frequency, resonance curves could be recorded. The resonance frequency ν and the width of the resonance $\Delta\nu$ were determined, thus yielding a loss factor:

$$\eta = \frac{\Delta\nu}{\nu}$$

Various samples were made of Al-12Si foam by foaming blocks of this material and cutting out the samples. The density covered a wide range between 0.67 and 2.65 g/cm³ (unfoamed precursor material). In this density range, η varied from 20×10^{-4} (at 0.67 g/cm³) to 12×10^{-4} (at 2.65 g/cm³).

In order to study the frequency dependence of the damping, the samples were shortened step-by-step, thus making the resonance frequency higher. The loss factor was measured for each length in the second mode of flexural vibration at the frequency determined by the cantilever length. It was found that the loss factor is not a smooth function of frequency for any of the samples, but fluctuates strongly as the frequency changes. The probable explanation is that the loss factor is nearly frequency independent for aluminum foams in reality and that frequency variations are not due to microstructural, frequency-dependent effects but are rather caused by some inhomogeneous material distribution that is characteristic for the particular sample. Therefore, the damping capacity of a highly porous metallic foam is not a simple materials property, but also characteristic of the part itself.

Damping is strongest in the foams with the lowest densities. It is well known that any kind of porosity enhances damping due to the stress concentration and what is called mode conversion around pores. This mechanism applies to microporosity as well as to the large pores found in metal foams. Especially in thin membranes an external force, even if small, can lead to high, multiaxial stresses that induce atomic rearrangements and viscouslike sliding of atoms relative to each other.

Another mechanism is of macroscopic origin: the cell walls of metallic foams sometimes contain cracks and holes that may either originate from the gas released by the foaming agent during the foaming process or from the contraction of the foamed body while cooling to room temperature after foaming. These defects may give rise to an extra frictional contribution caused by the relative movement of the crack or hole walls with respect to each other.

Compact precursor materials that are not foamed have a much higher loss factor than conventional cast aluminum materials. This is due to the P/M production of this material, which yields an aluminum matrix with embedded silicon particles, remnants of the oxide films that covered each aluminum powder particle and also foaming agent particles. This causes extra friction at the interfaces of these particles. It is also well established that P/M materials have higher damping capacities than cast ones.

Applications

One application of metal foams is for energy absorption. Aluminum foams can also be used for lightweight constructions. The replacement of honeycomb structures with sheets of foamed aluminum may lead to reduced costs and more isotropic properties. For example, the German automotive supplier Karmann is considering replacement of the bulkhead and the rear seat wall of convertible cars by sandwiches containing an aluminum foam core and aluminum face sheets (Fig. 9). The parts are up to ten times stiffer in comparison to the conventional steel parts used in the past and weigh 30 to 50% less.

Fig. 9 Sandwich part containing a porous aluminum foam core and two aluminum face sheets (length, 1 m; total width, approximately 60 cm; thickness, 8 to 10 mm). Courtesy of Karmann, Germany

Steel is also used for sandwich face sheets. In Fig. 10, steel sheets were roll clad to a sheet of foamable aluminum and then deep drawn to yield a three-dimensional structure. Subsequent foaming created the porous core.

Fig. 10 Sandwich part with steel face sheets and a porous aluminum foam core. Courtesy of Studiengesellschaft Stahlanwendungen, Germany

Because the elastic modulus can be varied within a wide range via the choice of the foam density, it is possible to match the resonance frequency of foamed parts. In this way, detrimental vibrations can be suppressed. Complex-shaped parts of foamed metals can also be used to encapsulate components that are hot or produce noise. In this case, the high thermal stability of foamed metals can be exploited.

Closed-cell foams are especially well suited to use as floating structures because of their high damage tolerance. These structures retain their buoyancy even when locally damaged. In particular, metal foams are able to withstand higher pressures or higher temperature than plastic foams.

Friction Powder Metallurgy Materials

Introduction

FRICION MATERIALS are the components of a mechanism that converts mechanical energy into heat upon sliding contact. The conversion product, heat, is absorbed or dissipated by the friction material. The coefficient of friction, an index of shearing force of the contacting parts, determines the degree of performance of the friction material. The required level of the coefficient of friction depends on the operating conditions and the end use of the product.

Sintered metal friction materials have been used as brake disks, especially for heavy-duty application. Because of their good breaking performance and low wear rate under high temperatures and heavy-duty conditions, sintered friction materials have become more important. Sintered friction materials typically comprise:

- Sinterable metal powders (e.g., copper and iron)
- Friction modifiers, such as abrasive particles (e.g., alumina, silica, and mullite) and lubricants (e.g., graphite and molybdenum disulfide)

Metallic friction materials are used in heavy-duty applications, such as in aircraft brake linings and as clutch facings on tractors, heavy trucks, earth-moving equipment, and heavy presses. There are two principal types of applications or operating conditions for metallic friction materials: "wet" and "dry." Under wet conditions, the friction components, such as clutches in powershift and automatic transmissions, are immersed in oil. Dry operating conditions involve direct contact of friction components without oil, such as in aircraft brakes and standard clutches.

A low apparent density (AD) is a key characteristic of metal powders for friction applications. For example, powders with high surface area and internal porosity enhance brake formulations by:

- *Lowering costs:* Lowest apparent density reduces brake weight and lowers total material usage.
- *Improving brake surface:* High internal porosity ensures a more homogeneous brake surface, and high surface area improves particle bonding with the matrix.
- *Increasing molded strength:* Higher green strength is achieved when compacting powders with lower apparent densities (Fig. 1).

Highly porous and irregular iron powders with very low apparent densities can be produced by the hydrogen reduction (Pyron) process. A comparison of iron powder apparent density follows:

- Hydrogen-reduced iron powder, 1.20 to 2.5 g/cm³
- CO-reduced powder, 2.30 to 2.60 g/cm³
- Atomized powder, 2.95 to 3.25 g/cm³

Manufacturing

Metallic friction materials are produced by compacting and sintering mixes of metal powders and friction-producing ceramic materials such as silicon dioxide or aluminum oxide. Friction materials consist of a dispersion of a friction-producing ingredient in a metallic matrix. Originally, a copper-tin alloy was used as the metallic matrix, in which copper powder, tin powder, the friction-producing ingredient in powder form, and other ingredients that modify the frictional behavior were mixed, compacted, and sintered. This matrix material is still used, but other compositions such as copper-zinc matrix materials have been developed, mainly for oil-immersed (wet) applications. The copper-zinc materials have the ability to maintain a strong, yet porous, matrix that retains oil. The more porous copper-zinc materials have higher friction coefficients and higher energy absorption capacity than copper-tin materials.

Raw Material Blending. Sintered metal friction materials involve a wide variety of compositions. The choice of the composition depends on the nature of the application, such as the use and energy-power requirements. In general, metallic friction materials can be classified as either copper or iron base. Table 1 provides the range of compositions of metallic friction materials. Proportions of the components greatly affect physical properties of the materials. By varying the percentages of the individual components, different coefficients of friction may be achieved. Before mixing, powders generally are brush screened to break up agglomerated particles. Mixing usually is done in cone-type blenders. During mixing, small amounts of additives are introduced, mainly to prevent possible segregation of components by specific gravity. These additions are light-fraction oils that are volatilized easily during sintering.

Table 1 Nominal compositions of copper-base and iron-base friction materials

Premix	Compositions, %						
	Copper	Iron	Lead	Tin	Zinc	Silicon dioxide	Graphite
Copper base	65-75	...	2-5	2-5	5-8	2-5	10-20

Compacting. Most compacting of powders is done in hydraulic presses. Compacting pressure varies from 165 to 276 MPa (12 to 20 tsi) and is determined by the type of powder and the compacted density required. Before starting a production run, a series of density checks should be made. Low densities often cause handling problems, especially with thin cross sections. This can be overcome by increasing pressure. Surface parallelism is a major consideration and, in general, parts are kept in the 0.05 to 0.10 mm (0.002 to 0.004 in.) tolerance range.

Sintering of Clutch Plate Facings. Green compacts, placed on supporting steel backing plates, are stacked in sintering furnaces. Backing plates or cores generally are cleaned and copper plated to achieve good bonding with the friction material. The type of sintering furnace used depends on the shape of the parts being produced. Bell-type furnaces are generally used for clutch discs because of the compression requirement. However, for disc brake pads and other odd shapes, the use of bell-type furnaces is not essential because compression is not required during sintering.

In bell furnaces, pressure is applied on the vertical stack of discs to reach the desired sintered density level and to prevent warpage or distortion. However, excess pressure causes high sintered densities and loss of low-melting-point metals from the friction material. Sintering is carried out at temperatures of 550 to 1000 °C (1020 to 1830 °F) in a protective atmosphere to prevent oxidation. Figure 2 shows the structure of a copper-base friction material, copper-plated layer, and steel backing plate after sintering at 650 °C (1200 °F) for 2 h.

Fig. 2 Structure of sintered copper-base friction material

Final Operations. Dimensional accuracy and additional design considerations are of major importance for applications. Parts are machined after sintering to meet dimensional specifications.

Grooving is required in the production of friction facing. Various types of grooves may be used, and each performs in a different manner. Two of the most frequently used types of grooves are combined in one friction facing (Ref 1). The purpose for grooving varies from wet friction to dry friction materials, but grooves are very important in wet clutch systems. In wet applications, the heat energy is partly removed by the oil. Grooves allow cooling oil to flow across the surface of the friction faces, yet allow fast oil runoff during engagement to minimize oil thickness on the surfaces and maximize the coefficient of friction.

In dry systems, grooves serve somewhat different purposes than in wet systems. These include (a) prevention of the crushing effect of thermal expansion during high application temperatures, as in the disc brake pads of heavy-duty vehicles; (b) removal of operation debris; and (c) transfer of water and other liquids if the surface becomes wet.

Friction Powder Metallurgy Materials

Friction Applications

The coefficient of friction (μ) is the most important property in selection of a facing material. Friction may be expressed as static or dynamic values. The static coefficient of friction is the friction value of two surfaces at zero speed, while the dynamic coefficient of friction is measured at speeds greater than zero. The coefficient of friction is a function of conditions such as rubbing speed, pressure, and temperature. The relationship between rubbing speed and the coefficient of friction is shown in Fig. 3. With increasing rubbing speeds of the two surfaces, the coefficient of friction tends to drop. Applied pressure has a similar effect on the stability of the coefficient of friction. In wet friction applications, any increase in the temperature of the two rubbing surfaces above 150 °C (300 °F) will cause a substantial drop in the coefficient of friction. This temperature is commonly referred to as "breakdown temperature."

Fig. 3 Effect of unit pressure and rubbing speed on the coefficient of friction in a wet system. Solid line indicates dynamic coefficient of friction. Dashed line indicates static coefficient of friction.

In wet applications, wear rates are usually low; therefore, thinner facings may be produced. Wear rate depends on factors such as temperature, number of engagements, mating or coupling plate surface finish, coupling plate, and facing material.

Dry friction applications are simple and lightweight compared to wet applications. Their major disadvantage is their erratic behavior in wet environments (Ref 2). For instance, on passenger cars, considerable fade is encountered when water enters the brake assembly. Figure 4 shows the effect of pressure and speed on the dynamic coefficient of friction of an automobile disc brake. Similar to wet friction materials, the drop in the dynamic coefficient of friction with pressure is noticeable.

Unit pressure		Coefficient of friction
kPa	psi	
32 km/h (20 mph) line		
2760	400	0.336
4825	700	0.336
6900	1000	0.317

64 km/h (40 mph) line		
2760	400	0.336
4825	700	0.306
6900	1000	0.298
8965	1300	0.277

Fig. 4 Effect of pressure and speed on the coefficient of friction in an iron-base by braking surface

Dry friction materials vary in composition from wet friction materials. In wet friction compounds, the matrix of the sintered material is copper, but in dry friction compounds, the percentage of copper is reduced and iron is increased. The effect of temperature on dry friction material is shown in Fig. 5(a) and fig 5(b). Between 95 and 315 °C (200 and 600 °F), the drop in the dynamic coefficient of friction is noticeable. After a certain level, the rate of decrease slows and eventually stabilizes.

Fig. 5 Effect of temperature on the coefficient of friction for a proprietary iron-base compound for brake usage

In some materials, a slight increase in the coefficient of friction with increasing temperature is found after stabilization. This is mainly because of a change in surface morphology and the high-temperature effect of graphite in the facing material. In many cases, the drop in the friction level is recoverable, as shown in Fig. 5(b). As the temperature drops, the coefficient of friction increases. At 95 °C (200 °F), frictional recovery is almost complete. However, the level of recovery depends on the material used.

Clutch and brake applications include:

Dry friction materials

- Earth moving equipment
- Agricultural equipment
- Cranes and hoists
- Lift trucks
- Highway trucks (clutches)
- Aircraft (brakes)

Wet friction materials

- Earth moving equipment
- Agricultural equipment
- Military
- Lift trucks (clutches)

Introduction

SELF-LUBRICATING BEARINGS are one of the oldest industrial applications of porous P/M parts, dating back to the mid-1920s (Ref 1, 2, 3). They remain the highest volume part produced by the P/M industry. The major advantage of porous bearings is that porosity in the bearing acts as an oil reservoir. The pores are filled with a lubricant that comprises about 25 vol% of the material.

When the journal in an oil-impregnated self-lubricating bearing starts to turn, friction develops, the temperature rises, and oil is drawn out of the press because of the greater coefficient of expansion of the oil compared with the metal and because of the hydrodynamic pressure differential in the oil film between the journal and the bearing. When rotation stops and the bearing cools, the oil is reabsorbed by capillary action.

For many self-lubricating bearings, lubricant contained in the pores of the bearing remains for the entire service life of the bearing. On some heavy-duty bearing applications, an oil reservoir that feeds additional oil through the bearing wall may be provided on the outside diameter of the bearing. Figure 1 shows typical examples of arrangements for supplementary lubrication of porous bearings. The most common shapes of self-lubricating bearings are shown in Fig. 2.

Fig. 2 Typical bronze self-lubricating bearings

Every component that requires rotary motion relies on a bearing of some type. P/M self-lubricating bearings can be found in almost every part requiring rotary motion. Examples of the wide usage of P/M bearings include:

- *Automotive:* Heater motors, window lift motors, air conditioners, windshield wiper motors, power antenna motors, trunk-closing motors, seat adjuster motors, and tape deck motors
- *Portable power tools:* Drills, reciprocating saws, jigsaws, and sanders
- *Home appliances:* Washers, dryers, refrigerators, blenders, mixers, food processors, fans, and clocks
- *Consumer electronics:* Phonographs, high-fidelity equipment, stereo equipment, tape players, and video recorders
- *Business machines:* Typewriters, computers, and copiers
- *Farm and lawn equipment:* Tractors, combines, cotton pickers, lawn mowers, string cutters, and chain saws
- *Marine equipment:* Outboard motors

Bearing Compositions

Porous self-lubricating bearings are divided into four groups:

- Sintered bronze bearings
- Iron-base sintered bearings
- Iron-bronze (diluted bronze) sintered bearings
- Iron-graphite sintered bearings

The original and most widely used P/M bearing material is 90%Cu-10%Sn bronze with or without the addition of graphite (1% fine natural graphite is often added to enhance processing as well as improve bearing properties and bearing operation). The 90%Cu-10%Sn bronze material is superior in bearing performance to the iron-base and iron-bronze compositions, which are lower in cost and used in less severe applications.

Sintered bronze bearings, which are covered in American Society for Testing and Materials (ASTM) standard B 438, are made primarily from elemental copper, tin, and graphite powders. These bearings are available in three grades, which consist of the basic bronze material with different percentages of graphite as shown in Table 1. Each grade is available in four types (except grade 3, which is available in two types), determined by density range. The density ranges are specified in Tables 2 and 3.

Table 1 Chemical composition of self-lubricating sintered bronze bearings

Element	Grade 1	Grade 2	Grade 3
Copper	87.2-90.5	85.7-90.2	83-88.5
Tin	9.5-10.5	9.5-10.5	9.0-10.0
Graphite	0-0.3	0.5-1.8	2.5-5.0
Iron, max	1.0	1.0	1.0
Total other elements by difference, max	1.0	1.0	1.0

Source: Ref 4

Table 2 Density requirements of sintered bronze bearings, grades 1 and 2

Type	Density, g/cm ³
1	5.8-6.2 ^(a)
2	6.4-6.8
3	6.8-7.2
4	7.2-7.6

Source: Ref 4

- (a) Maximum density limit of 6.2 g/cm³ has been established on type 1 to ensure meeting an oil content of 27% min. Satisfactory bearings can also be produced between type 1 and 2. These bearings have slightly higher strength constants and slightly lower oil content.

Table 3 Density requirements of sintered bronze bearings, grade 3

Type	Density, g/cm ³
1	5.8-6.2
2	6.2-6.6

Source: Ref 4

A maximum density limit of 6.2 g/cm³ has been established on type 1 to ensure a minimum oil content of 27%. Satisfactory bearings can also be produced between type 1 and 2--these bearings have slightly higher strengths with slightly lower oil content. Oil contents of the sintered bronze grades are shown in Table 4.

Table 4 Oil content of sintered bronze bearings

Type	Minimum oil content, vol%		
	Grade 1	Grade 2	Grade 3
1	27	25	11 ^(a)
2	19	17	... ^(b)
3	12	9	...
4	9	7	...

(a) At 3% graphite, type 1 will contain 14% min oil content.

(b) At 3% graphite, type 2 will contain 8% min oil content. At 5% graphite, type 2 will contain only a minimal amount of oil.

Sintered bronze bearings are also specified in Metal Powder Industries Federation (MPIF) standard 35. Refer to Table 5 for the MPIF specification for sintered bronze bearings.

Table 5 MPIF specification for sintered bronze bearings

- (a) These data are based on material in the finished condition.
- (b) Minimum oil content will decrease with increasing density. Those shown are valid at the upper limit of the density given.
- (c) Oil-impregnated. Assumes an oil density of 0.875 g/cm³.
- (d) For oil content of 27% min, density range will be 5.8-6.2 g/cm³, and *K* constant will be 105 MPa (15 ksi).
- (e) Iron 1 wt% max.
- (f) For oil content of 25% min, density range will be 5.8-6.2 g/cm³ and *K* constant will be 90 MPa (13 ksi).
- (g) At maximum graphite (5%) and density (6.6 g/cm³), this material will contain only a trace of oil. At 3% graphite and 6.2-6.6 g/cm³ density, it may contain 3-10 vol% oil.

Iron-base sintered bearings, which are covered in ASTM B 439, consist of four iron-base compositional grades (Table 6). Grades 1 and 2 are iron-carbon materials, while grades 3 and 4 are iron-copper materials. Density and oil content of these grades are specified in Table 7.

Table 6 Chemical composition of iron-copper carbon sintered bearings

Iron-bronze sintered bearings (diluted bronze) are covered in ASTM B 612. They are Fe-Cu-Sn graphite oil-impregnated bearings of one composition, commonly referred to as diluted bronze. This bearing grade is an excellent bearing material for standard applications where shaft speed is below 10,000 rpm and the bearing is subject to nominal loading conditions. It has the unique feature of being bronze in appearance but lower in material cost. The microstructure of a diluted bronze P/M alloy is shown in Fig. 3. The density range of this bearing grade is 6.0 to 6.4 g/cm³ and the oil content is greater than 17%. Chemical composition of this bearing material is shown in Table 9.

Table 9 Chemical composition of diluted bronze sintered bearings

Element	Composition, %

Iron-graphite sintered bearings, which are covered in ASTM B 782, consist of two iron-graphite base grades. These two material grades are the newest bearing materials that are finding widespread use in applications in the industry. Grade 1 has a very low coefficient of friction coupled with quiet operation. This grade has been very popular in numerous applications where quiet operation, low coefficient of friction, and normal operating loads are encountered. It also has the added feature of lower cost than the bronze or diluted bronze materials with equivalent performance under normal operating conditions. Grade 2 has found a unique use in high-speed applications, but it is important to note that hardened shafts are required for good operational success. Refer to Table 11 for chemical composition and Table 12 for density and oil content specifications.

Table 11 Chemical composition of iron-graphite sintered bearings

Powder Metallurgy Bearings

Norbert A. Arnold, Keystone Carbon Co., Victor C. Straub, Keystone Powdered Metal Company; Michael Schloder, Specialty Pressed Components, Inc.

Blending and Mixing

Mixing or blending of fine elemental powders normally is done in a double-cone blender. For bronze bearings, mixtures of electrolytic, reduced, or atomized copper powders, atomized tin powders, and natural graphite powders are used. The particle size distribution of the copper powder is 100% -100 mesh and between 40 to 70% -325 mesh. The tin powder is 95% -325 mesh. Both reduced and atomized iron powders are used for iron-base bearings. The powders are combined with a fine lubricant such as stearic acid, zinc stearate, or Acrawax. The lubricant, which burns off during sintering, acts as a die release.

Blending of elemental and/or prealloyed powders is done for a predetermined time to produce a homogeneous mixture of all components and to supply a mix that has a specific density, which is necessary for fixed fill die cavities. Thorough mixing is required to achieve uniform strength, density, and dimensional control during sintering. The idea is to obtain uniform melting and diffusion of low melting constituents such as tin in bronzes or copper in iron-base alloys.

Compacting. The mix or preblend of raw materials is then transferred to a hopper, which is attached to a mechanical or hydraulic press. Loose powder flows by gravity (some vibration may be required) to the die cavity, where it is compacted to the desired shape and density. Compacting pressure for typical bearing compositions varies from 138 to 413 MPa (10 to 30 tsi). Depending on final dimensional accuracy, the green compact, or bearing, is molded 1 to 5% oversize to allow for material movement during sizing.

Tools used to press the loose powder are precision tooling. The die and core pin normally are made of tungsten carbide, while the upper and lower punches are made of high-grade tool steel.

Sintering transforms the green bearing into a metallurgically bonded alloy. The green bearing, an elemental mixture of copper and tin, is transformed into a true α bronze alloy at a temperature that is below the melting point of copper but above the melting point of tin. Under these liquid-phase conditions, sintering occurs without an appreciable change in the size of the bearing.

Sintering temperature for bronze may vary from 830 to 900 °C (1525 to 1650 °F), depending on the time at temperature (normally 3 to 8 min) and the desired sintered size. Suitable bronze bearings have microstructures that are essentially α bronze, as shown in Fig. 4. Diluted bronze bearings require sintering temperature of 870 to 980 °C (1600 to 1800 °F), whereas iron-copper bearings should be sintered above the melting point of copper--normally in the range of 1105 to 1125 °C (2020 to 2060 °F). See the article "Production Sintering Practices" in this Volume for additional information.

Fig. 4 Alpha bronze microstructure in 90%Cu-10%Sn P/M bearing alloy. (a) 150 \times . (b) 300 \times

Sizing. Most precision bearings require a sizing operation after sintering. Sizing is done in highly polished, dimensionally accurate tools. Sizing pressures range from 206 to 551 MPa (15 to 40 tsi), depending on the amount of sizing required and the composition of the sintered part. Sizing is done primarily to improve dimensions; however, it cannot be done effectively without increasing density.

Typical sized inside diameter tolerances range from 0.0076 mm (0.0003 in.) for spherical bearings up to 16 mm (0.63 in.), with an overall length of up to 19 mm (0.8 in.). Straight-wall bearing inside diameter tolerances normally are 0.03 mm (0.001 in.) per 25 mm (1 in.) of diameter for lengths up to 38 mm (1.5 in.).

Impregnation. Powder metal bearings appear solid, but are actually 20 to 25% porous. This characteristic--porosity--makes parts made by P/M processing ideal bearing materials. Porosity consists of thousands of small capillaries that are interconnected throughout the structure of the bearing and act as a built-in reservoir for the lubricant. These pores can be filled with a lubricant that is sufficient for the life of the unit for most applications. However, for longer bearing life, oil-saturated felt or wicking can surround the bearing.

The pores are impregnated with oil normally under vacuum. Bearings are placed in the tank or autoclave, the lid is closed, and the vacuum pump is turned on. Pressure is reduced to at least 709 torr (28 in. Hg) before oil is permitted to flow over

the bearings. Oil is introduced into the tank without shutting off the vacuum pump, and the tank, now filled with bearings and oil, is evacuated for another few minutes or until the pressure is again reduced to 709 torr (28 in. Hg).

After obtaining the desired vacuum, the vacuum pump is shut off, a valve is opened, and the oil is forced out of the impregnating tank to the storage reservoir. A properly impregnated bearing contains sufficient oil to fill 90% of the available interconnecting porosity or approximately 20 vol% oil (standard density 6.4 to 6.8 g/cm³ bearing) and 2 ¹/₂ to 3 wt% oil.

The principal considerations in selecting a lubricant are the temperature of operation, bearing load or pressure between moving parts, operating speed, clearance between mating parts, and atmospheric conditions such as air temperature, dust, and moisture. In general, the most versatile type of lubricant for applications requiring self-lubricating bearings is a high-grade turbine oil. Several standard grades of oils for self-lubricating bearings, along with their properties, are listed in Table 14.

Table 14 Standard lubricants for porous bearings

SAE No.	Viscosity ^(a) at 38 °C (100 °F), s	Viscosity ^(a) at 99 °C (210 °F), s	Viscosity index	Pour point		Flash point		Recommended use

Load-Carrying Capacities

The *PV* formula should be used when determining the load-carrying capacity of self-lubricating bearing materials. The formula used to determine loads and speeds is:

$$PV = \frac{W}{Ld} \times \frac{\pi dn}{12} = \frac{\pi Wn}{12L}$$

where *P* is the load pressure on the projected bearing area (bearing inside diameter × length), *V* is the surface velocity of the shaft in feet per minute, and *W* is the bearing load in pounds. *L* is the bearing length in inches, *d* is the inside diameter of the bearing (also in inches), and *n* is the shaft speed in revolutions per minute. P/M self-lubricating bearing materials have a permissible *PV* factor of 50,000. Factors of *PV* above 50,000 are possible with special considerations. It should be noted that thrust bearings are the exception, where a maximum *PV* factor of 10,000 is recommended. Supplemental

lubrication increases the permissible PV . Adverse conditions, such as the presence of dirt or abrasive particles, misalignment of a shaft, or an operating temperature in excess of 93 °C (200 °F) reduce the permissible PV factor.

When determining bearing size, the shaft diameter is established by the requirements of the application. For the best performance, the bearing outside diameter should be at least 25% larger than the inside diameter (ID) (optimal oil reservoir and heat dissipation). Figures 5 and 6 can be used to determine bearing load. From Fig. 5, determine the shaft speed in feet per minute. From Fig. 6 where the bearing ID and length are the same, determine the load in pounds per square inch. If the load times the speed exceeds 50,000 PV , the bearing length must be increased.

Fig. 5 Bearing speed information for shaft revolutions per minute versus speed at varying diameters

Fig. 6 Bearing load pounds to psi at varying diameters and overall length (OAL)

Example. A bearing with 0.5 in. ID is running at 1800 rpm and supporting a load of 75 lb. From Fig. 5, the speed would be 230 ft/min. From Fig. 6, the load on a 0.5 ID × 0.5 OAL (overall length) bearing would be 300 psi. Then $300 \times 230 = 69,000 \text{ PV}$. Increasing the bearing length to 0.70 in., an estimation based on the amount the 50,000 *PV* was exceeded, 40% with a safety margin, would reduce the load to:

$$75 \text{ lb}/0.5 \times 0.7 = 215 \text{ psi} \times 230 \text{ ft/min} = \mathbf{49,450 \text{ PV}}$$

Permissible loads for P/M bearings are given in Tables 15, 16, and 17.

Table 15 Permissible loads for sintered bronze self-lubricating bearings

Shaft velocity ^(a)		Permissible loads, grades 1 and 2							
		Type I		Type II		Type III		Type IV	
m/s	ft/min	MPa	psi	MPa	psi	MPa	psi	MPa	psi
Slow, intermittent	Slow, intermittent	22	3200	28	4000	28	4000	28	4000
0.13	25	14	2000	14	2000	14	2000	14	2000
0.26-0.51	50-100	3.4	500	3.4	500	3.9	550	3.9	550
Over 0.51-0.77	Over 100-150	2.2	365	2.2	325	2.5	365	2.5	365
Over 0.77-1.02	Over 150-200	1.7	280	1.7	250	1.9	280	1.9	280

Note: With a shaft velocity of less than 0.255 m/s (50 ft/min) and a permissible load greater than 6.89 MPa (1000 psi), an extreme-pressure lubricant should be used. With good heat dissipation and heat-removal techniques, higher *PV* ratings can be obtained.

(a)

For shaft velocities over 1.02 m/s (200 ft/min), permissible loads may be calculated: $P = 50,000/V$ ($P = 1.75/V$).

Table 16 Permissible loads for iron-based sintered self-lubricating bearings

Shaft velocity ^(a)		Permissible loads			
		Grades 1 and 2		Grades 3 and 4	
m/s	ft/min	MPa	psi	MPa	psi

Powder Metallurgy Gears

George T. Shturtz, Carbon City Products

Introduction

POWDER METALLURGY (P/M) is a flexible metalworking process for the production of gears. The P/M process is capable of producing close tolerance gears with strengths to 1240 MPa (180 ksi) at economical prices in volume quantities. Spur, helical, bevel, face, spur-helical, and helical-helical gears are produced by P/M techniques. The process is particularly attractive when the gear contains depressions, through holes, levels, or projections.

The first application of P/M gears was for oil pumps in 1937/1938 (Ref 1). Gear pumps constitute a common type of application. Depending on application stress levels, different materials and density levels are used. For example, iron-carbon or Fe-Cu-C materials with densities of 6.0 to 6.8 g/cm³ are used in gear pumps for low-pressure applications such as engine lubrication and automatic transmissions. For higher stress applications up to 20 MPa (3 ksi), alloy steels at the minimum density of 7.1 g/cm³ are used. Powder metallurgy material requirements for gear pump applications at various stress levels are given in Table 1.

Table 1 Material requirements for P/M pump gear applications

Application	Material code
Output pressure less than 0.69 MPa (100 psi) and light service	FC-0208 type; as-sintered; 5.8-6.2 g/cm ³
Output pressure less than 6.9 MPa (1000 psi) but subject to high vibration and heavy service; hardened by heat treating	FC-0208 or FN-0106; 6.4-6.8 g/cm ³
Medium high pressure 6.9-8.6 MPa (1000-1250 psi) for short intervals; hardened by heat treating	FC-0208 type; 6.2-6.5 g/cm ³
General-purpose hydraulic pumps up to 10.3 MPa (1500 psi) continuous service	FN-0106 type; heat treated; 6.8-7.1 g/cm ³
General-purpose hydraulic pumps up to 17.2 MPa (2500 psi) continuous service	AISI 4630 type; heat treated; 7.2-7.6 g/cm ³

With the considerable progress in P/M technology over the years, the quality and application of P/M gears has increased. Progress in production, compaction, and sintering has resulted in new techniques such as infiltration, powder forging, surface rolling, and several finishing treatments. These developments, as discussed elsewhere in this Volume, have enabled the P/M parts to compete successfully with wrought metal counterparts.

Figure 1 summarizes the various P/M manufacturing methods used in gear production. Selection of a process method depends on factors such as dimensional accuracy and gear properties. In terms of dimensional accuracy, AGMA (American Gear Manufacturers Association) quality classes 5 to 7 can be obtained through conventional press-and-sinter operations. When AGMA quality levels above 7 are required, secondary operations such as coining, burnishing, and grinding typically are employed (see the section "Gear Tolerances" in this article for more information).

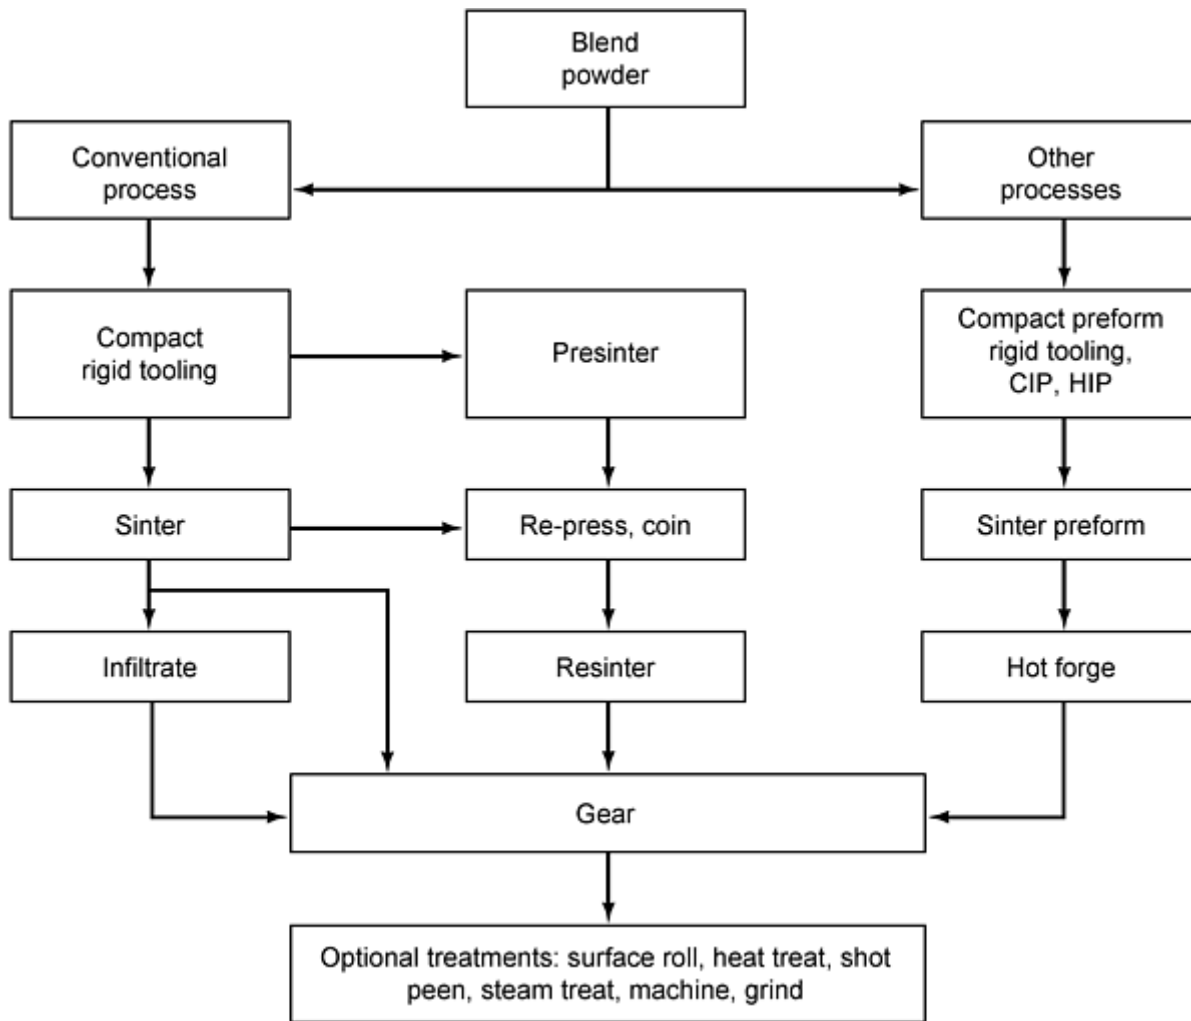

Fig. 1 P/M gear production process. CIP, cold isostatic pressing; HIP, hot isostatic pressing

Performance of any P/M part is influenced primarily by density. Theoretical density of steel is around 7.85 g/cm^3 , and Table 2 summarizes density levels obtained from various P/M processes for steel. All of these P/M methods are employed for gear manufacture, including various surface treatment such as carbonitriding, shot peening, and steam oxide treatments (Ref 2). More detailed information is given in specific articles in the Section "Shaping and Consolidation Techniques" in this Volume for the various processes listed in Table 2.

Table 2 Density range for P/M steel consolidation methods

P/M method	Density range, g/cm^3	Notes
Pressed-and-sintered steel	6.9-7.1	Conventional powder metallurgy
Double processing (press, presinter, restrike, full sinter, heat treat)	7.2-7.4	Restrike (or repress) tooling has tolerances closer to finish dimensions than the tooling for the first strike
Warm compaction (single pressed)	7.2-7.5	Specially formulated powders to obtain higher green strength at lower compaction pressure
Warm compaction (double pressed)	7.4-7.7	...
Cold densification (press, sinter, cold form, heat treat)	7.6-7.8	Cold forming improves fatigue and wear resistance
Powder forging (press, sinter, forge, heat treat)	7.6-7.8+	Limited to spur, bevel, and face gears although trials with helical gears have been done (Ref 2)
Powder injection molding	7.8+	...
Copper infiltrated steel	Near density	full Copper infiltration also improves machinability

Roll densification	7.6-7.8	Increases localized densification for wear and fatigue resistance
---------------------------	---------	---

A wide variety of base metals are available in powder form, such as brass, bronze, iron, low-alloy steels, and stainless steel. The selection is governed by required mechanical properties, physical properties, service conditions, and cost. Table 3 lists commonly used P/M materials and broad applications of standard grades. Customized mixing and blending of elemental powders also provides a variety of possibilities for the development of alloy compositions formulated for specific mechanical and physical properties.

Table 3 Commonly used metal powder grades

Material	Chemistry	Applications
F-0000	Pure Fe	Low strength at high density, soft magnetic properties
F-0005	Fe + 0.5% C	Moderate strength, medium-carbon steel
FC-0208	Fe + 2% Cu 0.8% C	Higher-strength structural components
FN-0205	Fe + 2% Ni + 0.5% C	High strength (heat treated), good impact resistance
FX-2008	Fe + 20% Cu + 0.8% C	Copper-infiltrated steel, high strength, machinable
SS-316L	316 stainless steel	Good toughness, corrosion resistance
SS-410	410 stainless steel	Good hardenability, abrasion resistance
CZ-2002	Brass	Good toughness, elongation, corrosion resistance
CT-1000	Bronze	Structural and bearing applications
CNZ-1818	Nickel silver	Decorative, tough, ductile, corrosion resistance

Powder Metallurgy Gears

George T. Shturtz, Carbon City Products

Capabilities and Limitations

Powder metal gears are used in various applications for appliances, office machines, machinery, machine tools, and automotive products. The P/M process offers various advantages over traditional gear manufacturing for various applications.

In traditional methods, gears are manufactured from blanks obtained by machining of castings, forgings, and rolled bar stock. These blanks are machined by various methods such as milling, hobbing, and shaping. For precision and high-speed applications, the gear teeth are finished by secondary operations such as shaving and grinding. Gear production by these methods has the following disadvantages:

- Processing times are long, particularly with difficult-to-machine alloys.
- Material utilization is very low.
- Machined gear teeth have an unfavorable grain flow pattern with flow lines intersecting the gear tooth profile.

In comparison to the traditional gear manufacture process, the P/M process offers several advantages, particularly the elimination of machining and scrap losses for the manufacture of various gear types such as helical, bevel (both straight and spiral), rack, face, internal and external spur gears, and also compound gears. Internal configurations (splines, keys,

keyways) also can be formed simultaneously with the gear profile during P/M manufacture, eliminating subsequent machining operations. Thus, P/M gear manufacturing allows efficient utilization of materials for moderate- to high-volume production. The minimum quantity required to make the P/M process economically competitive with machining depends on the size and complexity of the part and its accuracy and other property requirements. While powder metallurgy is best suited and most widely known for high-volume production quantities, there are numerous applications where small quantities (a thousand parts) can still offer cost benefits over traditional manufacturing methods.

General process advantages of P/M gear manufacture include:

- Economy in mass production
- Repeatability and uniformity of part features and dimensions
- Production of multilevel gears
- Close control of density or, conversely, porosity to suit a particular application
- Reduction or elimination of secondary operations
- Improved surface finishes on gear teeth by reducing or eliminating the machining marks (or "scoring") that can be imparted by conventional methods
- Self-lubricating ability from impregnation of oils and lubricants
- Noise reduction from the sound dampening qualities of the pore structure of a P/M component, high surface finish and tooth form consistency also can have an effect on overall reduction of noise in comparison to cut gear sets of comparable quality
- Weight reduction by incorporating weight saving or lightening holes (or similar shapes) in the initial tool design

Limitations of the P/M process for gear manufacturing include (Ref 2):

- Not economical in low- and medium-quantity production
- Not normally suitable for production of worn gears, herringbone gears, and helical gears with helix angle exceeding 35° because of various pressing and tooling considerations
- In view of the press capacities required for compaction, the sizes of gears are limited
- The gear thickness or face width is restricted by the requirement that the depth of the die cavity and the stroke of the press must be at least $2\frac{1}{2}$ times the gear thickness

Gear Forms

The size of P/M gears range from as small as a few millimeters to more than 300 mm in diameter. For all practical purposes the face width of P/M gears is limited to less than 75 mm (3 in.). The commonly used compaction presses have insufficient press stroke to consolidate the powder to greater than this length (face width).

The following types of gears can be produced by the powder metallurgy process:

- Spur gears
- Bevel gears
- Face gears
- Hypoid gears
- Helical gears of helix angle not exceeding 35°

Combination gears or multiple gears in which two or more gear forms are combined into one component are a specialty of the P/M process.

Some examples of P/M gear design are shown in Fig. 2, 3, 4, and 5. True involute forms (Fig. 3a) that are expensive to make by other methods can be easily made by the P/M process. The P/M process also is particularly advantageous for gear designs that have irregular curves, radial projections, keyways, or recesses, because these features are easily obtainable without requiring secondary machining operations. Full tooth face width for compound gears and sufficient fillet radii at the root diameter for tip clearance can be attained without allowances for cutter clearance.

Spur gears are the most common type of P/M gear in use today. The P/M process is capable of producing spur gears of many tooth forms and modifications. If an electrodischarge (EDM) electrode can be ground or cut, the mating form can be duplicated in P/M dies.

Compared to wrought metal gears, the face width or thickness of a spur gear is restricted in powder metallurgy in order that the density and mechanical properties are maintained fairly uniform throughout the section. Fine pitch (module <0.75 mm) spur gear teeth present powder filling problems, which are more serious if the face width is large.

Helical gears are also commonly made by the P/M process. However, in contrast to metalcutting processes, the helix angle of P/M gears is limited to approximately 35° . As with spur gears, many tooth forms and modifications are possible.

Helical gears have not been produced by powder forging, but recent production tests have been performed on a unique tooling method for powder forging of helical gears. One production trial involved the powder forging of a helical gear with a 31° helix angle and a normal pressure angle of 15° for an automotive transmission part (Ref 4). Experimental work later carried out by the German Research Society showed the superiority of the finished product in terms of toughness, tooth root fatigue, and contact fatigue (Ref 5). During powder forging of a helical gear, the die is the only helical part of the tool.

Bevel and face gears are readily made by the P/M process, but differ somewhat from spur and helical gears in mechanical property flexibility. Due to the nature of the compaction process, sections such as face gear teeth cannot be made to high densities without resorting to copper infiltration or repressing. Most bevel and face gear forms can be made providing they are not undercut, but the maximum mechanical properties attainable will be somewhat less than those that can be achieved for spur and helical gears.

All face tooth forms must be such that the green compact does not lock into the punch. For this reason undercut gear forms cannot be produced. Under the action of the punch, the crown area of face gear teeth also normally receives less

compaction than the root zone. This results in an undesirable density variation, which can be offset by copper infiltration or repressing.

Another method to offset density variations is by putting a nonfunctional gear form with its teeth in the offset position so that a tooth gap comes below a tooth crown; this allows full punch pressure to be exerted on the tooth crowns of the functional gear, enabling a better density distribution (Ref 3).

Combination Gears. Powder metallurgy gear manufacture allows the production of combination gears or multilevel (two-to-four level) gears resulting in a single part with two or more gear forms. All the gear forms can be positioned close to one another, thus making the part very compact. This helps in saving space and handling and assembly costs. Combination gears can be produced by either of the two methods:

- Compacting the part in the combined form
- Compacting separately, assembling them in green state and sintering

Powder Metallurgy Gears

George T. Shturtz, Carbon City Products

Gear Tolerances

Tolerances of P/M gears are determined by the compaction tooling, compaction process, sintering process, and the P/M alloy. Tooth form and dimensions remain relatively stable throughout the process. The density variation in the compact should not exceed 0.2 g/cm^3 , otherwise, dimensional control will be difficult during sintering.

Powder metallurgy gears are produced typically in AGMA 5 to 7 quality levels. Higher AGMA classification is possible, depending on the size of the compacted gear and the additional secondary operations. Higher AGMA classification increases the cost of manufacturing due to the secondary (machining) or restrike operations that are added to meet the tighter tolerances. In general, traditional press-and-sinter operations are economical for achieving AGMA quality levels 5 to 7. It is not advisable to produce higher quality levels through only compaction and sintering, as closer tolerances and tool wear will impact costs. Where higher accuracy is required, secondary operations such as sizing, shaving, burnishing, and grinding are required. Sizing (repressing) is the most common method because it improves mechanical properties through cold working.

Because dimensional variation is a function of part geometry, material, density, and subsequent thermal operations, dimensional tolerances may vary by application.

Powder metallurgy gear tolerances are determined by the compaction tooling, compaction process, sintering techniques, and the alloy. The tolerances can be divided into functional tolerances that directly affect gear function and nonfunctional elements that pertain to portions of the gear that are more properly termed general machine design considerations. Nonfunctional elements include such items as hub design dimensions, fastening designs such as keyways, set screw holes, inside diameters for press fits, and other special body configurations.

Functional gear tolerances are controlled by the compaction tooling, the processing methods, and gear material. Because most P/M gears are pressed in carbide dies, the tooth form and dimensions remain relatively stable and constant

throughout the process. Concentricity of the gear outside diameter and pitch diameter to the bore are also controlled by the tooling. If the pressing core rod or punches are eccentric to the die, the parts will be eccentric. Once the part is pressed, the material characteristics and sintering process determine the dimensional tolerance capability of the outside diameter, pitch diameter, test radius, and bore diameter.

Because of the number of variables within the P/M process it is not possible to state absolute dimensional tolerance capabilities. However minimum tolerances that one should expect for ferrous-base P/M gears without secondary operations are listed in Table 4 for spur and helical gears and in Table 5 for bevel gears. Typical tolerances for single press and sinter are listed in Table 6.

Table 4 Minimum tolerance capabilities for spur and helical P/M gears

Tooth-to-tooth composite tolerance	AGMA class 6
Total composite tolerance	AGMA class 6
Test radius	0.05 mm + 0.002 × diameter
Over-pin measurement	0.10 mm + 0.002 × diameter
Lead error	0.001 mm/mm
Perpendicularity--face to bore	0.05 mm + 0.001 × diameter
Parallelism	0.025 mm + 0.001 × diameter
Outside diameter	0.10 mm + 0.002 × diameter
Profile tolerance	0.008 mm

Tolerances with single press and sinter without secondary operations.

Source: Ref 3

Table 5 Minimum tolerance capabilities for bevel P/M gears

Tooth-to-tooth composite tolerance	AGMA class 6
Total composite tolerance	AGMA class 6
Outside diameter	0.10 mm + 0.002 × diameter
Perpendicularity-face to bore	0.05 mm + 0.001 × diameter

Tolerances with single press and sinter without secondary operations.

Source: Ref 3

Table 6 Typical tolerances of single pressed and sintered gears

See Tables 4 and 5 for specific gear forms.

Feature	Tolerance (without secondary operations)	
	mm	in.
Length	±0.125	±0.005
Flatness on end	0.05	0.002
Concentricity	±0.075	±0.003 ^(a)
Inside diameter	±0.050	±0.002 ^(a)
Profile tolerance	±0.0075	±0.0003
Tooth-to-tooth error	±0.025	±0.001
Circular tooth error	±0.05	±0.002
Parallelism on ends	±0.04	±0.0015
Lead error	±0.025	±0.001
Total composite error	±0.08	±0.0032 ^(b)
Outside diameter tolerance with pitch diameter up to:		
25 mm (1 in.)	0.075	0.003 ^(c)
50 mm (2 in.)	0.1	0.004 ^(c)
75 mm (3 in.)	0.125	0.005 ^(c)
100 mm (4 in.)	0.15	0.006 ^(c)

- (a) Tolerance depends on feature size.
- (b) Tolerance depends on gear size and number of levels.
- (c) Total tolerance on outside diameter and measurement over wires

Powder Metallurgy Gears

George T. Shturtz, Carbon City Products

Gear Design and Tooling

Properly designed gears and compaction tooling are the key factors in the economical production of P/M gears with consistent quality. Blended metal powder is usually compacted at room temperature, at pressures between 275 to 690 MPa (40 to 100 ksi) of projected surface area. The tooling for a single-level gear includes a die, an upper punch, and a lower punch. If the particular component to be formed requires a bore or other inside-diameter configuration, a core rod is also part of the tooling. Multilevel compound gears or other complex structural parts may have two or more upper and/or lower punches (Fig. 6).

Fig. 6 Compaction tooling for compound gear. Source: Ref 6

To form the gear, the die is filled with powder at a ratio of approximately two times the parts thickness; for example, a spur gear that has a thickness of 19 mm (0.75 in.) will be compacted from a column of 38 mm (1.50 in.) thick. During the compaction cycle of the more commonly used type of press, the upper punch enters the die while the lower punch, which in the fill position seals off the bottom of the die, remains stationary. As the upper punch travels downward, the compressive forces cause the die assembly to move downward in relationship to the lower punch, resulting in the same effect as if the lower punch were moving upward during the compaction stroke. The rate of movement and pressure of the

upper punch and the motion of the die are relatively equal to ensure uniform density within the compacted preform. After completion of the compaction cycle, the upper punch retracts from the die, and the lower punch initiates an upward motion, ejecting the preform from the dies.

The shape of the compacted preform is determined by the shape of the tooling and the axial motion of the compaction press. Two main factors influence part design: the flow behavior and characteristics of the metal powders and the movement of the tools within the pressing cycle. Metal powders do not flow hydraulically, and the allowance for friction between the powder particles themselves and with the moving tool members must be factored in the final P/M part design. The pressing action from both top and bottom largely governs the shape, length, and dimensional details of the preform. The clearance tolerance of the moving tool members, relative to the inside diameter or bore, contributes to a larger degree of eccentricity than with machined gears. Details, or features that increase the number of tool members compound the eccentricity. Concentricity can be improved with the addition of secondary operations, such as grinding the bore in relationship to the pitch diameter.

The compacted preform is sintered typically at temperatures of approximately 1120 °C (2050 °F) to obtain tensile properties around 125 to 620 MPa (18 to 90 ksi), depending on the material composition. The addition of heat treatment can increase ultimate tensile properties of a compacted-and-sintered steel component to 1240 MPa (180 ksi).

Design guidelines for P/M gears include the following considerations.

Ejection from the Die. Some features must be eliminated from the final part (or added through secondary machining operations) when they inhibit ejection of the preform from the die. For example, undercuts, reverse angles, details at right angles to the direction of pressing (e.g., holes, grooves), threads, diamond knurls and reentrant angles would interfere with smooth ejection.

Die Filling During Compaction. Gear design should allow for the movement of the metal powders throughout the tool members during the compaction cycle. Metal powders do not flow hydraulically. Therefore, extremely thin-walled sections, very narrow grooves, and deep counterbores should be avoided because the metal powders may not completely fill these details within the tool members.

Tool life can be improved by avoiding narrow deep grooves, very sharp edges, complete spherical profiles, and knife-thin tool thicknesses. Often design simplification of these features allows for a more robust or "practical" set of compaction tools without adding machining operations.

Clearance. Hubs or bosses for gears, sprockets, or cams can be readily produced, but the designs should ensure the maximum permissible material between the outside diameter of the hub and the root diameter of gear or sprocket features (Fig. 7) (Ref 6). Another consideration for gear design is to maintain sufficient clearance between the inside diameter and the root diameter, which can range from 0.9 mm (0.035 in.) on small pinions to 7.5 mm (0.30 in.) for more demanding applications. Design consideration should be given to maximize the clearance between the gear root diameter and compound gears, pinions, or features (i.e., cams, etc.) that are incorporated parallel to the gear teeth.

Fig. 7 Hub feature. Source: Ref 6

Thickness Changes. The configuration of the gear should limit major changes in section thickness (Fig. 8) for compound gear geometries such as gear-pinion and spur-face combinations, which are well within the capability of the P/M process. Uniform density and high strength is best achieved by limiting the number of section thickness changes (levels) that are designed into the preform. The number of levels a part may have is determined by the specific type of compaction press and/or the design of the compaction tooling.

Fig. 8 Preferred design for section thickness changes. Source: Ref 6

Right-Angle Intersections. The configuration of the gear should minimize right-angle intersections. Radii should be incorporated at right-angle intersection of section thickness changes. These radii improve the integrity of the preform. Gear engagement should be designed to occur above the radius. Often raised surface features can be added to the compacted preform to assist in this engagement.

Edge Detail. The configuration of the gear should incorporate edge detail (i.e., chamfers on top and bottom of the gear teeth and on outside and inside diameters) (Fig. 9). This edge detail of chamfer has two main purposes. First, it increases the density of the teeth. Higher tooth density results in improved mechanical properties, particularly strength. It also reduces the adverse effects of burrs. The chamfer detail will in most cases keep the burr within the overall thickness (width) of the gear. These burrs are a result of the fit clearance of the tool members and, if necessary, can be removed by a vibratory finishing (tumbling) operation.

Fig. 9 Edge radii design features. Source: Ref 6

Gear Performance

In general terms, gear teeth loading is akin to normal loading of two parallel cylinders with a combined sliding and rolling. In rolling contact, two elements roll in contact with each other without slippage. Both elements rotate at the same velocity. Gear teeth have sliding contact over most of their surfaces, with rolling contact occurring only at the pitch line. The amount of sliding varies with the distance from the pitch line. When the rolling and sliding are in the same direction, less damage occurs than with negative slide (Ref 7).

Gears can be damaged by several mechanisms such as bending fatigue or by surface fatigue mechanisms such as pitting or spalling. The origin of pitting occurs where the combination of pressure and negative sliding are the highest. On spur gears, this is usually at the lowest point of single-tooth contact on the dedendum of the drive gear (Ref 8).

As with any other material the choice of a P/M alloy is governed by the magnitude and nature of the transmitted load, the speed, the life requirements, the environment, the type of lubrication, and the gear and assembly precision. Allowable loads on contact surfaces of gears are limited by the occurrence of pitting, in most cases, provided they are not run at very high speeds to cause scoring (Fig. 10). Even at light loads, gear teeth experience relatively high concentrated stresses because contact areas are very small. In general, Hertz equations are used to design for contact stresses, and these equations consider compressive loads on stationary contact surfaces.

Fig. 10 Schematic of gear damage mechanisms. Source: Ref 15

Spalling damage of wrought and P/M alloys has similar appearance but different crack propagation mechanisms. In wrought alloys, most of the time is spent in the crack initiation phase (under high-cycle conditions) with relatively quick crack propagation once the crack is big enough. In P/M alloys, the porosity blunts crack growth to the surface. Until the crack can propagate to the surface, a band of subsurface cracking continues. The depth of the band is probably related to the depth of the maximum shear stress.

Selecting Gear Materials. Required strength is the first factor when selecting a gear material. In spite of the approximations involved, one can generally arrive at the correct material by using the methods outlined in the AGMA standards for rating the strength of spur, helical, and straight bevel gear teeth (Ref 9, 10, 11). A good approximation of compressive load carrying ability can be found by using the methods outlined in the AGMA standards for surface durability of spur, helical, and bevel gear teeth (Ref 12, 13, 14). In addition, the allowable contact stress S_{ac} , the elastic modulus, and Poisson's ratio of the P/M material must be determined.

Allowable Contact Stress. Tensile strength, elastic modulus, and Poisson's ratio for most ferrous P/M materials is given in MPIF standard 35. In the absence of data for allowable contact stress of ferrous P/M materials, an approximation of S_{ac} is 70 MPa (10 ksi) below the ultimate tensile strength ($S_{ac} = UTS - 10 \text{ ksi}$).

Allowable bending stress (S_{at}) for a P/M material can be approximated in the absence of data at 0.3 of the ultimate tensile strength of ferrous-base P/M materials ($S_{at} = 0.3 \text{ UTS}$). The only caution one should be aware of is that tensile data may be typical properties. The designer should consult the supplier or specifications for minimum property data.

Impact and Fatigue Strength. Most P/M gears are limited in performance by their impact and fatigue strength as opposed to their compressive yield strength and surface durability. Surface treatments such as shot peening, material cleanliness, and other factors influence contact fatigue. Additional information on these topics is contained in the article "Contact Fatigue" in *ASM Handbook, Fatigue and Fracture*, Volume 19. Detailed information on P/M gear fatigue testing and evaluation is discussed further in Ref 15 and 16. Additional information on fatigue is also contained in the article "Fatigue and Fracture Control for Powder Metallurgy Components" in this Volume.

Powder Metallurgy Gears

George T. Shturtz, Carbon City Products

Quality Control and Inspection

Inspection is one of the most important stages in gear production. Inspection and testing is done on dimensional specifications, mechanical properties, and surface durability (hardness). The information required to describe a gear for the P/M process and subsequent inspection methods are essentially the same as for a machine-cut gear. The part drawing should include:

- Number of teeth
- Diametral pitch (normal diametral pitch for a helical gear)
- Pressure angle (normal pressure angle for a helical gear)
- Tooth form for spur, helical, and straight bevel gears
- Helix angle and rotation (right or left hand) for a helical gear
- Pitch, face, root, and back angles for straight bevel gears

To assist in the qualification (i.e., inspection) the drawing should also include:

- Outside diameter (as a reference dimension for straight bevel gears)
- Root diameter
- Pitch apex to back face
- Total composite tolerance
- Tooth-to-tooth tolerance (not appropriate for straight bevel gears)
- Test radius

Measurement over wires (MOW) and measurement between wires (MBW) (for internal gears) are convenient measurable criteria that should also be included as drawing specifications. Master gear information (specification and/or data) should be included on the drawing. Tip radius detail for spur gears is also necessary. It is advisable that right-angle (rolling) fixtures be developed to check mesh and backlash. Often several ID (inside diameter) pins are required to confirm mesh, after/during critical processing operations (minimally, compaction, sintering, and heat treatment). Typically, these inspection fixtures are specified and purchased at the time the tooling is manufactured.

In production, it is common practice to check the face width, outside diameter, over-pin measurement, total composite error, tooth-to-tooth error, perpendicularity of face-to-bore, parallelism, and inside diameter of the gears. Also the tooth strength and macroscopic hardness are usually checked. The sampling plan and frequency of measurement varies and depends on the criticality of the application. A joint committee with representatives from the American Gear Manufacturers Association (AGMA) and the Metal Powder Industries Federation (MPIF) have formulated a "Specification for Powder Metallurgy Gears," which delineates the minimum data necessary to adequately specify P/M gears. This specification is available from AGMA or MPIF.

General gear terminology includes:

- *Pitch circle*: the circumference of a gear measured at the point of contact with the mating gear
- *Pitch diameter*: the measurement across the gear within the circumference (pitch circle)
- *Diametral pitch (DP)*: the ratio of the number of teeth in a gear to each inch of its pitch diameter. For example, a 30-tooth gear with a 125 mm (5 in.) pitch diameter would have 6 teeth/in. of pitch diameter, therefore would be a 6 DP gear.
- *Active profile*: the part of the gear tooth profile that actually comes in contact with the profile of the mating gear while in mesh
- *Addendum*: the height of the tooth above the pitch circle
- *Backlash*: the amount of movement or "play" between mating teeth of two gears in mesh
- *Center distance*: distance between the axes of rotation of two mating gears
- *Circular thickness*: the length of arc between the two sides of a gear tooth at the pitch circle
- *Dedendum*: the depth of the tooth below the pitch circle
- *Face width*: the length of the teeth in an axial plane
- *Fillet radius*: the radius of the fillet curve at the base of the gear tooth
- *Pressure angle*: the angle between the line of action and a line tangent to the pitch circle at the pitch point
- *Tooth thickness*: the thickness of the tooth measured at the pitch circle

Gear inspection terms include:

- *Runout (radial)*: the total variation of the radial distance of the gear teeth from the center or bore
- *Runout (axial)*: the total variation of gear teeth along its axis, measured from a reference plane perpendicular to its axis. Also referred to as "wobble" or face runout
- *Lead*: the axial advance of a gear tooth in one revolution (360°)
- *Lead variation*: the condition in a gear where some teeth vary in lead, plus or minus from the average lead
- *Total composite error*: the total variation of the center distance in one complete revolution
- *Tooth-to-tooth variation*: the variation of the center distance in a section of its circumference (the section of the circumference is an angle of $360/N^\circ$ where N is the number of gear teeth)

Mechanical Testing. Mechanical properties are also measured, and in many cases bench life and impact tests or field tests are made to check the gear functionality. Because tensile strength of a gear cannot be measured directly, it is appropriate to establish a minimum tooth breakage strength that can be used as a production acceptance criteria from either sample gears made from a die or gears cut from a P/M slug.

One quick and accurate means of measuring tooth strength of a spur gear is shown in Fig. 11. By mounting the gear between fixed supports and applying a vertical load, one can measure a tooth breakage strength. By testing a number of gears that perform successfully in the particular application, it is possible to calculate statistical limits for the tooth breakage strength that can be used as a future material strength acceptance. Helical and bevel gears are usually evaluated in torque-type tests and the same type of statistical analysis applied. The use of statistics is particularly expedient in gear strength testing because proper sampling allows process control to a normal statistical distribution (i.e., a $\pm 3\sigma$) minimum acceptance criteria ensures 99.85% confidence of adequate strength.

Fig. 11 Spur gear tooth strength test. Source: Ref 17

Surface durability is a specified and measured minimum Rockwell hardness because this macroscopic hardness relates to the compressive yield strength of the materials. The minimum Rockwell hardness depends on the material and can be established either from samples or from the supplier's historical information.

In cases where scoring may be a problem, in particular with heat treated gears, it is appropriate to specify and measure a microscopic hardness. This is accomplished with a diamond indenter, and the microscopic or individual particle hardness of the material is measured. The particle hardness specification is generally determined from historical data for the producer's material.

In contrast to most metals, P/M materials have both a macro- and microhardness as a result of porosity within the structure. Because the P/M structure consists of individual hard particles bonded together with interdispersed voids, the conventional Rockwell indentation registers a composite hardness. Because sliding and surface contact involves microscopic contact (individual asperities) the particle or microhardness of the P/M material influences the score resistance of the P/M material more so than the macro Rockwell hardness. As a generality, when a P/M gear is run against a wrought gear, the P/M particle hardness should be no harder than the hardness of the wrought gear to prevent wear of the mating gear.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Introduction

METALS AND ALLOY POWDERS are used in welding, hardfacing, brazing, and soldering applications. These applications include powders for hardface coatings, powders for use in the manufacture of welding stick electrodes and flux-cored wires, and additives in brazing pastes or creams. This article briefly reviews these applications and the specific powder properties and characteristics they require.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Powders for Manufacture of Stick Electrode and Flux-Cored Wires

Metal powders used in electrode coatings include a wide range of ferroalloys and pure metals. Some widely used metal powders for this application include chromium, iron, manganese, and nickel. A large variety of ferroalloys are used in the manufacture of electrodes: ferro-aluminum, ferro-boron, high-carbon ferro-chromium, low-carbon ferro-chromium, ferro-manganese, ferro-molybdenum, ferro-niobium, ferro-silicon, ferro-silicon-zirconium, ferro-titanium, ferro-titanium-boron, ferro-vanadium, and ferro-tungsten. In addition, carbide powders like boron carbide and chromium carbide are also used for this application. Further, a number of mineral and flux powders are used in the manufacture of stick electrodes and flux-cored wires; these powders include calcium carbonate, fluorspar, alumina, feldspar, iron oxides, titanium dioxide, and rutile.

Of the metal and alloy powders listed above, iron, chromium, manganese, ferro-chromium, and ferro-manganese powders are all used in fairly large quantities. The iron powder used for welding applications is typically water atomized. The chromium, manganese, ferro-alloys, and carbide powders are manufactured by mechanical size reduction.

Powder flow, particle shape, apparent density, and size distribution are very important characteristics for powders used for stick electrodes and flux-cored wires. In general, excessive fines in these powders are not desirable. In most cases, the chemistry of the material is extremely crucial and has a significant impact on the final weld-metal properties.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Stick Electrodes versus Flux-Cored Wires

For the manufacture of stick electrodes, typically various metal, alloy, and flux powders are combined with a binder to create a coating mixture. The coating is extruded onto steel rods of appropriate composition to create the correct type of electrode. The coating is baked and dried prior to packaging.

For the manufacture of flux-cored wires, however, various metal, alloy, and flux powders are combined to create a filler material. A steel strip of an appropriate composition is drawn into a U-shaped wire. The filler material is next deposited into this U-shaped wire, and the wire is drawn into a cylindrical shape and folded, and its diameter is decreased by a series of drawing operations to create a flux-cored welding wire.

The coating of the stick electrodes and the filler material of the flux-cored wires influence various welding parameters and also the final chemistry of the weld-metal.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Functions of Electrode Coatings or Filler Material

There are five general functions controlled or influenced by electrode coatings or filler material: welding parameters, slag property control, weld deposit quality, metal transfer, and compatibility with extrusion or drawing equipment. Success in fulfilling these functions depends on the proper balance of the constituents of the electrode coating.

Control of Welding Parameters. The electrode coating or filler determines the type of welding current and the arc stability. For example, core wire used for an E6010 direct current electrode can be the same as that used in an E7024 alternating current/direct current electrode, but the coatings are different. Arc voltage and optimum current are functions of the type and formulations of the coating or filler material; therefore, electrodes of the same classification produced by different manufacturers may require minor current adjustments for optimum welding in field applications. To prevent side arcing, the coating should be a good insulator.

Slag Property Control. Control of the many properties of a molten slag is very difficult. Wetting characteristics of the slag help determine the contour of the deposit and the degree of slag coverage. Expansion of the slag markedly affects the slag removal. Fluidity or viscosity of the slag alters the out-of-position characteristics of the finished electrode. Slag freezing point affects bead contour and is a controlling factor in determining the acceptance of the electrode for vertical and overhead positions. All these interrelated properties are controlled by the electrode-coating composition. Only extensive laboratory testing can produce a coating or filler material with the optimum balance of all these properties.

Weld Deposit Quality. The electrode coating or filler material controls the metallurgical structure and quality of the weld deposit. Service requirements demand that every weld deposit must be free from porosity and slag inclusions. The coating must contain a sufficient quantity of deoxidizing material to degas the molten metal and to ensure that all resulting oxide and silicate inclusions float off in the slag. The final weld-metal chemistry and properties are a direct function of the coating or filler material formulation.

Compatibility with Extrusion and Drawing Equipment. Modern high-speed extrusion equipment places rigid demands on electrode coating ingredients. A proper balance of particle size among the various ingredients is essential for ease of extrusion, ability to withstand mechanical damage, and a pore structure that permits immediate and continuous drying of the extruded coating. In the case of flux-cored wires, again, the size distribution of the various ingredients of the filler material are critical in determining the final diameter of the wire.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Electrode Coating and Filler Material Constituents

The constituents of coating and filler materials are divided into four categories: (a) binders and extrusion aids; (b) arc stabilizers; (c) fluxes and slag modifiers; and (d) alloying materials. Some of the materials might fall into two or more of the above categories if their overall effects are considered. For example, sodium and potassium silicate can be equally effective as binders, but potassium silicate is preferred where additional arc stability is desired. Titanium dioxide and titania-bearing materials frequently are used to improve arc stability. However, such additions can markedly alter the properties of the resultant slag.

Binders and extrusion aids commonly used by the electrode industry include liquid sodium and potassium silicates, celluloses, clays, bentonites, talc, and mica. The alkaline silicates and celluloses provide dry strength, green strength, or assist in controlling the drying characteristics. Other inorganic materials such as talc, mica, clay, or bentonite can be used to increase plasticity, that is, slippage under extrusion pressure.

Arc stabilizers are predominantly titanium- or potassium-bearing materials. Titanium dioxide, rutile, potassium titanate, ilmenite, and potassium carbonate or hydroxide are the most common. Lithium-bearing materials have arc-stabilizing properties, but their cost is somewhat higher.

Fluxes and Slag Modifiers. Almost all of the more common minerals and fluxes used by the ceramics industry have been employed as additions to electrode coating or filler material compositions. In commercial practice, calcium carbonate, fluorspar, silica flour, alumina, feldspar, manganese oxides, iron oxides, wallastonite, and zirconium-bearing materials appear to be the most widely used.

Alloying Materials. A wide variety of metal, ferroalloys, and carbide powders are commonly used in electrode coatings and filler materials. In addition to providing the necessary alloying contents, materials such as ferro-manganese and ferro-silicon also serve as deoxidizers.

As an example, Table 1 gives compositions of electrode coatings for classes of electrodes used in shielded metal arc welding of low-carbon steel and lists the primary and secondary functions of the coating constituents. The thickness of the coatings varies from 10 to 55% of the total diameter of the coated electrode, depending on the type of coating.

Table 1 Functions and composition ranges of coating constituents on low-carbon steel arc welding electrodes

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Types of Iron Powder for Welding

Iron powder is typically one of the major components for electrode coatings and filler materials. In general, iron powders used for welding applications are of coarser size compared to those used for powder metallurgy applications. The iron powders used for welding applications are produced by a variety of methods. A brief summary of these production methods follows. Detailed information of these processes can be found elsewhere in this Volume.

Reduced iron is the oldest iron powder production method in which pure magnetite (Fe_3O_4) is reduced by a carbonaceous material. Table 2 lists compositions and properties of reduced iron welding-grade powders.

Table 2 Typical properties of reduced and water-atomized iron welding powders

Property	Powder				
	1 ^(a)	2 ^(a)	3 ^(a)	4 ^(b)	5 ^(b)
Chemical composition, %					
Iron, total	98.20	98.0	98.0	98.0	98.0
Hydrogen loss	0.40	0.45	0.45	0.50	0.50
Carbon	0.05	0.05	0.05	0.05	0.05

-200+325	24
-325	27

- (a) Reduced iron powder.
- (b) Water-atomized iron powder

For certain welding applications, especially for small-diameter electrodes, fine grades (-100 mesh) of sponge iron powder having an apparent density of 2.50 g/cm³ are used. This powder has a large specific surface due to the microporous particles and irregular grain shape. This contributes to increased electrical conductivity, good arc stability, and smooth arc action of the welding electrode.

Coarser sponge iron powder (-40+200 mesh) having an apparent density of 2.40 g/cm³ are used in the manufacture of certain low-hydrogen electrodes. It is also used in rutile and acid electrodes with low to medium deposition efficiency.

Atomized Iron. Water-atomized iron powder is also used in electrode coatings. Properties and compositions of these powders are given in Table 2. The low carbon and iron oxide content produces a smooth arc and a slag that is easy to remove. This type of powder, which has an apparent density of 3.20 g/cm³, is designed for production of low-hydrogen and titania-type electrodes using 50% iron powder in the coating.

High-density (≥ 3.50 g/cm³) atomized iron powder has relatively smooth particles that help reduce manufacturing costs and facilitate the use of high-depositions-efficiency electrodes. Low-hydrogen electrodes (Type E7028) can be made with coatings containing 65% iron powder. Such electrodes have deposition efficiencies to 225%. This type of iron powder also can be used for E6027, E6024, E7024, and gravity feed electrodes having deposition efficiencies from 190 to 210%. Classifications of coated electrodes are listed in Tables 3 and 4.

Table 3 Electrode classification of iron powder, titania, and low-hydrogen electrodes

Iron powder content, %	AWS classification	Type of covering	Capable of producing satisfactory welds in positions shown ^(a)	Type of current ^(b)
E60 series: minimum tensile strength of deposited metal in as-welded condition, 410 MPa (60 ksi) or higher				
10 max	E6010	High cellulose, sodium	F, V, OH, H	DCEP
10 max	E6011	High cellulose, potassium	F, V, OH, H	ac or DCEP
10 max	E6012	High titania, sodium	F, V, OH, H	ac or DCEN
10 max	E6013	High titania, potassium	F, V, OH, H	ac, DCEN, or DCEP
25	E6020	High iron oxide	H-fillets	ac or DCEN
			F	ac, DCEN, or DCEP
30-45	E6027	Iron powder, iron oxide	H-fillets	ac or DCEN
			F	ac, DCEN, or DCEP
E70 series: minimum tensile strength of deposited metal in as-welded condition, 480 MPa (70 ksi) or higher				
U.S.	European			
18	25	E7014 Iron powder, titania	F, V, OH, H	ac, DCEN, or DCEP
25-35	44	E7018 Iron powder, low hydrogen	F, V, OH, H	ac DCEP

45-50	65	E7024	Iron powder, titania	H-fillets, F	ac, DCEN, or DCEP
50	65	E7028	Iron powder, low hydrogen	H-fillets, F	ac DCEP

- (a) Abbreviations indicate these welding positions: F, flat; H, horizontal; H-fillets, horizontal fillets; V, vertical; OH, overhead.
- (b) DCEN, direct current electrode negative (straight polarity); DCEP, direct current electrode positive (reverse polarity)

Table 4 Classification of low-hydrogen, high-strength electrodes

Iron powder content, %	AWS classification	Type of coverage	Capable of producing satisfactory welds in positions shown ^(a)	Type of current ^(b)
E70 series: minimum tensile strength of deposited metal in stress-relieved condition, 480 MPa (70 ksi)				
25-35	E7018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP
35	E7020-X	High iron oxide	H-fillets	ac or DCEN
			F	ac, DCEN, or DCEP
20-45	E7027-X	Iron powder, iron oxide	H-fillets	ac or DCEN
			F	ac, DCEN, or DCEP
E80 series: minimum tensile strength of deposited metal, 550 MPa (80 ksi)				
30	E8018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP
E90 series: minimum tensile strength of deposited metal, 620 MPa (90 ksi)				
30	E9018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP
E100 series: minimum tensile strength of deposited metal, 690 MPa (100 ksi)				
25	E10018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP
E110 series: minimum tensile strength of deposited metal, 760 MPa (110 ksi)				
20	E11018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP
E120 series: minimum tensile strength of deposited metal, 830 MPa (120 ksi)				
15-20	E12018-X	Iron powder, low hydrogen	F, V, OH, H	ac or DCEP

- (a) Abbreviations indicate these welding positions: F, flat; H, horizontal; H-fillets, horizontal fillets; V, vertical; OH, overhead.
- (b) DCEN, direct current electrode negative (straight polarity); DCEP, direct current electrode positive (reverse polarity)

In the manufacture of electrodes, the higher-density, relatively smooth particles require less silicate, allow higher extrusion pressure, and have faster extrusion rates, better brushing, and less swelling in baking. The resulting high-strength coating resists chipping and cracking.

Use of high-density iron powder electrodes saves time and cost through high deposition rates, longer lead lengths, better penetration, no undercutting, and slag that is self-removing. Powder characteristics promote smooth arc action and better recovery of metallics, providing uniform physical properties.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Other Metal and Alloy Powders for Welding

Typically, metal and alloy powders other than iron powder, which are used for welding applications, are made via mechanical size-reduction. These include chromium, manganese, all ferroalloys, and the carbide powders. In these cases, the starting material is in a lump state, typically 4 in. \times D in size. The starting raw material is crushed using a series of crushers to a size of less than $\frac{1}{4}$ in. Next the material is milled and screened to generate the required size distribution. Powder sizes used in the welding industry include 50 \times 325 mesh, 80 \times 325 mesh, <100 mesh, <120 mesh. The selection of a particular size is dictated by the welding consumable being manufactured.

Influence of Powder Characteristics on the Manufacture of Welding Electrodes

Currently, welding electrodes are produced by a continuous high-speed production system. Consistent physical properties of electrode coating and filler material components help to attain shorter throughput times. Extrusion and drawing problems tend to multiply as coating thickness and the amount of metal powders added to the coating are increased.

As an example, extrusion pressure is influenced greatly by the physical properties of iron powder and the amount of silicate added to the electrode coatings. Figure 1 shows results from extrusion tests on a rutile high-yield electrode. By using 65% of iron powder having a 3.50 g/cm^3 apparent density at a coating-to-core-wire ratio of 2 to 1 and 170 g silicate/kg (75 g silicate/lb) of dry coating material, a welding efficiency yield of 185% was obtained from this electrode. A pressure range of 35 to 45 MPa (5000 to 6500 psi) provided the best conditions. The ideal extrusion pressure of 39 MPa (5600 psi) was arrived at by testing the following additions of silicate:

Iron powder apparent density, g/cm^3	Amount of silicate added, g
3.50	150
2.85	185
2.40	215

The slopes of the curves in Fig. 1 show that comparatively small changes in quantity of added silicate or in the physical properties of the iron powder make the extrusion pressure fall beyond the best extrusion conditions. Pressures that are too high would cause longitudinal cracks immediately after extrusion. Transversal cracks might appear after baking. Conversely, an extrusion pressure that is too low produces a coating that is too soft. In such a case, the electrode can easily be deformed during handling and transportation.

Fig. 1 Effect of silicate content on extrusion pressure

For those high-yield electrodes investigated, it was found that when silicate addition was unchanged, a powder with smooth surface structure gave a comparatively lower extrusion pressure. When adding large portions of iron powder, rough, irregularly shaped grains might critically augment the internal friction within the coating material, thereby increasing the extrusion pressure. Use of a smoother, heavier powder makes possible the use of similar additions of

silicate or other plasticizing ingredients. This is desirable technically and economically, especially in the production of this type of high-yield electrode.

Basic electrodes are somewhat of an exception to this observation. Cracks in the coating can appear after the electrode is baked; they might also be due to the coating composition or the relatively high temperature applied. The coating can be reinforced through large silicate additions, counteracting the tendency to form contraction cracks during baking. It has also been observed that light, fine iron powder allows an increased addition of silicate without rendering the coating too soft after extrusion. With basic electrodes, improved arc stability is desirable. One way to attain this is by increasing the addition of potassium silicate; however, such an increase can make the coating more hygroscopic, which is a disadvantage. Therefore, when choosing raw materials for welding electrodes, the advantages and disadvantages must be evaluated.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Performance of Powder-Coated Electrodes

The deposition efficiency (yield) of an electrode is calculated as follows:

$$(A \div B) \times 100 = R$$

In this equation, A is the deposited weld metal, B is the weight of melted core wire, and R is the deposition efficiency (yield).

Both the deposition efficiency (yield) and performance of welding electrodes can be influenced by the amount of silicate added and the apparent density of the iron powder used in the coating. The tests on which Fig. 2, 3, 4, and 5 are based were carried out with a high-yield rutile electrode. Normally, such an electrode will have a yield of 180 to 185%, provided that 61% of high-density iron powder and approximately 150 g silicate/kg (70 g silicate/lb) of dry coating are added. This electrode is characterized by very good welding performance when operating on horizontal fillet welds.

Fig. 2 Deposition efficiency (yield) of a coated electrode as a function of apparent density of iron powder addition. Electrodes extruded at 39 MPa (5600 psi)

Fig. 3 Weight of a coated electrode (after baking) as a function of the apparent density of the iron powder addition

Fig. 4 Effect of silicate content and extrusion pressure on deposition efficiency of coated electrodes. Electrodes extruded with high-density (3.5 g/cm³) iron powder

Fig. 5 Amount of weld metal deposited (melting rate) as a function of welding amperage for extruded coated electrodes. Electrodes contain iron powder of varying densities, as indicated in the figure.

Figure 2 illustrates yield as a function of the apparent density of the iron powder used for electrodes extruded at 39 MPa (5600 psi). Approximately 15% lower yield was obtained from the electrode made with iron powder that had an apparent density of 2.4 g/cm³, as compared to an electrode made with iron powder that had an apparent density of 3.5 g/cm³.

Figure 3 illustrates data that explain this observation. The actual weight of the electrode after baking varies with the apparent density of the powder. The nature of the curve is the same as that in Fig. 2, indicating the oxidation losses are independent of powder particle shape and apparent density. However, this only applies when the amounts of carbon and iron oxide in the iron powders are fairly equal. When using iron powder with very large amounts of both carbon and iron oxide, the deposition efficiency (yield) can drop considerably because of increased spatter losses.

Figure 4 shows the deposition efficiency (yield) of electrodes extruded with high-density iron powder (3.5 g/cm³) as varying amounts of silicate were added. The deposition efficiency decreases sharply when the amount of silicate is increased. The correct amount of silicate addition with respect to extruding pressure would be 160 g/kg (72 g/lb) of dry mix. With such an addition, the electrode will give a yield of 175%.

Figure 5 shows the melting rate calculated as weight (kilograms or pounds) of weld deposit per hour as a function of the welding amperage applied on various electrodes. The electrodes were extruded by using iron powder with varying apparent densities. Faster welding speeds can be achieved when using high-density iron powders. The amperage considered maximally applicable in normal welding practice is higher for electrodes made with high-density iron powders; thus, the differences between various iron powders are more pronounced under practical conditions, such as welding of horizontal V-fillet welds or horizontal fillet welds.

The following conclusions can be drawn from the examples in Fig. 2, 3, 4, and 5:

- The amount of silicate added for a specific type of electrode and a specific extrusion pressure depends on the apparent density, particle shape, and sieve analysis of the powder.
- Deposition efficiency and melting rate rise when the silicate content is reduced and the apparent densities of the iron powder are increased; therefore, only high-density iron powder welding grades are recommended for high-yield electrodes that have deposition efficiencies greater than 160%.
- Narrow specification ranges for physical properties, particle shape, apparent density, and sieve analysis of the iron powder are necessary for reproducible production of welding electrodes.

Metal Powders for Hardfacing

Hardfacing is the application of hard, wear-resistant material to the surface of a component by welding, thermal spraying, or a similar process, mainly to reduce wear. The control of wear is growing in importance because wear adversely affects the performance of equipment and components. Wear can cause inefficient performance of equipment or costly downtime. Hard-facing is used on components of original equipment, as well as for the repair and rebuilding of worn components. Hard-facing filler (consumable) material is available in different forms, such as powder, solid welding rods or wires, and tubular rods or wires.

This section discusses hardfacing processes and applications that directly use powders. The use of metal powders in the fabrication of consumable electrodes for hardfacing has already been discussed in the section above. In addition, applications in which corrosion or oxidation resistance is of prime importance, in addition to surface modification techniques such as flame hardening, nitriding, and ion implantation, are not covered in this article.

Hardfacing of a selected alloy onto a base metal (substrate) provides a protective surface layer that resists wear or loss of material by adhesion, galling, abrasion, impingement erosion, cavitation erosion, or fretting.

Adhesive wear is caused by the sliding action between two metallic components. At some transition load, metallic bonds form between the surface asperities of mating materials and wear becomes severe. The term "galling" is used to describe conditions in which adhesive wear is severe enough to cause seizure of the moving components.

Abrasive wear is caused by the cutting action of sliding abrasives between mating surfaces that suffer scratches or gouges. Impingement erosion refers to the type of material loss that is caused by the cutting action of moving particles. Cavitation erosion is caused by shock waves that result from collapse of air bubbles on the metal surface in turbulent fluid flow. Fretting is a combination of mild adhesive (oxidative) and abrasive wear caused by very small amplitude vibrations at mechanical connections.

In severe abrasive wear service, such as rock crushing and pulverizing, several pounds of material can be rapidly worn away. In control valves, however, a few thousandths of an inch of wear is intolerable. Wear and corrosion are encountered in knives used in the food processing industry and in valves and pumps handling corrosive fluids. Diesel engine valve seats are subjected to severe conditions involving erosion fatigue and hot corrosion. Commercially available hardfacing materials help solve these industrial problems.

The choice of filler material requires careful consideration of service conditions, available equipment, hardfacing processes, equipment and process cost, hardfacing operation, and equipment downtime. Technical assistance from the powder supplier is strongly recommended, as is the testing of samples under operating conditions.

Many of these material systems are used as powders because of their specific advantages. A wide range of compositions is possible through powder processing; some of these cannot be made by conventional techniques. Powder use allows uniformity of composition and microstructural features. Powder processes minimize heat input to the base metal and hence dilution of the deposit. Furthermore, in many applications, powder techniques provide more effective coating of intricate surfaces.

General Powder Characteristics

Gas and water atomization are the most widely used methods for producing hardfacing powders. However, for a growing number of specialized applications, powders are made by milling and crushing operations. Some examples of powders made by crushing and milling include tungsten carbide powders, ferro-chromium powders, chromium carbide powders, some grades of nickel-base powders, and other friable materials. These methods generate broad ranges of particle size and size distribution; therefore, screening (sieving) and air separation are used to create specific size distributions for special grades of powder.

Figure 6 shows typical particle size ranges of different grades of powder used for various hardfacing processes. Approximately 85 wt% of any grade of powder falls within the ranges shown. For the same process, however, equipment made by different manufacturers can require different particle size ranges.

Fig. 6 Powder size ranges for different hardfacing processes. At least 85% of the powder by weight is in the size range shown.

As an example, the plasma spray operation requires fine powders in the 10-45 μm size range because of the high jet speed and short dwell time of the particles in the heating zone (even though the zone temperatures are high). However, special dispensing devices are required to prevent powder flow problems. In some applications, like plasma transferred arc (size range, 45-150 μm), use of excessive fines is damaging to the deposit because fines tend to have higher surface oxides and burn-off tendencies, causing smoking. On the other hand, certain hardfacing techniques, such as bulk welding processes, require much coarse powder in the 100-600 μm range.

Type of application also governs powder size requirements. For instance, thin overlays typically use fine powders. Therefore, the user must consider the process, equipment, and final application before selecting powder size. Powder shape and cleanliness are also important considerations in any hardfacing operation. For most applications, the deposit must be nearly free of porosity or entrapped fluxes. The use of spherical powders is beneficial to the service and integrity of the coatings. Spherical powder flows better than angular powder because of minimal interparticle friction; this is important when using gravity powder-feed devices.

Larger atomized particles sometimes have smaller particles, or satellites, attached. If excessive, these satellites can cause flow problems; if loosely attached, they can break up during spraying, resulting in oxidation and smoking. Gas-atomized powders generally are spherical in shape and prone to satellite formation. Water-atomized powders can be irregular or spherical in shape, depending on the alloy used and the quenching rate. Surface oxidation is a potential problem with water-atomized powder (particularly in cobalt-base alloys). Self-fluxing nickel-base powders are routinely made by this process, because oxygen pickup is minimal and the process is more economical.

Apparent density and flow rate also depend on the characteristics mentioned above. Irregular particle shape, numerous satellites, or a narrow size distribution lowers apparent density and slows the flow rate of the powder. Equipment with gravity powder-feed devices requires powders that flow faster. In any specific application, compatibility between the equipment and operating conditions, in addition to reproducibility of these powder properties, is a consideration.

Deposit hardness depends on the powder composition, as well as on the conditions used for depositing. Hardness range frequently is reported in relation to powder characteristics. The bulk hardness of a deposit, as measured on the Rockwell C scale, for example, depends on the deposit matrix hardness; it depends as well on the type and quantity of hard constituents, such as carbides and borides, or phases, such as martensite or Laves phase intermetallics.

Hardness is also influenced by the degree of dilution. For a specific base metal and powder alloy combination, hardness normally decreases with increased dilution of the deposit by the base metal. Dilution of 5% means that the deposit contains 5% base metal and 95% hardfacing powder alloy. Dilution increases as the base metal receives more heat input and more of base metal melts. The plasma transferred arc process provides more dilution than the manual torch process, whereas plasma spray provides essentially no dilution. More dilution can make the deposit tougher and more resistant to cracking.

In practice, hardfacing processes and techniques should be selected to control dilution to less than 20%. In a multilayer deposit, the first layer experiences the largest degree of dilution and is the softest. Generally, deposit hardness can be used to verify powder quality only if the testing method is rigidly standardized; even then, hardness may differ from the hardness of the deposit on the components to be hardfaced.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Powder Composition

Chemical composition of hardfacing powders is the most important influence on the properties of the deposit. The main criteria in selecting an alloy for a given hardfacing application are its response to the type of wear encountered, the base metal to be hardfaced, and material cost. Other influential properties are impact strength, corrosion, oxidation, and thermal behavior.

Generally, impact resistance of hardfacing alloys decreases as the carbide content increases. Consequently, in applications in which a combination of impact and abrasion resistance is desired, a compromise between the two must be achieved. In applications in which impact resistance is important, austenitic manganese steels are used to build up worn parts.

Frequently, wear is accompanied by aqueous corrosion from acids and alkalis, as in the chemical processing and petroleum industries or in flue gas scrubbers. Few iron-base hardfacing alloys possess the necessary corrosion resistance in such aqueous mediums. As a result, nickel- or cobalt-base surfacing alloys generally are recommended when a combination of corrosion resistance and wear resistance is required. For example, knives used to cut tomatoes in a food processing plant will last many times longer if their edges are made of a cobalt-base alloy rather than tool steel.

Oxidation and hot corrosion resistance of iron-base alloys is also generally poor. Typically, boride-containing nickel-base alloys do not contain sufficient chromium in the matrix to resist oxidation. Hence, Laves phase or carbide-containing nickel- or cobalt-base alloys typically are recommended for applications in which wear resistance combined with oxidation or hot corrosion resistance is required.

The ability of an alloy to retain strength at elevated temperatures is important for wear applications such as hot forging dies or valves for service at 870 °C (1600 °F), as well as service in coal gasification or liquefaction applications. Iron-base alloys with martensitic structures lose hardness at elevated temperatures. Generally, the high-temperature strength retention of a hardfacing alloy increases with its tungsten or molybdenum content. In applications requiring elevated-temperature strength and wear resistance, cobalt-base alloys or Laves phase alloys are recommended.

Wear-resistant materials typically are classified by type and alloy content, which largely determine their properties. These materials have structures consisting of hard phases (carbides, borides, or Laves phases) in a matrix that is hardened to a level that depends on the desired alloy properties. Table 5 provides a comprehensive guide to selection of surfacing alloy systems. Powder alloys can be custom made for various applications by using the same composition, but varying the sieve size or distribution. Because American Welding Society (AWS) designations do not exist for many of the hardfacing alloys discussed in this article, tradenames will be used. It should be noted that many of these compositions are available from various manufacturers under different names.

Table 5 Selection guidelines for hardfacing alloy systems

Surfacing material type	Composition, %	Hardness		Maximum Temperature		Resistance to wear ^(a)	
		Hot	Cold	°C	°F	Abrasion	Impact
Iron-base, low alloy	0.3-1.0 C, 1.0-7.0 W, 3.0-5.0 Cr, 4.0-9.0 Mo, bal Fe	47 HRC at 595 °C (1100 °F) 30 HRC at 650 °C (1200 °F)	55-60 HRC (30 HRC, annealed)	595	1110	Superior to low-carbon steel	Moderate; increases with temperature
Iron-manganese	0.5-0.9 C, 11.0-16.0 Mn, 2.75-6.0 Ni, or 0.5-1.5 Mo, bal Fe	...	170-230 HB (workhardens to 450-550 HB)	260-315	500-600	Moderate	Excellent
Iron-chromium	3.0-5.0 C, 4.0-8.0 Mn, 26.0-32.0 Cr, 2.0 Mo, bal Fe	47 HRC at 480 °C (900 °F) 5 HRC at 650 °C (1200 °F)	51-62 HRC	425-480 ^(b)	800-900 ^(b)	Excellent for low-stress abrasion	Good for light impact
Cobalt-chromium	0.7-3.0 C, 2 Mn, 3-14 W, 3 Ni, 25-33 Co, 5 Fe, bal Cr	20-39 HRC at 650 °C (1200 °F)	23-58 HRC	980	1800	Excellent in low-stress; wears 5-20% as fast as carbon steel	Fair; deteriorates as carbon increases
Nickel-chromium	0.3-1.0 C, 1.0-1.5 Co, 8.0-18.0 Cr, 1.25-5.5 Fe, 2.0-4.5 B, 1.25-5.5 Si, bal Ni	19-42 HRC at 540 °C (1000 °F)	24-62 HRC	955	1750	Excellent in low-stress; increases with carbon content	Good for light impact; decreases as carbon increases
Copper-base	0.25-5.0 Fe, 0.01-15.0 Al, 0.02 Zn, 0.04-4.0 Si, 9.0 Sn, bal Cu	...	70-320 HB	205	400	Poor	CuAl: good, decreases with increased Al content; CuSi: good; CuSn: poor; CuZn: very poor
Tungsten-carbide	60% carbide granules, 40% steel tube	41-47 HRC at 650 °C (1200 °F)	90-95 HRA (granules) 30-60 HRC (bonding matrix)	540	1000	Excellent	Good under light impact
Surfacing material type	Resistance to wear ^(a)		Mechanical properties	Machinability	Microstructure	Heat treatment	Applications
	Corrosion	Adhesion					
Iron-base, low alloy	Fair to poor	Good	Good compressive strength; takes a high polish for low coefficient of friction	Good; anneal, machine, then retreat to harden	Martensite, austenite, carbides	Surfacing: preheat base metal to 150 °C (300 °F)	Where hardness and toughness are required to 595 °C (1100 °F); cutting tools, shear blades, reamers, dies, ingot tongs

Iron-manganese	Low (similar to carbon steel)	Excellent	Low yield point deformation	Poor; grind if required	Austenite saturated with carbon; iron-manganese carbides at grain boundaries in thin, flat, brittle plates	Heat to reaustenitize; water quench	High-impact service; rail tracks, frogs, switches; use on carbon or manganese steel base
Iron-chromium	Resists oxidation except in moist air; poor in liquid service	Excellent	Low coefficient of friction; high strength	Difficult to grind	Hard carbides in austenite matrix	None	Agricultural machinery, coke shutes, brick-making equipment
Cobalt-chromium	Excellent for salt, steam, and some acids up to 980 °C (1800 °F)	Excellent for low-stress; poor for high-stress; increases with carbon content	Excellent metal-to-metal; takes a high polish, low coefficient of friction	Poor	Chromium, tungsten, cobalt carbides	None	High-temperature, high-corrosion applications; pump shafts, engine valves
Nickel-chromium	Excellent for salt, steam, some acids and alkalis	Excellent for low-stress	Excellent metal-to-metal wear	Poor; finish by grinding	Chromium carbides, chromium borides, in eutectic matrix	Preheat to 315-425 °C (600-800 °F) to prevent cracking; slow cool	Seal rings, cement pump screws, valves, cams
Copper-base	Oxide coating, good protection from atmosphere; good for many acids, bases, and saltwater	Good	Elastic limit 35-1170 MPa (5-170 ksi)	Good	See composition	None	Gears, sheaves, cams, bearings, wear plates, dies for forming stainless steel, carbon steel, aluminum
Tungsten-carbide	Similar to steel; low resistance in oxidizing mediums	Poor	Yield same as high carbon steel	Unmachinable; finish with diamond grinding wheel	W and WC granules in a ferritic matrix	Carburizing and hardening may harden base metal	Cutting teeth and edge holding surfaces of rock drill bits; quarrying, digging, earthmoving equipment

(b) Softens but retains other properties up to 908 °C (1800 °F)

Cobalt-Base Powders

The two types of commercially available cobalt-base hardfacing alloys are carbide-containing alloys and alloys containing Laves phase, which are described later in this article. Carbide-containing cobalt-base alloys have been widely used since the early 1900s, when a cobalt-base alloy with the nominal composition of Co-28Cr-4W-1.1C was first developed. Typically, this alloy, referred to in the hardfacing industry as Alloy No. 6, is a eutectic alloy containing 16 to 17 vol% M_7C_3 -type carbides in a cobalt-base matrix alloyed with chromium and tungsten.

The lightest colored phase in the microstructure is the matrix, which has a face-centered cubic (fcc) crystal structure. The dark phase is M_7C_3 ; the exact composition is $(Cr_{0.85}, Co_{0.14}, W_{0.01})_7C_3$, which has a hexagonal crystal structure. The carbide phase in Alloy No. 6 forms between matrix dendrites. These carbides are often referred to as eutectic carbides. Generally, resistance to abrasive wear is imparted by the presence of carbides, whereas resistance to corrosion and/or elevated-temperature hardness retention is imparted by the matrix. Galling and metal-to-metal wear properties are similarly determined by the matrix alloy. The hardness of Alloy 6, which is designated by AWS as RCoCrA, is 35 to 43 HRC.

Nominal compositions and average deposit hardness data for a number of alloys in the Co-Cr-W-C system are given in Table 6. These alloys retain high hardness at elevated temperatures primarily from carbide and solid-solution strengthening rather than precipitation hardening. They contain up to 30% Cr, up to 15% W, and up to 3.0% C. Some of these alloys also contain combinations of nickel, silicon, molybdenum, boron, and manganese.

Table 6 Chemical compositions and hardnesses of typical cobalt- and nickel-base hardfacing alloys

Alloy	Composition, wt%										Hardness	
	B	C	Co	Cr	Fe	Mo	Mn	Ni	Si	W	HRC	Diamond pyramid
Cobalt-base alloys

(a) Spray-and-fuse powders.

Alloys No. 1 (AWS RCoCrC) and 12 (AWS RCoCrB) are higher hardness modifications of Alloy No. 6 because of additional carbon and tungsten contents. For example, Alloy No. 1 contains primary M_7C_3 , eutectic M_7C_3 plus matrix, and secondary M_6C . Alloy No. 12 is similar to Alloy No. 6, except it has more M_6C and, therefore, contains interdendritic eutectic carbide (tungsten and chromium rich). As shown in Table 7, the weight percent of carbides decreases, as does abrasion/erosion resistance, when comparing these alloys. Specific abrasive and adhesive wear, hot hardness, and corrosion rates for some of these alloy designations are given in Tables 8 and 9.

Table 7 Carbide percentage and hardness of cobalt-base alloys

Alloy	Carbides, wt %	Hardness, HRC
Alloy No. 1	28-29	48-55
Alloy No. 12	16-17	43-50
Alloy No. 6	12-13	35-43
Alloy No. 21	<5	28-32

As the weight percent of carbides decreases, so does abrasion/erosion resistance. Source: Cabot Corp.

Table 9 Corrosion rates for typical cobalt- and nickel-base alloys

Alloy	Corrosion rates for:			
	30% formic acid at 66 °C (150 °F)	30% boiling acetic acid	5% sulfuric acid at 66 °C (150 °F)	65% nitric acid at 66 °C (150 °F)
Cobalt-base alloys				
Alloy No. 1	E	G	S	G
Alloy No. 6	E	E	E	U
Alloy No. 12	E	G	E	E
Alloy No. 21	E	E	E	E
Nickel-base alloys				
Alloy No. 60	G	U	U	U
Alloy No. 50	S	U	U	U
Alloy No. 40	S	U	U	U

Five 24 h test periods; determined in laboratory tests; samples should be tested under actual plant conditions. E (excellent) 0.13 mm/yr (5 mils/yr); G (good) 0.13 to 0.51 mm/yr (5 to 20 mils/yr); S (satisfactory) greater than 0.51 to 1.27 mm/yr (20 to 50 mils/yr);

Cobalt-base alloys, when used in overlay applications, are prone to cracking during cooling. Typically, this problem can be overcome by preheating the base metal prior to application. These alloys are deposited readily by plasma transferred arc, which is a low-dilution, high-deposition-rate process. Cobalt-base hardfacing powders are unsurpassed for use in combined wear-resistant, corrosion-resistant, and high-temperature applications. Cost of these materials is affected by the prevailing price of cobalt and tungsten and tends to be higher than nickel- and iron-base alloy powders. Several alloys with lower cobalt content, or no cobalt, have been developed as low-cost replacements for cobalt-base grades. However, these substitutes have not found broad commercial acceptance.

Nickel-Base Powders

Commercially available nickel-base hardfacing alloys can be divided into three groups: boride-containing alloys, carbide-containing alloys, and Laves phase-containing alloys, which are described later in this article. Based on the Ni-Cr-B-Si system, these alloys are finding increased usage for wear-resistant surfacing applications, particularly in oil pumping and in glass, ceramic, cement, plastic, and steel production. The oil pumping and glass industries are the major users of nickel-base powders.

Additions of boron and silicon to nickel lower the melting point so that an oxyacetylene torch can be easily used. Nickel and boron form a Ni-Ni₃B eutectic at 1092 °C (1998 °F). Silicon additions further lower the eutectic. However, excessive additions of boron and silicon lower plasticity. Because silicon forms a substitutional solid solution with nickel, and because the solubility of boron in nickel is small (0.1 wt%), the abrasion resistance of these alloys is a function of the amount of hard borides present. Most of these alloys contain nickel boride (Ni₃B), chromium borides (CrB, Cr₃B, and Cr₂B), and other complex borides as hard phases.

Typical alloy compositions are listed in Table 6. Deposit hardness in these alloys is as high as 60 HRC, depending on the chromium, boron, and silicon contents. Usually, the boron content varies from 1.5 to 3.5%, while chromium varies from 0 to 17%. Alloys containing large amounts of boron, such as Ni-14Cr-4Si-3.4B-0.75C, are extremely abrasion resistant, but have poor impact toughness.

The Ni-Cr-B-Si alloys are self fluxing. The low-melting eutectic combines with the surface oxides on powders to form borosilicates, which promote wetting of the substrate. Some manufacturers add copper and molybdenum to improve corrosion and pitting resistance. However, hot tearing has been reported due to copper additions. These alloy powders have good abrasive and metal-to-metal (adhesive) wear resistance, although hot hardness and corrosion resistance are slightly inferior to those of cobalt-base alloys (Tables 8, 9). The most common use of Ni-Cr-B-Si powders is in spray-and-fuse and manual torch applications in the glass industry. They are also used in the plasma transferred arc process.

The use of carbide-containing nickel-base alloys has been limited. The most popular and widely used alloys in this group are included in the Ni-Cr-Mo-C system. A typical alloy in this system is Hastelloy Alloy C, which has a nominal composition of Ni-17Cr-17Mo-0.12C and a hardness level of 95 HRB. This alloy, which has good inherent corrosion resistance, is normally deposited by the plasma spray process.

Carbide-containing nickel-base alloys of the Ni-Cr-Mo-Co-Fe-W-C system are gaining popularity as low-cost alternatives to cobalt-base alloys. A typical alloy in this system is Haynes Alloy 716, which has a nominal composition of Ni-11Co-26Cr-29Fe-3.5W-3Mo-1.1C-0.5B and a hardness of 32 HRC. These alloys, depending on precise composition, contain M₇C₃- or M₆C-type carbides. They are normally deposited by the plasma transferred arc process.

Carbides

Carbide hardfacing powders are used for severe abrasion and cutting applications. Tungsten carbide is the most widely used carbide in these types of powders. Comminuted tungsten carbide usually has a mixture of WC and W₂C carbides. (Tungsten carbide/cobalt powder contains WC and M₆C carbides.) Fine carbides are used when smooth surfaces and improved impact resistance are desired.

Larger particles yield a rougher surface and improved abrasion resistance, but lower toughness, which often results in fracture and subsequent loss of carbides. Some commercial grades also contain percentages of cobalt and nickel to improve aqueous corrosion or high-temperature oxidation resistance of the deposit. However, oxidation of tungsten carbide particles limits the upper service temperature to 600 °C (1100 °F). These powders are used primarily in plasma spray and manual torch processes, with small amounts used in plasma transferred arc and spray-and-fuse powders. Table 10 lists the hardnesses of various carbides and select materials.

Table 10 Approximate hardness of carbides and select materials

Material	Hardness		
	DPH	HK	Mohs

Iron-Base Powders

Iron-base hardfacing alloys are more widely used than cobalt- and/or nickel-base hardfacing alloys and constitute the largest volume used of hardfacing alloys. Although iron-base powders are most frequently used as a filler material in consumable electrode hardfacing processes, they are also used in hardfacing techniques that use powder as the consumable. Iron-base hardfacing alloys offer low cost and a broad range of desirable properties.

Most equipment that undergoes severe wear, such as crushing and grinding equipment and earth-moving equipment, is usually very large, rugged, and often subject to contamination. Parts subjected to wear usually require downtime for repair. For this reason, they are usually hardfaced with the lowest cost and most readily available materials. As a result, literally hundreds of iron-base hardfacing alloys are in use today.

Due to the large number of alloys involved, iron-base hardfacing alloys are best classified by their suitability for different types of wear and their general microstructures rather than by chemical composition. Most iron-base hardfacing alloys can be divided into: pearlitic steels, austenitic steels, martensitic steels, or high-alloy irons. Properties of several typical iron-base hardfacing alloys of major types are listed in Table 11 as a general guide for selection of hardfacing materials.

Table 11 Composition and hardness of select iron-base hardfacing alloys

Nominal composition	Nominal hardness		Unlubricated sliding wear volume ^(a) , mm ³	Abrasive wear, volume ^(b) , mm ³	Density, g/cm ³
	DPH	HRC			
Pearlitic steels					
Fe-2Cr-1Mn-0.2C	318	32	0.5	55	7.75
Fe-1.7Cr-1.8Mn-0.1C	372	38	0.6	67	7.47
Austenitic steels					
Fe-14Mn-2Ni-2.5Cr-0.6C	188 HRB	88 HRB	0.4	86	7.75
Fe-15Cr-15Mn-1.5Ni-0.2C	230	18	0.3	113	7.75
Martensitic steels					
Fe-5.4Cr-3Mn-0.4C	544	52	0.4	54	7.47
Fe-12Cr-2Mn-0.3C	577	54	0.3	60	7.47
High-alloy irons					
Fe-16Cr-4C	595	55	0.3	13	7.47
Fe-30Cr-4.6C	560	53	0.2	15	7.19

(b) Wear measured from dry sand rubber wheel abrasion tests. Tested for 2000 revolutions at a load of 14 kg (30 lb) using a 23 cm (9 in.) diam rubber wheel and

Pearlitic steels are essentially low-carbon steels with minor adjustments in composition to achieve weldability. These alloys contain low carbon (0.25%) and low amounts of other alloying elements, resulting in a pearlitic structure. Pearlitic steels are useful as buildup overlays, used primarily to rebuild machinery parts back to size. Examples include shafts, rollers, and other parts in heavy machinery subjected to rolling, sliding, or impact loading. Typically this group of alloys has high impact resistance and low hardness (25 to 35 HRC), as well as excellent weldability.

Austenitic Steels. Austenite in this group of alloys is usually stabilized by manganese additions. Austenitic iron-base hardfacing alloys essentially are modeled after Hadfield steels. Most commercially available alloys in this category can be broadly subdivided into low-chromium and high-chromium alloys.

Low-chromium alloys usually contain up to 4% Cr, 12 to 15% Mn, and some nickel or molybdenum. Low-chromium austenitic steels generally are used to rebuild machinery parts subjected to high impact, such as impact crushers or shovel lips. Low-chromium austenitic steels are not recommended for joining manganese steel parts due to the possibility of cracking. Welding to plain carbon steels should be carefully executed. Martensite sometimes forms in zones that are low in manganese content, thereby embrittling the interdiffusion zone.

High-chromium austenitic steels, which normally contain 12 to 17% Cr in addition to about 15% Mn, were developed to preclude diffusion zone embrittlement. Furthermore, the as-deposited hardness of high-chromium steels is higher (16 to 20 HRC) than that of low-chromium austenitic steels (86 to 88 HRB). High-chromium austenitic steels typically are used for rebuilding manganese steel and carbon steel parts subjected to high metal-to-metal pounding, such as railroad frogs and steel mill wobblers, as well as for joining manganese steels.

Martensitic Steels. Alloys in this category are designed to form martensite on normal air cooling of the weld deposit. As a result, these steels are often termed "self-hardening" or "air hardening," and they resemble tool steels with hardness in the range of 40 to 45 HRC. The carbon content of the martensitic steels ranges up to 0.5%. Other elements such as molybdenum, tungsten, nickel (up to 3%), and chromium (up to 15%) are added to increase hardenability and strength and to promote martensite formation. Manganese and silicone usually are added to aid weldability. The major hardfacing applications for martensitic steels include unlubricated metal-to-metal rolling or sliding parts such as undercarriage parts of tractors. The impact resistance of martensitic steels is inferior to that of pearlitic or austenitic alloys, but there is a compensating increase in hardness and resistance to abrasive wear.

High-Alloy Irons. This group of alloys is referred to as irons because of their similarities to cast irons. These alloys contain large amounts of chromium and/or molybdenum carbides in what is essentially a martensitic matrix. The carbon content ranges from 2 to 6%, providing large amounts of carbides. Accordingly, resistance to abrasion is improved considerably over the low-carbon iron-base alloys. Impact resistance and toughness of these alloys, however, are correspondingly lower. In certain alloys and for certain applications, carbon contents of the powders can be as high as 9% with chromium contents around 68%.

High-alloy iron hardfacing deposits usually are limited to one or two passes in thickness due to an extremely high susceptibility to form tension cracks. In some alloys containing 4 to 8% Mn or up to 5% Ni, the austenitic phase is stabilized in the matrix, which reduces the tendency to crack on cooling. Most high-alloy irons have extremely high compressive strength, but very low tensile strength. The hardness range for high-alloy irons is typically 52 to 62 HRC.

Special Compositions

Each manufacturer produces many different powder compositions, some of which are unique. Several examples of powders with unique properties are discussed below.

Laves Phase Alloys. Laves phase is a type of topologically close-packed intermetallic compound. Historically, the presence of Laves phase has been avoided in most alloys due to its detrimental effect on mechanical properties. However, in the early 1960s, the usefulness of Laves phase in resisting metal-to-metal wear was discovered; subsequently, alloys containing Laves phase have become commercially available.

The deposits have smooth surfaces that can be finished to a 2 μm (78 $\mu\text{in.}$) surface finish. Alloys are particularly well suited to applications in which adequate lubrication is a problem. Laves phase materials maintain mechanical properties

over a wide range of temperatures. Their main uses are for plasma spray hardfacing operations such as plasma spray coating of gas turbine blades.

There are two different Laves phase-containing cobalt-base alloys commercially available for hardfacing applications: Co-28Mo-8Cr-2Si and Co-28Mo-17Cr-3Si. These alloys contain at least 50 vol% of Laves phase bound in a cobalt-base matrix that is alloyed with chromium and molybdenum.

Laves phase has a hexagonal structure similar to M_7C_3 carbides, but a hardness value between 1000 and 1200 DPH, which is less than that of carbides. Consequently, the Laves phase-containing alloys are less abrasive to mating materials than carbide-containing alloys in metal-to-metal wear situations.

Only one Laves phase-containing nickel-base alloy is commercially available: Ni-32Mo-13Cr-3Si. This alloy, like most nickel-base alloys, is difficult to weld using the oxyacetylene process, but can be readily welded using gas tungsten arc welding or the plasma transferred arc process. It can also be applied using the plasma or detonation gun spray technique. Although it has excellent metal-to-metal wear resistance and moderate abrasive wear resistance, it exhibits poor impact resistance.

Nickel-Aluminum Powders. Protective coatings based on nickel-aluminum composite powders are deposited by plasma spray techniques. Such composite powders are inherently heterogeneous, in that each particle consists of a nickel core and an aluminum coating. The main advantage of using nickel-aluminum powders is their superior bond strength, which results from exothermic reactions that occur within or on the surface of the powders as they pass through the plasma spray flame. Some diffusion also results in the substrate (in the absence of heat), further improving the overall coating bond strength. These composite powders are also referred to as self-bonding, one-step, or exothermic hardfacing powders.

Ceramics are being used increasingly as hardfacing powders. In addition to resistance to wear, they can have other desirable properties such as insulation and chemical resistance. The processes used for depositing ceramics include plasma spray and detonation gun techniques. The material can be a single oxide, mixed oxides, or other type of ceramic. Examples of some materials in this category are alumina (Al_2O_3) and chromium oxide (Cr_2O_3). Ceramic coatings have high hardnesses, ranging up to 1200 DPH, and very little porosity. In addition, these coatings can be ground and lapped to obtain a very smooth surface finish.

High-Temperature Powders. A relatively new type of hardfacing powder is that based on the (Fe, Ni, Co)-Cr-Al-Y system. These yttrium-containing powders are used for selective coating of gas turbine blades by the plasma spray process. The coating is highly resistant to high-temperature oxidation and corrosion and is claimed to be superior to coatings made by the pack cementation, diffusion coating technique.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Hardfacing Processes

For satisfactory performance of the coating, selection of the proper hardfacing process is equally as important as selection of the proper hardfacing material. Process selection requires careful consideration of many factors, such as required coating thickness, metallurgical integrity of the coating, size and shape of the component to be hardfaced, compatibility with the base metal, welder skill, cost of filler material, and equipment downtime.

The term "hardfacing" is sometimes used to describe true welding processes, in which both the filler material and a small amount of the base metal are molten and bonded metallurgically. Such processes are preferred for applications that require dense and relatively thick coatings with excellent bonding between the hardfacing material and the base metal. Thermal spray processes are used for applications that require a thin, hard coating applied with minimum work distortion and where a purely mechanical bond between the hardfacing material and the base metal is acceptable. Unless otherwise stated, the term "hardfacing" is used in this section to include both the welding and thermal spray types of processes.

As discussed earlier, the properties of the hardfacing material are affected by dilution, which in turn varies with the hardfacing process. The success of a hardfacing operation depends on factors such as surface preparation of the base metal, preheating conditions, and specific process parameters.

Spray-and-Fuse Process

The spray-and-fuse process is a two-step process in which powdered coating material is deposited by conventional thermal spraying, usually using either a combustion gun (or torch) or a plasma spray gun, and subsequently fused using either a heating torch or furnace. Coatings usually are made of nickel or cobalt self-fluxing alloys to which hard particles, such as tungsten carbide, can be added for increased wear resistance. Deposits ranging from 0.51 to 2.5 mm (0.020 to 0.100 in.) thick can be made by building up several layers at a rate of 0.13 to 0.25 mm (0.005 to 0.010 in.) per pass.

Deposit thickness is controlled by the traverse speed of the torch, speed of rotation (when done between centers on cylindrical parts), powder flow, and the number of layers applied. Deposit rates of 3.5 to 5.5 kg/h (8 to 12 lb/h) can be achieved. Spray-and-fuse hardfacing is particularly effective on small cylindrical parts, as well as on irregular shapes. Cylindrical parts can be sprayed and fused between centers on a converted lathe. Work travels at about 0.8 m/s (150 sfm).

Several types of combustion powder spraying systems are used for the initial deposition step, differing primarily in the method used to feed the powder into the flame. Compressed air can be used as a propellant for the powder, which is injected directly into the flame through a central orifice in the nozzle. Another system feeds the powder into aspirating gas positioned ahead of the nozzle prior to ignition. As shown in Fig. 7, gravity feed can be used to feed the powder directly into the flame. Powder is then conveyed to the workpiece by the force of the combustion gases.

Fig. 7 Spray-and-fuse torch in which the powders is conveyed by gravity into the flame and conveyed to the workpiece by the force of the combustion gases

Acetylene combined with oxygen typically is used as the fuel gas, although other fuel gases such as propane and MAPP gas are sometimes used. Powder can also be encapsulated in plastic tubing for use with wire-type spray equipment. Alternatively, a plasma spray torch rather than a combustion gun can be used. In all setups, the powdered alloy becomes molten or semimolten as it passes through or into the combustion flame or plasma effluent, thus facilitating the required initial bond prior to fusing.

Fusion is usually accomplished in a separate operation using an oxyacetylene torch with a multitip flame designed to spread the heat over a wide area. Alternatively, fusion can be accomplished by induction heating, or by heat treatment in a vacuum or reducing atmosphere furnace. As-sprayed coatings are stressed; consequently, fusing should immediately follow spraying to eliminate the possibility of cracking of the coating.

In the spray-and-fuse process, the component, usually cleaned by grit blasting, is heated uniformly to approximately 345 °C (650 °F). The torch is then placed over the area where fusion is to initiate, and the temperature of this area is raised to about 760 °C (1400 °F). Torch movement is then stopped, and the heat is concentrated at the starting point.

The temperature is raised at this position until the surface exhibits a shiny molten layer (glazing). The torch is then moved along the coating to fuse it uniformly, as indicated by glazing: heating should not be excessive, or loss of shape or running may result. Fusing should not be interrupted, and the entire coating should be fused at once. The as-deposited powder coating is bonded mechanically, and upon fusing, a high-quality metallurgical bond also results between the deposit and the base metal.

The spray-and-fuse process can be used to coat a wide range of materials. However, some materials, such as tool steels, austenitic stainless steels, and steels with carbon contents higher than 0.25%, require preheating and careful cooling after fusing to prevent cracking the deposit. Use of type 303 stainless steel or other free-machining metals containing sulfur, manganese, phosphorus, lead, or selenium can result in porous overlays due to the emanation of gas during fusion; these materials usually are not considered for this process. Titanium- or aluminum-bearing alloys (type 321 stainless steel) are also not considered because the highly stable oxide layers on these base metals interfere with proper bonding of the overlay to the base metal during the fusion operation.

Self-fluxing nickel-base powders are the most common hardfacing materials used with the spray-and-fuse process. As shown in Table 6, these powders are available for a wide range of deposit hardness. The lower hardness grades find extensive use in the glass mold industry. The higher hardness grades are used extensively on pump components, particularly in the oil industry.

The quality and properties of the deposit depend not only on the hardfacing powder composition, but also on the particle size distribution and the care exercised in making and fusing the deposit. Porosity up to 5% is common in the majority of hardfacing applications. The spray-and-fuse process is also used with cobalt-base powders (Table 6), and with carbide-containing composite powders. Composite powders are more difficult to use, and their deposits exhibit more porosity.

Spray-and-fuse powders generally are applied to cylindrical parts such as pump shafts, packing gland sleeves, and pistons. Other typical applications include ammonia applicators, cams, fan blades, glass molds, pump sleeves and pump plungers, valve seats and stems, bushings, sprockets, wire drawing capstan rings, overlays on dies and molds, and casting repairs.

Plasma Spray Process

In the plasma spray process, a plasma gas stream heats and propels powder particles into the workpiece surface. Because plasma temperatures are extremely high, the plasma spray process can be used to apply refractory coatings that cannot be applied by the spray-and-fuse process.

Although plasma spray coatings have inherent porosity and are principally mechanically bonded to the substrate, they generally have higher density and better adhesion than is achieved with single-step flame spraying. Powders can be applied manually or with mechanized equipment at rates ranging from less than 0.45 kg/h (1 lb/h) to over 14 kg/h (30 lb/h), depending on power of the equipment and type of powder used. In most applications, coating thickness is in the range of 0.13 to 0.4 mm (0.005 to 0.015 in.); depending on the application, much thicker coatings, such as thermal barrier coatings, can be applied. Usually, the workpiece is maintained below 150 °C (300 °F), resulting in little or no distortion of the component and no dilution of the coating by the substrate. Very smooth deposits can be obtained, and finishing may not be required.

Figure 8 schematically depicts a typical plasma spray gun, showing alternative powder inlet positions. A gas, usually argon or nitrogen (or a mixture of these) with hydrogen or helium, flows through a water-cooled copper anode, which serves as a constricting nozzle. An arc is maintained internally from an axial rear tungsten electrode.

Fig. 8 Schematic of plasma

Powder introduced into the plasma stream is heated to a molten or semimolten state and propelled at high velocity onto the substrate. Plasma spray deposits with some high-velocity (<305 m/s, or 1000 ft/s) torches can have bond strengths in excess of 70 MPa (10 ksi). The powder is fed at a precisely regulated rate into an inert carrier gas stream and is usually introduced into the plasma stream either in the diverging portion of the nozzle or just beyond the exit.

Usually, the carrier gas is the same composition as the primary plasma gas (argon and/or nitrogen). The choice of powder-feed rate is important. If the powder is fed faster than it can be properly heated, deposition efficiency decreases rapidly, and the coating contains trapped, unmelted powder. In contrast, if the feed rate is too low, operation costs significantly increase.

Materials for the plasma spray process must be in powder form and must be sized appropriately to achieve melting. For the highest coating density, powders are sized between about 44 μm (325 mesh) and 10 μm . The lower limit ensures free flow. Coarser powder can be sized up to 100 μm , with typical distribution falling between 88 μm (170 mesh) and 44 μm (325 mesh). Powder shape ranges from spherical to acicular, though reduced surface area and consistent flow make spherical shapes the best.

Any material that melts without subliming and is available as a properly sized powder has potential as a plasma spray process coating. Plasma spray coatings can be elemental (aluminum, molybdenum, nickel, or chromium), alloyed (nickel-, iron-, or cobalt-base), compounds (Al_2O_3 , Cr_2O_3 , or Cr_3C_2), composites (nickel-aluminum, cobalt-bonded tungsten carbide, TiO_2 , or clad Al_2O_3), or mechanical blends.

In one process variation, the plasma gun and workpiece are enclosed in a vacuum chamber, and the entire operation is carried out in an inert atmosphere at low pressure (50 torr). Advantages of this low-pressure plasma technique include improved bonding and density of the deposit, improved control over coating thickness (even with an irregular work surface), and higher deposit efficiency. However, facility cost is higher, and workpiece size is limited by the vacuum chamber size. This modification is suitable for coating turbine airfoils, blade tips, and shroud segments.

Very fine powder (-325 mesh) generally is used for low-pressure plasma spraying to achieve maximum density. If high-purity coatings are also desired, then the powder must be manufactured under inert cover and atomized in an inert gas to preserve purity.

Suitable applications for plasma spraying include those requiring a thin, smooth, wear-resistant coating, with low heat buildup in the workpiece. This process is used for hardfacing seal rings of aircraft jet turbine engines and for other turbine components. The coating provides a thermal barrier, resists high-temperature erosion, and forms a tight seal between

rotating parts. Other applications include bottling machine parts, mixer and feeder parts, shafts and sleeves, wear rings, arc disks, and thread guides.

Plasma Transferred Arc

Plasma transferred arc surfacing, as shown schematically in Fig. 9, is a welding process in which the powder is introduced into a combined arc/plasma stream to form a molten pool on the workpiece. The resulting deposit is homogeneous and dense, and provides excellent metallurgical bonding with the base metal (workpiece). This process uses a constricted arc. The alloy is carried from a powder feeder to the plasma torch in a stream of argon gas, which forms the plasma and is directed away from the torch into the arc effluent, where it is melted and fusion bonded to the base metal. A direct current power source connecting the tungsten electrode and the workpiece provides energy for the transferred arc. A second direct current power source connecting the tungsten electrode and the arc-constricting orifice supports a nontransferred arc. This non-transferred arc supplements the heat of the transferred arc and serves as a pilot arc to initiate the transferred arc. Argon is passed through a gas diffuser to provide a blanket of shielding gas in and around the arc zone.

Fig. 9 Schematic of the plasma transferred arc hardfacing process

Deposits ranging from 0.64 to 3.2 mm (0.025 to 0.125 in.) thick can be produced rapidly in a single pass. Penetration into the base metal can be controlled closely to very low levels. However, a dilution of 5 to 20% in the deposit is typical. Powder used for plasma transferred arc surfacing typically ranges from about 150 to 45 μm in size. Coarser powders can be used, because the transferred arc can easily melt the powder. Use of particles finer than 45 μm must be limited to prevent smoking and oxide inclusions in the deposit.

The plasma transferred arc process is well suited to automation operation and is therefore a frequent choice for high-volume applications such as valves. The exhaust valves of internal combustion engines are subjected not only to mechanical degradation (due to impact and sliding stresses) but also to hot corrosion from the by-products of combustion. In diesel engines, hot corrosion is particularly detrimental, especially if low-grade (residual) fuels are used. To combat hot corrosion and mechanical wear of valve seat faces that must maintain integrity for efficient engine operations, these components are commonly coated with cobalt-base alloys.

Manual Powder Torch Welding

Also termed "powder welding," manual powder torch welding is a true welding process in which powder application and fusion occur in a single operation using a special oxyacetylene torch. Powder is fed from a small hopper mounted on a gas welding torch into the fuel gas supply and conveyed through the flame to the workpiece surface. By following general oxyacetylene surfacing practice, smooth, thin, dense deposits are obtained. Deposit thickness is controlled by powder flow rate and movement of the torch. A dilution of 1 to 5% in the deposit occurs from this process.

Deposits ranging from 0.76 to 3.2 mm (0.030 to 0.125 in.) in thickness can be applied at a rate of 1.3 mm (0.050 in.) per pass. Sweating of the base metal during surfacing generates a fusion-type bond with the hardfacing alloy. Ease of application and material recovery are enhanced because of close control of the powder flow into the welding flame.

Oxyacetylene torch flame adjustment is essential to produce good powder deposition. The amount of excess acetylene required for hardfacing varies depending on alloy composition. The amount of excess acetylene is conveniently measured in terms of the flame geometry as the ratio between the length of the oxyacetylene feather and the inner cone. The length of the inner cone, indicated by the value X , is the distance from the torch tip to the extreme end of the inner cone.

The length of the oxyacetylene feather is measured from the torch tip to the extreme end of the intermediate zone, generally expressed in multiples of the length of the inner cone. A neutral flame is thus classified as $1X$. Cobalt-base powders are usually applied using $2X$ to $3X$ flame. The oxyacetylene feather is two to three times the length of the inner cone.

Tungsten carbide-containing composite powders should be applied using a $1.5X$ flame. Nickel-base powders are welded with a neutral or slightly oxidizing flame. Because flame characteristics change somewhat when powder is being sprayed, the powder feed handle should be depressed and final flame adjustment made while the powder is being sprayed. Alloys commonly welded with this process contain boron and silicon, which slag off any oxide skin to provide a clean weld pool.

The manual torch process is well suited for small repairs or for hardfacing of small areas requiring a wide range of hardness (about 20 to 60 HRC). Typical applications of manual torch welding include glass dies and molds, brick molding equipment, components for cement industry, cast iron parts for foundries, feed screws, hammer mill hammers, and pump parts.

Detonation Gun

The detonation gun spray process is markedly different from other flame spraying processes and was initially developed for the deposition of hard, wear-resistant materials such as oxides and carbides. The extremely high particle velocities achieved in the detonation gun result in coatings with higher density, greater internal strength, and superior bond strength than can be achieved with conventional plasma spraying or single-step flame spraying.

This process, which is depicted schematically in Fig. 10, uses a controlled series of explosions of a mixture of oxygen and acetylene to blast the powder onto the surface of the workpiece. The powder to be sprayed is introduced into the long chamber in the mixture of oxygen and acetylene. When the gas mixture is ignited, the detonation products rapidly heat and accelerate the powder particles. Temperatures of 3300°C (6000°F) are reached inside the gun.

Fig. 10 Schematic of detonation gun hardfacing process

The process is capable of spraying a wide range of both metallic and nonmetallic powders with thicknesses of up to 0.5 mm (0.020 in.). The coating produced is similar to, but denser than, a plasma spray coating. It has an excellent bond strength and can be finished to an excellent surface finish. The workpiece can be processed below 150 °C (300 °F) in a carbon dioxide spray cooling system. This process has found wide acceptance in aerospace and oil exploration industries.

Jet Kote Surfacing System

This is a high-pressure combustion thermal spray process, in which the spray gun burns a fuel (either MAPP gas or propane) with a high volume of oxygen within a combustion chamber. Using a nitrogen carrier gas, the powder is injected into the combustion products and is rapidly heated and accelerated to impact at high speed against the work surface to be coated. Unlike the detonation gun process, the Jet Kote system (Cabot Corp.) is based on continuous combustion within the gun.

Systems with high operating pressure provide a smooth, dense coating that is comparable to coatings produced by the detonation gun process. The process can also use both metallic and ceramic powders comparable to those used in plasma spraying. One of the main advantages of the Jet Kote system is low capital equipment cost compared to plasma spraying. Typical applications include those in which high-quality, thermal spray coatings are required, such as in the oil exploration industry.

Bulk-Welding Process

The bulk-welding process, also referred to as joint welding, is an "add-on" to conventional submerged arc welding. It utilizes the existing heat produced by a conventional submerged arc weld to melt powders ahead of the melt pool to increase overall deposition rates. The process uses a powder composition that matches the feed wire composition.

The quantity of powder used is governed by the application. The powder metal to wire ratio can be as high as 2 to 1; however, for most applications, this ratio is 1 to 1. A schematic of the process is shown in Fig. 11. Advantages associated with the bulk-welding process are:

- Deposition rate with bulk-welding can be increased two or three times over single-wire submerged arc welding without increasing heat input. The deposition rate depends on the amount of powder metal used in relation to the wire.
- Flux consumption per pound of deposited metal is reduced considerably.
- Less distortion is evident due to lower heat input.
- Accurate powder metering prevents spreading and other related problems, such as unmelted powder and rough edges, and improves overall deposition efficiency.
- A reduction in weld passes is possible. One-pass welding can be done on most applications.

Fig. 11 Schematic of the bulk-welding process using metal powder joint fill

The process is used for shipbuilding, heavy machinery, bridges, vessels, and building fabrication in which partial- or full-penetration weld and fillet welds are required. Most powders used are iron base. However some cobalt-base powders are also used.

Conforma Clad Process

This process uses a flexible cloth made of polytetrafluoroethylene and a hardfacing powder of desired composition. The main benefit derived from this technique is that the cloth can be cut into any required size and placed on the surface to be coated, regardless of the profile of the workpiece. During subsequent furnace brazing, polytetrafluoroethylene is vaporized, and the hardfacing powder forms the deposit layer. The powder particles can be irregular or spherical in shape and can vary in size from 1 to 150 μm . Typical powder compositions are similar to the nickel-base alloys 40, 50, and 60 and cobalt-base alloy SF6 in Table 6. In addition, composites of these nickel-base alloys with tungsten carbide or chromium carbide are also produced.

Deposits produced by this process are highly dense and wear resistant. The primary advantage is the ability of Conforma Clad process to build up thick coatings (up to 2.5 mm or 0.1 in. thick) on selected areas of parts. Typical applications of the process are for agricultural equipment and valves.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Brazing and Soldering Powders

Metal Powders are used extensively as filler metals in the brazing and soldering industries. These powders offer a convenient method of applying filler metal to parts, although alternative filler metal forms (wire, rod, clad sheet, foil, preforms, and plating) also are used. For brazing, filler metals have a liquidus temperature above 450 °C (840 °F) and below the solidus of the base metal. For soldering, filler metals (solders) have a liquidus temperature below 450 °C (840 °F) and below the solidus of the base metal. In both brazing and soldering, the filler metal, when heated to a suitable temperature with a suitable flux or protective atmosphere, is distributed between closely fitted surfaces of the joint by capillary action.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Powder Types

Atomized Powders. Most powders currently are produced by atomization because it offers a convenient and cost-effective means of producing large quantities of powder. Atomization consists of melting the metal and alloy in an induction melting furnace and then pouring it into a crucible, which has a hole in its bottom and is fitted with a gas nozzle at the bottom of the hole. In most atomizing processes, a high-pressure stream of fluid (usually water or gas) impinges on the molten metal stream, breaking it into droplets.

Materials such as solders can be readily air atomized, while most silver-base, nickel-base, and other alloys are atomized with a high-pressure argon or nitrogen gas. Powders are subsequently screened to the desired particle size distribution. Most brazing filler metals are sieved to one of four standard sieve analyses as follows:

Sieve size	Size analysis, %
100 mesh	
-60	100 min
-100	95 min
140 C mesh	
+100	Trace
+140	10 max
-325	20 max
140 F mesh	
+100	Trace
+140	10 max
-325	55 max
325 mesh	
+200	Trace
+325	10 max
-325	90 min

Brazing filler-metal atomizer powders are available in the following types:

- Nickel alloys
- Cobalt alloys
- Silver alloys
- Gold alloys
- Copper-phosphorus alloys
- Copper
- Aluminum-silicon alloys

These powders are generally screened to American Society for Testing and Materials standard ASTM B 214 ("Standard Method for Sieve Analysis of Granular Metal Powders"), using sieves with size to ASTM E 11 ("Standard Specification for Wire-Cloth Sieves for Testing Purposes"). Table 12 lists the compositions of various brazing powders, as well as their respective solidus, liquidus, and brazing temperatures.

Table 12 Compositions and properties of typical brazing alloy powders

(a) Single values are maximum percentages, unless otherwise indicated.

Fine prealloyed solder powders (-325 mesh) are used to make soldering pastes and creams, in which the solder alloy is suspended in the fluxing material. The ratio of solder to flux is 80 to 90 wt%. A standard specification for solder metal can be found in ASTM B 32. Table 13 lists the compositions of some typical solder alloy powders used in soldering pastes and creams, as well as their respective solidus, liquidus, and soldering temperatures.

Other solder alloys are also available in paste form. Typical compositions, impurity levels, and designations are given in ASTM B 32.

(a) Maximum level

Ball Milled Powders. Historically, nickel filler metals have been produced by ball milling. In this process, alloy shot is ball milled into fine powders. Currently, atomization techniques are used to produce these powders.

Mechanically Filed Powders. Early filler metal powders made of silver and gold filler metals were mechanically filed using standard commercial filing machines. These powders, however, were not as readily usable in paste form since the long, thin filings do not flow through a thin nozzle; consequently, mechanical filing, while still available, is decreasing in usage and has been converted mostly to atomized powder manufacture.

Oxide Powders. Most past-type copper filler metals are made of red copper oxide that has been milled to a fine powder. This powder is then mixed with a vehicle that provides a convenient paste for the filler metal application. Because copper oxide dissociates readily, it makes a good filler metal for furnace brazing of carbon steels in strongly reducing atmospheres such as combusted city gas (nitrogen/carbon monoxide/ hydrogen) or prepared mixed atmospheres (nitrogen-hydrogen).

Preforms from Metal Powders. Preforms are used because they are readily applied with automated equipment. Preforms are easily produced from wire and sheet; consequently powders are generally not used to make preforms other than stamping from transfer tape materials, which are plastic-bonded sheets with an adhesive on one side. Solder powders generally are not used for making preforms.

Flux-Powder Mixtures. Brazing fluxes used in flux-powder applications are generally proprietary. These fluxes usually are composed of various mixtures of some of the following: borates of sodium, potassium, and lithium; fused borax; fluoroborates of potassium or sodium; fluorides of sodium, potassium, and lithium; chlorides of sodium, potassium, and lithium; boric acid (frequently calcined); alkalis such as potassium hydroxide and sodium hydrides; wetting agents; and water.

Depending on the desired reactivity of the brazing flux and its melting characteristics, these materials are used in various quantities. Some fluxes are suitable for direct manufacture of flux-powder pastes, while other flux powder pastes are made using a long-chain viscous organic vehicle that can exhibit thixotropic properties.

Solder fluxes are categorized as corrosive, intermediate, and noncorrosive fluxes. These fluxes are mixed with fine solder powder to form solder creams and pastes. Corrosive fluxes contain one or more of the following components:

- Zinc chloride
- Ammonium chloride
- Stannous chloride
- Sodium or potassium chloride
- Lithium chloride
- Aluminum chloride
- Sodium or potassium fluoride
- Boron trifluoride
- Hydrochloric acid
- Hydrofluoric acid
- Orthophosphoric acid
- Fluoboric acid

Intermediate-type powder/paste fluxes contain one or more of the organic acids (lactic acid, citric acid, stearic acid, and oxalic acid, for example) or organic hydrohalides (glutamic acid hydrochloride, aniline hydrochloride, and hydrazine hydrochloride, for example). Amines and other compounds such as urea, glycerol and diethylene diamine, or triamine also are used. For flux-powder pastes, one or more of these fluxing agents is added to the powder and is mixed with a long-chain viscous organic vehicle that can exhibit thixotropic properties.

Noncorrosive flux-powder pastes contain rosin as the main constituent, which is active at soldering temperatures but inactive at room temperature. Occasionally, additives are used to increase the reactivity of the rosin.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Paste Mixtures

Brazing paste mixtures usually are prepared for furnace brazing in a protective atmosphere. Consequently, they do not require flux additions. For special-purpose applications, a small amount of flux occasionally can be added.

Copper oxide powder pastes are extremely fine; consequently, vehicles such as ethylene glycol and mineral oil are used to form the paste mixture. On heating in the presence of copper or copper oxide, these vehicles chemically crack, leaving a residue of carbon. At the brazing temperature, carbon reacts with the water in the higher dew point (-1 to 26 °C, or 30 to 80 °F) furnace brazing atmosphere to produce carbon monoxide gas, eliminating the carbon from the surface of the part. If the furnace atmosphere is too dry, the carbon remains on the surface of the part.

Paste mixtures of nickel, silver, and gold filler metals use a long-chain organic vehicle that can exhibit thixotropic properties. These vehicles or binders are vaporized on heating and are forced out of the furnace by the gas atmosphere. If sufficient moisture exists in the furnace atmosphere (approximately -1 to 26 °C, or 30 to 80 °F, dew point) the vehicle reacts with the moisture to produce hydrogen and carbon monoxide. In a high-vacuum furnace (approximately 10^{-3} torr and below), the vehicle vaporizes when heated and is forced out into the cold portions of the furnace and usually is pumped out of the system.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Application of Filler Metal

Filler metal can be easily applied with the use of automated brazing machines by using powder in a paste mixture of either flux and/or binder, as required by the particular type of equipment. If the parts are to be brazed in an automated machine with air-gas torch heating, the use of flux is required to provide a suitable braze and to protect parts from oxidation, while allowing brazing or soldering filler metal to wet and flow over the part. When powder is to be used in automated equipment or in furnaces with controlled atmospheres, flux is not required. A binder is used to hold the powder to the work; when heated, it is gassed off and pumped out of the system.

Brazing and soldering powders, pastes, and creams are applied in different manners. One method consists of the use of an inexpensive plastic bottle that allows manual application of the filler metal during brazing or soldering furnace operations. The operator puts the parts on the furnace belt, then drops a quantity of filler metal in the proper location at the joint. More sophisticated types of application equipment apply the filler metal pneumatically or volumetrically to the parts to be brazed or soldered on an automated brazing or soldering machine. Powder and flux can be added either separately or as a single material on the brazed joint as the parts move through the machine.

Solders generally are supplied in paste or cream form, which can be applied by screening, brushing, extruding, or rolling onto the substrate surfaces. Solder pastes and creams, which are used widely in microelectronic component soldering, are often applied using a syringe. Other methods of application of brazing filler metal include spraying, dipping, applying with a syringe, or applying dry powder and wetting with a binder.

Mechanical Properties

The mechanical properties of joints made with powdered filler metals have properties comparable to those of joints made from solid rod, wire, and foil, provided that the powders are clean and free of oxides, and that the protective flux or atmosphere is maintained as necessary to prevent oxidation of the specific metal or alloy. Solder pastes and creams containing fluxes protect these powders from oxidation.

Brazing filler metals that contain chromium, silicon, boron, and other highly oxidizing elements experience some oxidation when heated to the brazing temperature. When the furnace atmosphere is not properly controlled, the large surface area of the brazing powder particles may pick up enough oxygen to encapsulate each particle or may remove most of the boron, causing poor brazing. This constitutes inadequate quality control and is easily avoidable.

Powder particle size can affect the flow of the brazing filler metal when it contains elements with stable oxides such as chromium, silicon, boron, aluminum, or titanium. The high surface area of -325 mesh powders, which contain elements with oxides that are difficult to dissociate, can pick up sufficient oxygen from the atmosphere to reduce the flow of the filler metal. The degree of oxygen pickup depends on the specific element present and the partial pressure of oxygen present in the brazing atmosphere during the heating portion of the cycle.

For example, if Ni-19Cr-10Si filler metal (BNi-5) is heated in a marginal atmosphere on type 304 stainless steel base metal, the base metal can emerge bright and clean. As the brazing temperature is approached, however, the chromium and silicon in the powder filler metal will oxidize to some extent. The degree of oxidation depends on the partial pressure of oxygen in the atmosphere surrounding the powder. In a high-quality atmosphere, the degree of oxidation is so minimal that there is no deleterious effect on the melting and flow characteristics of the brazing filler metal.

As the partial pressure of oxygen in a brazing atmosphere increases, more surface oxidation of the powder occurs; smaller particles may be completely oxidized and thus will not melt and flow when the brazing temperature is reached. Larger particles may not be completely oxidized and thus will melt and flow; however, oxides and residual unmelted powders remain at the point of application. Unmelted powder results from the loss of silicon through oxidation.

Because high-surface-area brazing filler metal powders (-325 mesh) are more susceptible to oxidation, the majority of brazing operations utilize 140 F mesh powders. It should be noted, however, that if the brazing atmosphere is strictly controlled to maintain a low partial pressure of oxygen, -325 mesh powders that contain one or more of the elements having stable oxides can be used. For a lower quality atmosphere (higher partial pressure of oxygen), a coarser powder such as 140 C mesh is used.

As a result, brazing filler metal powder that is of a given mesh size and that contains one or more readily oxidizable elements is a good indicator of atmosphere quality. Every time the melting and flow characteristics of one of these filler metals is tested, the quality of the brazing atmosphere is being tested to an even greater extent. For this reason, extreme care must be exercised when interpreting the results of melting and flow tests. With proper control of the furnace brazing cycle (including atmosphere), each type of filler metal, regardless of its form (wire, sheet, or powder) will have the same mechanical properties in the joint.

Metal powder cutting is a technique that supplements an oxyfuel torch with a stream of iron or blended iron-aluminum powder to facilitate flame cutting of difficult-to-cut materials. The powdered material propagates and accelerates the oxidation reaction, as well as the melting and spalling action of the materials to be cut. Metal powder cutting was developed after World War II to provide an effective method of cutting stainless steels. These highly alloyed materials resist conventional oxyfuel cutting because a refractory oxide layer forms when stainless steel is heated in the presence of oxygen.

In all oxyfuel cutting processes, cutting is accomplished through a thermochemical reaction in which preheated metal is cut, or removed, by rapid oxidation in a stream of pure oxygen. During metal powder cutting, finely divided iron powder is carried by dry compressed air or nitrogen into the cutting oxygen stream along the line of the cut. Combustion of this powder increases the temperature of the heated zone; consequently, the refractory oxides are melted and fluxed by the action of the powder particles.

The extreme heat created by the burning of the powder enables cutting without preheating of the metal. As the cut progresses, the heat and fluxing action of the burning iron powder enable the cutting oxygen stream to oxidize the base metal continuously.

Metal and Alloy Powders for Welding, Hardfacing, Brazing, and Soldering

Revised by Deepak S. Madan, F. W. Winter Inc. & Co.

Powder Selection and Production

Many metallic and nonmetallic powders have been used for cutting operations. The ideal powdered solid fuel, whether metallic or nonmetallic:

- Exhibits nonhygroscopic action (does not readily absorb moisture)
- Liberates considerable heat during combustion
- Generates combustion products that flux refractory oxides
- Generates nonirritating and nontoxic combustion products
- Provides good process economy

Nonmetallic powders, such as sodium bicarbonate, remove refractory oxides by forming liquid slags that have a fluxing effect. Such powders, however, give off little or no heat. Consequently, cutting speeds are significantly slower than for metallic powders. The most suitable metallic powders for cutting applications are iron and iron-aluminum blends. For metal powder cutting of stainless steel, iron powder can be used. For cutting oxidation-resistant materials other than stainless steels, blends containing iron and atomized -100+325 mesh aluminum powder are preferable.

Iron powder used for metal cutting applications is produced by water atomization, or by a combination of granulation of molten iron by high-pressure water jets and chemical reduction. According to the Metal Powder Industries Federation, 2% of all iron powder produced in North America is used for cutting applications. Table 14 provides data on iron cutting powder produced by the Quebec Metal Powder (QMP) process. Cutting-grade iron powder of similar density and composition also is produced by the Domfer Process.

Table 14 Typical properties of iron powder used for metal powder cutting

Screen analysis

Silica acid insolubles	0.30 max
Physical properties	
Apparent density	2.9 g/cm ³
Flow rate	26 s/50 g

Aluminum powder is sometimes added to iron powder to form blends used for cutting and lancing concrete, firebrick, difficult-to-cut nonferrous metals, and refractory-laden scrap, such as slag deposits on ladle pouring spouts. Table 15 provides data on cutting-grade aluminum powders that are produced by air atomization of molten aluminum. Detailed information on the production and properties of atomized aluminum powder can be found in the article "Production of Aluminum and Aluminum Alloy Powder," in this Volume.

Powder blends consisting of iron and 10 to 40 wt% Al are used to cut a variety of materials. Although preblended compositions consisting of iron and 15 wt% Al are available, iron and aluminum powders can be custom blended for specific applications, as shown in Table 16.

Table 16 Iron-aluminum blends used for cutting and lancing difficult-to-cut materials

Nominal composition	Applications
Fe-10-15Al	Refractory scrap, thin nonferrous sections up to 25 mm (1 in.) thick
Fe-25Al	Aluminum, brass, bronze
Fe-30Al	Nickel, Monel, Inconel, Hastelloy, and concrete
Fe-40Al	Copper, brass, and bronze heavy sections 15 cm (6 in.) thick and up

To blend powders properly, components should be poured simultaneously into a dry, nitrogen-filled container and tumbled for about 5 min. Additional blending occurs as the iron-aluminum powder is screened in the powder dispenser. Slight nonuniformities in the mixture have little effect on cutting performance.

Equipment

Metal powder cutting processes require a means of introducing and burning powder in the cutting oxygen stream after the powder is conveyed to the cutting torch. To accomplish this, a typical powder cutting equipment setup includes the following components:

- Dispenser to supply powder during cutting
- Source of dry compressed air or nitrogen to convey powder from the dispenser to the cutting oxygen stream
- Powder nozzle or attachment to introduce the powder into the cutting oxygen stream
- Cutting torch (blowpipe) to control the gases required to burn the oxygen/powder mixture

Powder dispensers can be of two general types, pneumatic and vibratory. Generally, all dispensers consist of a compressed air/nitrogen filter and regulator, a powder hopper, and a means of expelling the powder from the dispenser. In a pneumatic dispenser, powder flow to the ejector unit is the result of gravitational force and pressure differential from compressed air (or nitrogen) passing through the ejector, which draws powder from the ejector baffle plate into the gas stream. Vibratory dispensers allow a quantity of powder to be dispensed from a hopper that is governed by a vibrator. Powder flow can be controlled by adjusting the amplitude of vibration. Vibratory dispensers are generally used where uniform and accurate powder flow is required. Typical applications include precision cutting of materials, such as stainless steel, as well as production of high-quality, sharp top edges on cuts in carbon steels.

Powder-Cutting Apparatus. Attachments for metal powder cutting are designed for use with conventional oxyfuel cutting torches. Attachments are available in three types: single-tube, multijet, and dual-tube. In addition to powder cutting attachments, specially designed powder cutting torches are available.

Applications

Metal powder cutting is frequently used in cutting, scarfing, and lancing of oxidation-resistant materials. This type of metal cutting was originally developed for cutting stainless steels. The alloying elements (chromium and nickel) that impart desirable properties to stainless steels have made these steels difficult to process by conventional oxyfuel cutting. Chromium is the most detrimental; when oxyfuel cutting is applied to stainless steels, chromium, which has a high affinity for oxygen at elevated temperatures, immediately forms the highly refractory chromium oxide on the faces of the kerf and prevents further oxidation. These refractory oxides are melted and fluxed by the combustion of the powder particles during metal powder cutting.

Nonferrous metals with the following thicknesses are suitable candidates for powder cutting:

Material	Thickness	
	cm	in.
Aluminum	25	10
Nickel	15	6
Brass and bronze	25	10
Copper	15	6
Hastelloy	16.5	6.5
Inconel and Monel	25	10

Powder Scarfing. In steel mills, powder metal cutting is used to scarf metals with alloy contents that are too high for oxyfuel scarfing. Typical applications include powder scarfing of large, bloomed ingots and small, unrolled ingots, slabs, and billets. Conditioning of these product forms by powder scarfing is less expensive and less time consuming than mechanical methods such as grinding.

Powder lancing is a piercing process in which the energy of the powder reaction is applied to oxygen lancing, permitting rapid, effective piercing of many materials that are difficult to pierce with a standard oxygen lance. These include iron and steel containing inclusions, reinforced concrete, firebrick, cinder block, aluminum billets, and sand and metal incrustation inside large castings.

Typical powder lancing applications include:

- Removal of blast furnace bosh plates
- Removal of large masses of iron (salamanders) that are deposited at the base of the blast furnace
- Cleaning of furnace lining
- Tapping furnace to remove slag
- Cleaning of soaking pits
- Removal of ladle skulls
- Piercing holes in reinforced concrete walls and floors

The efficiency of the powder lance in piercing reinforced concrete is preferred to the time-consuming, costly alternative of drilling with pneumatic tools.

Specialty Applications of Metal Powders

Introduction

METAL POWDERS are used in many diverse applications besides the traditional production of pressed and sintered parts. The primary market for metal powder is the production of powder metallurgy (P/M) parts, which are dominated primarily by iron and copper powders. Iron powders constitute the largest share, where over 80% of iron powders (on a tonnage basis) are used for P/M parts. Copper and copper-base powders follow iron in volume of powder used in P/M fabrication. Approximately 45% of all copper powder is used in the manufacture of self-lubricating bearings. It also is used as elemental additions in ferrous P/M parts. Another 40% is used for making P/M parts for builders' hardware, such as locksets, door latches, and other components that require a decorative finish as well as corrosion resistance.

Although iron and copper powders represent the largest share of P/M powder applications, they do not represent the entire range of P/M usage. Table 1 gives major applications of metal powders. This includes many nontraditional applications that do not involve parts production. For example, approximately 10% of iron powders (on a tonnage basis) are used for welding electrodes. Another 2% of the market is iron powders used for cutting, scarfing, and lancing operations (where

the iron powder is injected into oxyacetylene flames to raise the temperature of the cutting zone). The remainder (8%) is used in various applications, including pharmaceuticals, food enrichment, copier powders, and other miscellaneous applications.

Table 1 Major applications of metal powders

Application	Powder used
Abrasive finishing	
Shot cleaning	Iron, steel, stainless steel
Abrasive wheels	Iron, steel, copper, tin, nickel
Alloy production (steels, electrosag steel, free-machining steel, cast iron, ductile iron)	Nickel, lead, ferro-tungsten, ferro-silicon, ferro-molybdenum, ferro-manganese, iron, aluminum, tungsten, molybdenum, selenium, tellurium
Agriculture	
Animal feed	Iron
Animal medication	Cobalt
Chelate fertilizers	Iron
Farm machinery	Iron, steel, copper, bronze
Food enrichment	Iron, copper, manganese
Fungicides	Copper
Lawn and garden equipment	Iron, steel, iron alloy, copper, bronze
Seed cleaning	Iron
Seed coating	Aluminum
Soil conditioning	Iron, copper
Aerospace	
Brake linings	Copper, lead, tin, high-nickel alloys, graphite, iron
Cores (electronic components)	Iron, MolyPermalloy
Counterweights	Tungsten, copper, nickel, iron
Filters for fuel, hydraulic fluids, air	Bronze, stainless steel, nickel
Hardware	Aluminum, beryllium, titanium, iron
Heat shields	Beryllium, tungsten
Heat shield coating	Aluminum
Jet engine components	Superalloys
Magnetic shields	Aluminum, nickel, cobalt
Measuring aircraft drift	Aluminum
Rocket fuels	Aluminum
Repairing of components	Nickel chromium, nickel aluminum, stainless steel
Fretting/wear spraying	Molybdenum, copper nickel alloys, cobalt alloys, chrome carbide
Automotive^(a)	
Air conditioners	Iron, steel
Alternator regulator, contacts, pole pieces	Platinum alloy, iron
Body solder	Steel, aluminum, lead, lead alloys
Bushings, bearings	Copper, lead, tin, iron, aluminum, graphite, bronze
Contacts	Tungsten, silver
Filters	Stainless steel, bronze
Fuel pump parts	Iron, copper, tool steel
Polychrome body finishes	Aluminum
Shock absorbers	Iron, aluminum
Spark plug (body)	Iron
Spark plug (corrosion protection)	Zinc
Transmission parts	Iron, copper, steel
Truck signal flares	Aluminum
Brake bands, linings	Copper, iron, lead, tin, graphite, brass, zinc
Tire studs	Tungsten carbide
Valve inserts	Tool steels, stainless steel
Building and construction	
Aerated concrete	Aluminum, iron
Asphalt roof coating	Aluminum
Caulking compound	Aluminum
Conductive and non-spark flooring	Copper

Decorative plastics and linoleum for floors, walls, and counter tops	Iron, brass, copper, aluminum, stainless steel
Lancing	Iron, aluminum
Protective coatings for canvas awnings and decks	Aluminum, zinc
Pipe joint compounds	Zinc, lead, copper
Carbides	Tungsten, titanium, tantalum, niobium
Catalysts	
Gasoline synthesis	Platinum, nickel
Hydrogenation	Platinum, platinum alloys, tungsten, molybdenum, rhenium
Promote combustion in space heaters	Platinum
Alkyls	Aluminum
Purifying hydrogen	Ruthenium, palladium
Reacting hydrogen and oxygen	Palladium
Raney catalyst	Nickel, aluminum
Rocket fuels	Iron
General chemical catalysts	Iron, copper, copper oxides
Cemented carbides	Cobalt, molybdenum, titanium, tungsten, nickel, tantalum, niobium
Chemical	Aluminum, lead, tin, copper, iron, nickel, manganese
Coatings	
Anti-fouling paints	Copper, copper oxide
Conductive paints and plastics	Silver, copper, nickel
Corrosion-resisting paints	Stainless steel, aluminum, zinc, lead
Decorative paints	Aluminum, brass, bronze, zinc, stainless steel, lead, copper
Fabric coatings	Aluminum
Heat-reflecting paint	Aluminum
Hard facing	Cobalt alloys, nickel alloys, tungsten, molybdenum, stainless steel, tungsten carbide
Lacquers	Silver, brass, bronze, aluminum
Mechanical (peen) plating	Zinc, lead, tin, brass, copper, cadmium
Slurry coating	Nickel
Roof coatings	Aluminum
Spray coating	Iron, aluminum, zinc, tin, nickel alloys, copper, bronze, stainless steel, tungsten carbide, titanium carbide, silver, cadmium
Vacuum metallizing	Aluminum, copper, zinc
Coinage	Nickel, copper-nickel, titanium
Diffusion coating	Aluminum-titanium alloys, chromium, zinc, hafnium
Electrical and electronic	
Acoustical elements to improve microphone response	Stainless steel
Batteries	Nickel, zinc, silver, iron, lead, graphite
Breathers	Stainless steel
Brushes	Copper, silver, graphite
Cathode-ray tubes	Graphite, nickel
Contacts	Copper, silver, tungsten, molybdenum, iron, tin, platinum alloys, graphite, carbon
Crystal supports	Silver, copper, tungsten
Delay lines, computers	Iron, MolyPermalloy
Fuel cells	Nickel, zinc
Motor pole pieces	Iron, silicon-iron
Printed circuits	Copper, silver, palladium, gold, platinum
Relays	Iron, nickel, molybdenum
Semiconductors	Lead
Solenoids	Iron
Telephone components	Iron, brass, bronze, palladium, stainless steel
Terminals	Nickel
Thin-film resistors	Palladium, silver
Electrical discharge machining electrodes, preforms	Tungsten, copper, silver
Electrochemical machining electrodes	Copper, silver, tungsten
Hardware (lock components)	Brass, bronze, iron, stainless steel
Heat treatment	

Furnace heating elements	Platinum alloys, tungsten, molybdenum
Furnace shielding	Aluminum, tungsten
Infiltration	Copper, brass, silver, manganese
Protection tubes	Platinum alloys
Thermocouples	Platinum alloys, tungsten, molybdenum, rhenium
Industrial (general)	
Air tool exhaust muffler	Stainless steel, bronze
Bearings and bushings	Copper, tin, lead, bronze
Bonded asbestos brake linings	Zinc, graphite, brass
Cutting tools	Tungsten, cobalt
Filters (liquids, gases)	Bronze, nickel, stainless steel, superalloys, titanium
Flame cutting and scarfing	Iron, aluminum
Fluids for magnetic clutches	Stainless steel (magnetic)
Friction material	Copper, tin, zinc, iron, lead, graphite
Gas engine exhaust purification	Platinum
Grinding wheels	Brass, bronze
Sound deadening plastic	Lead, graphite
Industrial explosives for mining	Aluminum
Joining	
Brazing	Copper, nickel, silver, cobalt, brass, gold, aluminum, nickel-cobalt-iron-chromium alloy, nickel-silicon-boron alloys
Coated and tubular electrodes for arc welding	Iron, nickel, chromium
Resistance welding electrodes	Tungsten, copper, silver, molybdenum, manganese
Soldering	Lead, tin, solder alloys
Thermit welding	Aluminum
Lubricants	
Anti-galling pipe joint compound	Copper, lead, zinc, graphite
Copper lubricants	Copper
Greases	Lead, graphite
High-temperature lubricants	Aluminum, graphite
Plastic-filled metals	Iron, copper
Magnetic	
Clutches	Stainless steel (magnetic), iron
Inks for paper and tape	Iron
Permanent magnets	Iron, nickel, cobalt, aluminum, barium, ferrite, iron-aluminum alloys, molybdenum
Pole pieces, relay parts	Iron, iron-cobalt, silicon-iron
Soft magnetic parts	Iron, nickel-iron, silicon-iron
Traveling wave tube magnets	Platinum, cobalt
Medical and dental	
Dental amalgam	Silver, gold, alloys
Prosthetics	Superalloys
Insulin production	Zinc
Operating room air filters	Stainless steel, Monel, cobalt alloys
Pharmaceutical final filters	Stainless steel, Monel
Porcelain overlay dental restorations	Palladium
Prevention of infection of open wounds	Aluminum
Surgical gauzes and pins	Tantalum, zirconium
Surgical implants	Nickel and cobalt alloys
Orthopedic external fixation system	Titanium
Radiation shielding	Tungsten
Metal recovery	
Copper cementation	Iron
Gold cementation	Zinc
Metals from solution	Aluminum
Nondestructive testing	
Magnetic particle inspection	Iron
Nuclear engineering	
Control rods and reflectors	Zirconium, beryllium, hafnium, uranium
Filters for liquid sodium-potassium, gas, heavy water	Stainless steel, nickel alloys

Fuel elements	Iron, stainless steel
High-density concrete	Iron
High-density rubber	Lead, brass
Shielding	Aluminum
Shielding (gamma ray)	Tungsten, nickel, copper, lead
Shielding (neutron)	Boron, nickel, iron, lead
Computers	Iron
Office equipment	
Copying machine parts	Iron, stainless steel, bronze, aluminum
Facsimile equipment	Aluminum, steel, bronze, stainless steel
Recording tapes	Iron
Toner for electrostatic copying machine	Iron
Business machines	Steel, iron, stainless steel, brass, aluminum
Ordnance (military)	
Ammunition	Graphite
Armor-piercing cores	Tungsten, copper, nickel, cobalt
Anti-personnel bombs	Iron
First fire mixes and fuzes	Aluminum, graphite
Frangible bullets	Iron, lead
Fuze parts	Brass, stainless steel, iron, steel
Incendiary bombs, flares, tracers, torpedoes, etc.	Iron, aluminum, copper, cerium, magnesium, zinc, silicon
Missile filters	Nickel-base alloys
Projectile rotating bands	Copper, iron, brass
Proximity fuze cup	Nickel
Rocket launcher parts	Stainless steel, aluminum
Solid missile fuel	Aluminum, magnesium
Personal products	
Cigarette lighter flint	Cerium alloy
Cordless electric toothbrush and razor	Copper, nickel, brass, iron, bronze
Cosmetics	Zinc, aluminum
Enriched foodstuffs and cereals	Iron
Fingernail lacquer	Aluminum, copper
Floating soap	Aluminum
Mirror silvering	Iron
Pen points	Platinum, ruthenium, tungsten, stainless steel
Photography flash bulbs	Zirconium, cerium
Poker chips	Brass, bronze, copper-nickel
Vitamins	Iron
Petroleum and petrochemical	
Hydrocracking	Platinum alloys
Hydrogenation of olefines	Platinum
Petroleum fuels reforming	Platinum
Purifying hydrogen	Ruthenium
Oil drilling	Tungsten carbide, tungsten alloys
Plastic reinforcing	
Body solders	Steel, aluminum, lead
Cements for repairing castings and metal parts	Iron, stainless steel, aluminum, silver
Hull-smoothing cements	Iron, aluminum
Tools and dies	Iron, aluminum
Printing inks	
Metallic inks for offset, letterpress, rotogravure, etc.	Copper, brass, aluminum
Process industries	
Aluminum alkyls	Aluminum
Catalyst for promoting synthesis of water	Palladium
Coatings for papers	Aluminum, copper, tin
Control of beer fermentation	Stainless steel
Decolorizing alum solutions	Aluminum
Filters in chemical reactors	Stainless steel

Hydrogenation, etc.	Platinum metals, aluminum, nickel
Optical glass processing	Platinum alloy
Rayon production	Platinum alloy
Synthesis of caffeine	Iron
Synthesis of hydrocarbons	Iron
Pyrotechnics	Aluminum, graphite, iron, magnesium
Radio and television	
Cores	Iron, MolyPermalloy
Getters (TV tubes)	Barium, nickel
Permanent magnets	Iron, nickel, cobalt, aluminum, barium, ferrites, rare earths
Printed circuits	Copper, silver
Receiving tubes	Tungsten, molybdenum, nickel
Recreation	
Golf clubs	Tungsten, iron, brass
Sporting darts	Tungsten
Hunting knives	Brass, stainless steel, iron, nickel, silver
Shotguns	Iron, stainless steel
Fishing rod reels	Iron, brass, stainless steel
Outboard motors	Brass, steel
Sailboat hardware	Stainless steel, bronze
Self-lubricating parts	
Oil-filled	Copper, tin, lead, iron, aluminum, graphite, bronze
Plastic-filled	Iron, copper, silver
Sheet and strip	
Alloy	Cobalt, iron, nickel, aluminum, tungsten, molybdenum
Glass sealing	Iron, cobalt, nickel alloy
Nickel, cobalt	Nickel, cobalt
Steel	Iron
Ships	
Anti-fouling paints	Copper, copper oxide
Hull-smoothing cements	Iron
Ship-bottom paints	Aluminum, zinc
Soundproofing	
Acoustical plastics	Lead, graphite
Waterproofing	
Concrete	Iron, aluminum
Roof coatings	Iron, aluminum

(a) About 50% of all P/M parts are used in automobiles, many in engine and transmission applications.

Nonferrous powders are also used in diverse applications. For example, copper powders are used as pigments for marine paints and as additives for metallic flake paints. Aluminum powder is also used extensively for explosives and pyrotechnics. This article briefly reviews some of these diverse and emerging applications of ferrous and nonferrous powders.

Primary emphasis is on various chemical applications of metal powders. The extremely high surface area of powders in general, and sponge powders in particular, has made them very valuable for uses where the rate of a chemical reaction is important. Not only can reaction rates be maximized by the use of powders, but they can be tailored very precisely, by varying particle size, size distribution, and morphology. For instance, fine iron powder is used in many applications where other metal ions need to be removed from a solution, especially copper. Important characteristics here are the fineness of the iron powder (<325 mesh), high surface area (sponge powder), and low cost.

Mirror backings are another application area of iron powder. Mirror backings are produced by laying down a coating of silver nitrate solution on glass, followed by a reduction of the nitrate by a sugar containing solution. The very thin layer of silver that is deposited is then backed by copper precipitated out of a cospray of a copper sulfate solution and fine iron powder suspended in water. This process was developed over 100 years ago and is still used for producing virtually all mirrors.

Copper also is receiving increasing attention from an environmental standpoint due to its toxicity. It can be precipitated out of many chemical process effluent streams by the addition of fine iron powder. This not only protects the environment

but recovers a valuable resource. Conversely, the toxicity of copper can be put to good use. Copper is a potent biocide and is added to boat-bottom paints to prevent encrustation by various forms of marine life. Copper oxide has been used in the past, but is only suitable for epoxy-based, color-limited paints. Recent latex-based paints have been developed that use metallic copper and extend the color range available.

Specialty Applications of Metal Powders

Stephen Claeys, Pyron Corporation; Steven Lampman, ASM International

Copier Powders

Copier powders perform three essential functions in electrostatic image development: (a) they charge the finer toner particles to the proper level and appropriate polarity so that they can be attracted to the latent electrostatic image; (b) they physically transport toner from the developer reservoir, or sump, to the photoreceptor surface, where they are presented for development and, ultimately, are deposited in charged image areas; and (c) they act as a cleansing medium to remove toner particles that have been spuriously deposited in nonimage areas. In the cleansing function, copier powders also serve to scavenge background toner deposits, depending on machine design configuration. To accomplish these functions, electrostatic carrier powders must have the proper chemical, electrical, physical, and magnetic properties.

Core Powder

The majority of copier powders are coated with a thin resin to improve copy quality and life (see the section "Coatings and Surface Treatments"). The core powder is formed from sand, glass, iron, steel, nickel, aluminum, or ferrite materials. Ranging from approximately 40 to 600 μm in diameter, these granules can be irregular or spherical (often called "shot") in shape. These developer beads carry much smaller toner particles (from 5 to 30 μm in diameter) on their surfaces. They bring the toner powder close enough to the charged, latent image for development to occur. Electrostatic attraction causes the fine toner particles to be stripped from the carrier bead and to be deposited in image areas on the photoreceptor drum or copy sheet.

Iron and Steel. Irregularly shaped iron powders were first used in the early electrofax machines of the 1960s. These magnetic brush devices required a conductive, ferromagnetic granule to carry toner. Cascade developers that used spherical steel powders became prominent in the late 1960s. Magnetic brush devices use a variety of metal powder shapes, including sponge, fragment, and flake iron powders.

Ferrite. The introduction of spherical ferrite copier powders was a major advancement in the field of carrier bead technology. Spherical ferrites and spheroidized magnetite powders offer certain advantages over iron carrier core materials. Due to low remanence, these powders have improved flow properties, which enable rapid release from the magnetic brush roller when the field is relaxed. They are more resistant to changes in resistivity, even when uncoated, because the material is already in its fully oxidized state. An increase in resistivity causes a decrease in the solid fill. Furthermore, spherical ferrite copier powders are easier to reclaim from an exhausted developer mix, either by solvent washing or by high-temperature firing. As metal oxides, however, they have higher resistivities than metallic copier powders.

Sand. Uniformly graded sand was the first carrier core material used in office copiers based on cascade development. In these machines, the raw sand, or "flint shot," is coated with a dyed resin lacquer composition. In the United States, many of these older copiers and duplicators have been refitted with magnetic brush-type developer assemblies. Because the newer models use iron beads, the requirement for flint shot is relatively small. However, sand cascade machines are still in operation in many overseas markets.

Glass. Glass shot is a substitute for sand in cascade developer systems. This shot consists of extremely fine spherical beads. Although improved shape offers certain advantages in mixing and flow characteristics, higher cost has limited its use.

Aluminum. Another copier powder used in cascade development is aluminum shot. Initially, its low bulk density had strong appeal for equipment designers because it required minimal torque for mixing and blending. Also attractive were its low cost and conductive properties that yielded improved print quality over insulating-type cascade carrier core materials. Aluminum is not widely used as a core material, however, because it is nonmagnetic and has been superseded by the more advanced magnetic brush-type xerographic systems.

Nickel. Spherical or nodular-shaped nickel powder enjoys limited application as a carrier core material. Although relatively expensive, this material is not prone to oxidation and tends to maintain a uniform resistivity throughout the life of the developer mix.

Coatings and Surface Treatments

Carrier coatings serve as a release layer to prevent toner from impacting (filming) on the bead surface. Additionally, they provide a smooth, uniform carrier surface for toner attraction. Carrier coatings inhibit oxidation of steel powders and reduce the moisture sensitivity of the developer mix.

Carrier coatings prolong the life of the developer mix and protect the photoreceptor from abrasive carrier core materials. They control charge polarity through the use of certain dyes or other charge control agents that can be incorporated in the coating layer. Also, carrier coatings enhance the triboelectric effect.

Controlled electrical discharge is the basis of the xerographic process. Proper carrier coating is an effective way of exercising this control. Coatings vary from 0.2 to 4.0% of the core material weight, depending on the porosity of the carrier bead. The more porous carriers, such as reduced (sponge) iron, require a heavier coat weight.

The use of external additives that are dry blended with the developer mix is another method of controlling electrical discharge. These additives usually are incorporated in small amounts, from 0.25 to 2.0 wt%. They improve powder flow, modify triboelectric charge generation, increase carrier life, and improve photoreceptor performance. Furthermore, the proper additive can prevent toner accumulation on the carrier surface, the photoreceptor drum, or both. Amorphous silica is the most frequently used external additive because of its excellent performance as a promoter of powder flow or as a flow lubricant. Zinc stearate is used frequently in the toner industry as an anticaking and drum cleaning agent.

Carrier coatings and treatments include a broad variety of methods and materials, ranging from the use of raw or solvent-washed developer beads to the use of a controlled oxidation process to treat the surface of iron and steel powders. "Blued" iron and steel powder is frequently used as a carrier in the electrostatic copier industry.

Surface resistivity is lowest with uncoated or oxidized carriers. As the surface coating becomes thicker, the resistivity increases, thus making the particle less capable of effecting complete discharge of the developed image through the grounded magnetic brush. Lacquer-coated carriers provide the best compromise between print quality (low resistivity) and developer life (good release properties). A variety of polymeric materials have been used effectively for carrier core coatings. Styrene-acrylic copolymers, vinyl chloride-acetate copolymers, cellulose acetate butyrate, and nitrocellulose compositions are perhaps the most popular.

Powder Coating Processes. Four processes are used frequently for copier powder coating: surface oxidation, lacquer coating, fluorinated polymer coating, and powder coating. Of these, the first three currently are the most popular. Some original equipment manufacturers use a combination of oxidation and lacquer coating techniques.

Surface Oxidation. Iron and steel copier powders can be "blued" by a heat treatment to produce a surface layer of iron oxide. The process is carried out in an oven at approximately 285 to 290 °C (550 °F) for 15 to 20 min. Control of both air flow and moisture content is critical for ensuring color uniformity.

Equally important is powder circulation, which provides uniform exposure to the oxidizing environment for the entire surface of each bead. This can be accomplished by treating the metal powder in shallow, open trays with periodic agitation. Vibrating trays can be used to keep the steel powder in constant motion. Alternately, tube furnaces have been employed in which the carrier is contained inside a slowly rotating cylinder.

Lacquer Coating. Resin solutions, usually in the range of 10 to 20% solids, are applied to raw or oxidized carrier core materials in one of four equipment types: vibrating tub, cement mixer, vacuum tumble dryer, or fluidized bed coater. In each process, the lacquer is prepared separately by dissolving the appropriate resin, charge-orienting dyes, and other additives in a volatile solvent, typically toluene or methyl ethyl ketone, at elevated temperature.

The raw copier powder is heated separately to approximately 80 to 95 °C (175 to 200 °F) prior to introducing the hot lacquer solution. The lacquer is added rapidly to the agitated powder in a vibrating tub or cement mixer. Good ventilation is essential for safe operation. As the lacquer dries, the solid-liquid blending operation passes through a critical phase in which a tendency for agglomeration exists. The dry powder must be screened to remove doublet, triplet, and other multiparticle clumps.

Particle agglomeration can be controlled by using either a vacuum tumble dryer or a fluidized bed coater. Because they are closed systems, these devices afford a means for recovering the lacquer solvent. They are more economical to operate than either the vibrating tub or the cement mixer, both of which discharge to the atmosphere. The lacquer solution is normally injected slowly, and the highly agitated powder charge provides a better mechanism for separating individual granules during the coating and drying cycles.

Fluorinated Polymer Coating. The fluidized bed coater is used almost exclusively to apply polytetrafluoroethylene coatings to carrier core materials. Polytetrafluoroethylene resins require a high-temperature curing cycle, usually ranging from 285 to 345 °C (550 to 650 °F). These temperatures are beyond the capability of most tumble dryers.

Electrostatic powder coating is the same as the powder painting process used to coat appliances, lighting fixtures, and various metal parts. It is a solventless coating method in which the coating resin, in the form of a finely divided powder, is sprayed onto or blended with the agitated carrier beads at room temperature. An applied electrical field or triboelectric force causes the fine resin particles to cling to the surface of each bead. During subsequent heating, the resin particles melt and coalesce to produce a uniform coating.

Specialty Applications of Metal Powders

Flake Pigments

Metallic flake pigments are additives that are mixed directly into paints or other coating vehicles. Aluminum, copper, and gold bronze constitute the vast majority of metallic flake products sold in the United States. However, other metallic flake pigments are produced.

Stainless steel flake pigments have been available since the late 1940s. Originally, stainless steel flake was available in a variety of alloys, but currently only the 316L alloy is available. Stainless steel flake is used in high-durability coatings that are exposed to highly corrosive atmospheres. Weathering improves the appearance of stainless steel by actually polishing the coating, thus making it smoother and brighter.

Zinc flake has been used in corrosion-resistant paints because of the chemical properties of zinc; however, zinc dust is inexpensive and can perform the same function.

Nickel and silver are also available in flake form. Because of their superior conductivities, they are employed mainly in electrical applications.

Aluminum Flake Pigments. Aluminum pigments for coatings generally are classified into four types--leafing paste, leafing powder, nonleafing paste, and nonleafing powder. These types are further classified by fineness. The American Society for Testing and Materials (ASTM) has issued specifications for aluminum flake pigments (ASTM D 962, Part 28). Testing methods are described in ASTM D 480. Specifications are given for screen analysis of the coarse portion of the product, percentage of nonvolatiles, and leafing values, however, specific surface area of the flake and optical properties of each type are not covered. Aluminum flake powders used in noncoating applications, such as pyrotechnics and commercial explosives, also are not covered by these specifications.

Finely divided aluminum is extremely reactive with acids, bases, chlorinated solvents, and water. One of the by-products of the reaction is hydrogen gas, which can produce bulging and possible rupture of closed production containers. As an air-borne dust cloud, finely divided aluminum is potentially explosive. A dust cloud of aluminum powder will flash if an ignition source is present, and an explosion will occur if the concentration is within explosive limits.

Aluminum flake pigments should not be exposed to high-shear, high-speed agitation during mixing because this tears the delicate flakes, strips the protective lubricant coating from the particle surfaces, and creates reaction sites. This type of agitation reduces the amount of leafing and reduces the brilliance of the coating of leafing aluminum pigments. High temperatures during mixing affect the thin stearic acid layer on leafing pigments, resulting in loss of leafing properties and luster.

Leafing is the ability of the flake to rise to the surface of a coating and remain there in spite of a higher specific gravity than the coating vehicle. Flakes have a thin layer of a lubricant, such as stearic acid, and when they rise to the coating surface through currents caused by the evaporation of the solvent, they are held there by the surface tension of the vehicle. A minimum of 25 dynes/cm surface tension is required for successful leafing. Higher surface tension solvents such as high aromatic solvents are suitable for leafing.

Lead and zinc dryers deleaf the flakes and have been used to change leafing grades to nonleafing paste. Good leafing vehicles typically are simple compositions, such as a varnish. Nitrocellulose is complex and renders a leafing grade of aluminum nonleafing.

Roof coatings comprise the largest market for leafing aluminum paste. Aluminum roof coatings are either fibrated or nonfibrated asphalt. In nonfibrated systems, a coarse grade of aluminum paste (ASTM D 962 type 2 class C) is used. Coarse leafing grades have a rapid rate of leafing, resulting in a continuous metallic film on the surface of nonfibrated asphalt. The use of fine grades of flaked powder tends to produce a spotty appearance. Typical aluminum paste pigmentation quantities for nonfibrated asphalt are 240 to 360 g/L (2 to 3 lb/gal).

In fibrated systems that contain approximately 5% fiber, such as asbestos, a fine grade of aluminum paste is required for a bright metallic appearance. Fibrated coatings are applied in thick layers so that speed of leafing is not as important as the surface area of the pigment flakes. However, different asphaltic cutbacks can be used in roof coatings. In fibrated coatings, typical pigmentation amounts are in the range of 120 to 360 g/L (1 to 3 lb/gal), with the majority around 180 g/L (1.5 lb/gal).

Aluminum is well suited for roofing applications because it provides a moisture barrier and has high reflectivity. Black asphalt roof coatings absorb and transmit heat into the building, resulting in increased air conditioning costs in the summer. Aluminum reflects much of the heat, resulting in lower interior temperatures, as well as extending the life of the roof.

Aluminum paints exhibit special properties, such as moisture resistance, good durability, and high reflectivity, which account for their wide industrial usage. Moisture resistance enhances protection of structural steel, while high reflectivity increases the usefulness of aluminum paint coatings on highway bridges and guard rails. Usually, aluminum paint is used as a topcoat because it does not exhibit the corrosion resistance of pigments such as zinc dust.

However, urethane primers containing nonleafing aluminum are gaining acceptance. Urethane paints increase coating life and chemical resistance. Structural steel coatings usually contain a standard lining paste (ASTM D 962 type 2 class B). Aluminum pigmentation rates vary between 180 and 240 g/L (1.5 and 2.0 lb/gal).

Aluminum pastes are used in heat-resistant coatings on surfaces such as smoke stacks. The use of silicone resins has resulted in coatings with good durability at temperatures up to 400 °C (750 °F). Aluminum pastes should be a standard leafing lining paste (ASTM D 962 type 2 class B) or a fine lining paste (ASTM D 962 type 2 class A). For these paste coatings, aluminum pigmentation is typically between 120 and 180 g/L (1 and 1.5 lb/gal).

Water-dispersible aluminum flake pastes are available for use in water-reducible paints. Flake grades have added surfactants that allow the mineral spirits in the paste to mix with water.

Automotive coatings comprise the largest market for nonleafing pastes. Properties required for this application include acid stain resistance, sparkle, seeding, hiding power, and gloss. Standard grades of nonleafing aluminum are produced from commercially pure aluminum (a minimum of 99% Al). When aluminum particles in a coating are exposed

to the atmosphere, as in the one-coat finishes normally used in automotive coatings, they may react and stain the coating. High-purity aluminum (99.98% Al) is less reactive than commercially pure grades and offers some protection against staining. Grades of nonleafing aluminum pigment that use high-purity aluminum are referred to as "acid stain resistant."

When flake particles align parallel to the surface of the paint film, the appearance is typical of a standard leafing pigment. When the flake orients at various angles to the surface, light reflects in a scattering pattern, which is described as "sparkle." The sparkle effect causes extremely fine flakes to appear much larger, giving a more metallic appearance without seeding problems. Seeding problems occur when flakes project above the surface of the paint film.

High gloss in automotive coatings is achieved by using an aluminum flake pigment with a short flake diameter. To obtain the combination of a highly metallic appearance and high gloss, more than one aluminum pigment frequently must be used in a coating.

Printing inks use aluminum pigment to simulate the richness of silver at a much lower cost. Aluminum pigmented inks can be used in offset, letterpress, flexogravure, and rotogravure printing. Rotogravure inks pigmented with 10 to 20% Al are printed at extremely fast speeds and use fast-drying solvents. The brilliance of the aluminum depends on the size of the flake. The larger the flake size, the higher the brilliance of the coating. However, maximum usable flake dimensions depend on the depth and width of the etching on the printing cylinder surface.

Ink is picked up in the etching and transferred to the paper. Coarse particles overfill the etching and are removed by a doctor blade before reaching the paper. Leafing is not important in this application because the ink is applied and dried quickly. However, most tinted metallic inks used in rotogravure printing require leafing grades of aluminum flake powder.

Flexogravure inks are similar to those used in rotogravure. A standard lining grade is recommended. If maximum hiding effect is required, fine lining grades should be used.

Letterpress inks pigmented with 20 to 30% Al require a fine lining grade of leafing paste or flake. There is more transfer of the ink in this application, and optimum transfer properties are obtained with pigments that have short flake diameters. Letterpress inks dry more slowly than rotogravure and flexogravure inks, so leafing properties are important. All pastes contain mineral spirits or a combination of mineral spirits and a high aromatic solvent. Offset printing requires fine lining grades and is similar to letterpress in that a short flake diameter and high leafing are important.

Plastics. Aluminum is used in plastics to provide a silver color and opacity. Aluminum flake powders are normally blended to a paste consistency with a compatible plasticizer and sold to a compounder. This product is mixed with a plastic and extruded, usually in pellet form. The pelletized colorant is then mixed at low concentrations with a higher melting plastic, followed by heating and extruding into final form. The fineness of powder used depends on the effect desired; coarse grades provide high brilliance, and fine grades provide higher opacity at the sacrifice of higher brilliance.

Copper and Gold Bronze Pigments. Gold bronze pigments are brass alloy flake powders ranging in composition from 70Cu-30Zn to 90Cu-10Zn. Copper and gold bronze flake pigments are made by either stamping or dry ball milling. The recent trend has been toward ball milling.

The color shades of gold bronze are determined by the alloy composition used and by subsequent heat treating. Heating brass flakes results in partial oxidation of the flake surface, imparting a deepening of color. The higher the level of zinc, the greener the shade; the lower the zinc level, the redder the shade. The red shade is generally termed "pale gold," and the green shade is called "rich gold." Partially oxidized or heat treated powders are referred to as "deep golds" or "colored bronze."

Unlike aluminum, gold bronze powders are not color stable and may tarnish on exposure to the surrounding environment. Tarnish-resistant grades of gold bronze are produced, but heat treating usually results in lower brilliance and opacity.

Decorative Applications. Gold bronze is used primarily for decorative purposes, such as cigarette packages, cigar boxes, wrapping paper, greeting cards, and picture frames. Coarse grades (having up to 60% +325 mesh) are used in lithograph dusting, in which an adhesive is applied to the surface to be printed, and dry powder is dropped onto the wet adhesive. Excess powder is then lightly brushed off, and the powder is retained only where the adhesive was applied.

Paints. Ready mixed paints pigmented at approximately 360 g/L (3 lb/gal) use standard fineness pigments, which yield a smooth, brilliant surface. Leafing is required for this application, and the standard fineness grades (having 1 to 5% +325 mesh) exhibit good leafing properties. Aluminum ready mix paints require a nonreactive coating vehicle, such as varnish.

Aerosol-propelled paints demand a fine lining powder (having less than 0.1% +325 mesh) with good leafing properties. Coarser grades should be avoided because they contain large particles that would clog the spray nozzle. The sprayed paint film should have a continuous film of metal flake on its surface (leafing). Brilliance is determined by flake size, leafing value, and amount of polishing performed on the flake during manufacturing.

Gold bronze and copper powders react with vinyl resins, which causes gelling. Many types of stabilizers have been used, such as organotin, organozinc, barium, cadmium, and zinc complexes. A stabilizer should be chosen according to application.

Gold bronze and copper react with nitrocellulose lacquers, causing greening and gelling of the lacquer. Citric acid has been useful in improving stability, but must be evaluated for each application. Most gold bronze nitrocellulose lacquer mixes are used immediately after production because of inherent product stability problems.

Plastics utilize gold bronze and copper pigments for aesthetic reasons. Unlike aluminum, these pigments usually undergo one heating cycle. Gold bronze and copper powders do not pose the same explosion hazard as aluminum powders and can be mixed dry with the plastic, rather than molded into a pellet. Also, gold bronze oxidizes with heat, so heating must be kept to a minimum, or flake discoloration will occur. The fineness of the powder used depends on the desired effect. Coarse grades produce brilliance, and fine grades produce high opacity.

Printing ink pigmentation is similar to that of aluminum inks, but the pigmentation rate is much higher. Typical rotogravure and flexogravure inks contain between 30 and 40% gold bronze, due to the difference in density between brass and aluminum. Letterpress and offset ink pigmentation is approximately 50%. Almost all of the gold bronze powders used in printing inks are 99.9% -325 mesh.

One method of evaluating flake pigments is by a water coverage technique, in which the surface area of flake coatings is approximated. A fixed weight of flake is spread on water and mixed until the flake layer is approximately one flake thick. The area of the flake is then measured and calculated into square centimeters per gram. Powders can also be evaluated by measuring the particle size by optical or mechanical methods.

Both particle size and water coverage are important controlling factors. In rotogravure and flexogravure printing, a large size particle results in high brilliance, while a high water coverage powder results in high opacity. In letterpress and offset inks, small flakes have the best transfer properties, producing higher opacity and a more brilliant finish.

Specialty Applications of Metal Powders

Stephen Claeys, Pyron Corporation; Steven Lampman, ASM International

Fuels

Metal powders are used as fuels in solid propellants, pyrotechnic devices, explosives, and similar applications. These applications require properties of high density, high flame temperature, and high energy output per unit of expended fuel. The most widely used type of metal powder for propellants, pyrotechnics, and explosives is aluminum powder. Other metals used, particularly pyrotechnics, include magnesium, zirconium, titanium, tungsten, manganese, beryllium, and cerium. Table 2 lists properties of aluminum, magnesium, zirconium, and titanium.

Table 2 Properties of reactive materials

Material	Density, g/cm ³	Melting point (approximate)		Boiling point		Heat of fusion ^(a)		Heat capacity		Combustion temperature ^(b)	
		°C	°F	°C	°F	kJ/mol	cal/g mol	J/g · °C	cal/g · °C	°C	°F
Aluminum	2.70	660	1220	2467	4472	0.790	2550	0.90	0.215	3500	6300
Magnesium	1.74	649	1200	1090	1994	8.954	2160	1.02	0.244	3100	5600
Titanium	4.54	1660	3020	3287	5948	6.90	5000	0.27	0.064	3000	5400
Zirconium	6.51	1852	3365	4377	7910	15.450	5500	0.52	0.124	4500 ^(c)	8100 ^(c)

- (b) The adiabatic (no gain or loss of heat) combustion temperature in oxygen at 100 kPa (1 atm) pressure.
- (c) Metals such as zirconium produce temperatures that approach the maximum possible in a chemical reaction.

In fuel applications, the metals undergo highly exothermic (heat-producing) chemical reactions to yield stable oxides. Table 3 gives data for the heats of formation of some oxides. Comparison of the values for the metals given with those for carbon shows that all four produce more heat per unit than carbon. Carbon is the basis of many common fuels because it is easily ignited, safe, reasonably stable, abundant, inexpensive, and its products of combustion are gaseous.

Table 3 Heats of formation of inorganic oxides

Reaction	Heat of formation, $\Delta H_0^{(a)}$		
	g cal/mol	kJ/mol	g cal/g
2 Al(solid) + 3/2 O₂(gas) = Al₂O₃	-404,080	-1691.5	-3962
Mg(solid) + 1/2 O₂(gas) = MgO	-144,090	-603.2	-3602
Ti(Al) + O₂(gas) = TiO₂	-228,360	-955.9	-2858
Zr(Al) + O₂(gas) = ZrO₂	-262,980	-1100.8	-2134
C(graphite) + O₂ = CO₂	-93,690	-392.2	-2129

- (a) Negative values mean heat is given off.

For many metal-oxygen systems, the combustion temperature is limited to the boiling point of the oxide. Because aluminum and magnesium form oxides with high heats of formation and very low dissociation pressures, they are extremely stable. Dissociation pressure for a reaction such as:

is the partial pressure of oxygen in equilibrium with the metal and oxide phases at a given temperature. This equilibrium oxygen pressure is referred to as the dissociation pressure of the oxide and is an indication of its thermal stability.

Solid Propellants. To obtain higher energy in solid propellants, metal powders such as aluminum, boron, or beryllium may be added. Beryllium, however, is not currently used, because of toxicity problems. Solid propellants used in rocket propulsion systems are composite structures that consist of a solid oxidizer, solid fuel, and polymeric fuel binder, mixed and formed into a monolithic grain or unit. These grains, which range from several millimeters to several meters in length, are usually cylindrical in shape and have various configurations to facilitate the type and rate of burning desired. Recent advances include the development of hybrid fuel-oxidizer systems that spontaneously ignite in the presence of metal powders (Ref 2).

Ammonium perchlorate is the major oxidizer used in solid propellants, but ammonium nitrate also has limited special applications. Examples of binders are polyesters, polyethers, and polybutadienes terminated with chemically reactive groups such as carboxyl or hydroxyl. Two advantages of using aluminum as a fuel in solid propellants are its high combustion energy and its ability to reduce water and carbon dioxide to lower molecular weight (MW) gases during

burning. Low molecular weight gases are desirable because the energy output of a propellant is inversely proportional to the square root of the average molecular weight of product gases. Thus, a mixture of diatomic hydrogen (MW = 2), carbon monoxide (MW = 28), and diatomic nitrogen (MW = 28) is more energetic than a mixture of water (MW = 18), carbon dioxide (MW = 44), and diatomic nitrogen (MW = 28). The disadvantages are vaporization and ignition difficulties, slow burning rate, formation of reaction products of higher density than the metal, and, often, lower combustion efficiencies.

The fuel on the Space Shuttle solid rocket boosters is aluminum powder mixed with ammonium perchlorate in a rubber binder. Important characteristics here are the particle size and especially the distribution of the particles within the binder mix. Aluminum as a rocket fuel has a very high specific impulse, but suffers from some obvious disadvantages in a solid rocket application, not the least of which is the lack of controllability, or the ability to be throttled up or down. Engines have been proposed that use aluminum powder in a slurry, which when mixed with a suitable oxidizer, allows throttle control.

Iron powder has several novel applications as a fuel source. In a reversal of the process that uses hydrogen to reduce iron oxide to iron, iron powder itself has been proposed as a energy storage medium. The familiar reduction reaction, which produces water vapor, occurs readily at temperatures near 1000 °C. However, at temperatures near 300 °C, the reverse reaction is favored, where water vapor will oxidize iron, with the liberation of hydrogen. This concept is used in the steam treating (blackening) of P/M parts. It has been proposed that iron powder could be used to "fuel" vehicles by passing water vapor over a bed of heated powder and burning the hydrogen produced. The spent (oxidized) powder would be returned to a centralized facility for reduction.

Automobile air bag inflators use sodium azide and iron oxide powder as the propellant. It is important in this application that the gas produced be inert because it is exhausted into the interior of a vehicle during use. The reaction is:

Early inflators were either too explosive in their release of gas, or burned too slowly. By tailoring the particle size distribution of the ingredient powders, the burn rate has been controlled.

Hand warmers for use in cold weather use iron powder as fuel. Because iron oxidizes in a slow and controllable fashion, these devices can be manufactured quite easily and inexpensively with a guaranteed measure of safety. In an extension of this application, foods packaged in self-heating containers are now available. These were first developed for the military, but have found a wide demand in the consumer marketplace.

Specifications for Aluminum. Atomized aluminum is the most widely used metal powder in the propellant, explosive, pyrotechnic, and incendiary fields. The most important factors affecting properties of aluminum are method of manufacture, chemical purity or grade, particle size or class distribution, surface area, and apparent density. Both spheroidal and flake powders are used. Aluminum flake powders are produced by milling regular atomized powders under controlled conditions. Some flake powders are coated with stearic acid and show good stability against gassing in an aqueous environment.

Dedusted grades have been specially treated to reduce the dust hazards associated with flake powders. The treatment consists of adding a nominal 0.1% Teflon, which after processing, weakly binds the aluminum flake powder and prevents dust formation. Further processing in slurries breaks the Teflon bonds, restoring the powder to its effective state. This treatment does not disturb the integrity of the stearic acid coating on the flakes, and the powders maintain good sensitizing properties.

Magnesium powders gained importance during World War II, when large quantities were used for pyrotechnics and explosives. They currently are used to (a) manufacture Grignard reagents, which are organometallic halides such as ethyl magnesium chloride ($\text{C}_2\text{H}_5\text{MgCl}$) that are used in organic synthesis to produce pharmaceuticals, perfumes, and other fine chemicals; (b) effect chemical reductions, as in the manufacture of beryllium and uranium; (c) act as a light source in flares and photoflash bombs; (d) modify metallurgical properties of other metals, such as in the production of ductile iron and the removal of sulfur from hot iron products of blast furnaces; and (e) function as additives in electric welding electrode flux. At one time, magnesium powders were extruded into sections for structural applications. However, they are no longer used to produce such parts.

Almost all powder is produced from pure magnesium, although some magnesium-aluminum alloy powder containing up to 50% aluminum is used for photoflash bombs and for desulfurizing hot metal. Powder is produced by a variety of methods of comminution of solid or liquid metal.

Magnesium powders produced by chipping and milling are used for military flares, fireworks, and production of uranium. In addition, these powders are used in the chemical and pharmaceutical industries and in the iron- and steel-making industries, where they are used as desulfurizing agents and inoculants for the nodulation of gray iron. Another method produces powder of less than 325 mesh for flares by grinding.

Magnesium has been used to a small extent as a fuel in solid propellants. Compared with aluminum, it has a lower specific impulse, and there are hazards in handling the fine powder. Substitution of particles of a magnesium-aluminum blend reduce the tendency to agglomerate, but the specific impulse decreases with increasing magnesium content of the particles.

Important properties of magnesium powder include form, composition, granulation, and apparent density. Information on the forms and chemical requirements is given in Tables 4 and 5, respectively.

Table 4 Types and forms of magnesium powder

Type	Manganese ^(a) , %	Form
Type I, grade A	99.80 min	Shavings, turnings, flakes, or combinations of these
Type I, grade B	^(b)	Same as above
Type II	99.80 min	Oblong chip-like particles with rounded edges
Type III	99.80 min	Granular or spheroidal particles
Type IV	95.50 min	Shavings, turnings, flakes, or combinations of these

(a) Present in manufacturing stock.

(b) To meet specification

Table 5 Chemical requirements for magnesium powders

Chemical requirement	Composition, %

Manganese. Manganese powder is employed in delay cartridges (grade I) and pyrotechnic mixtures (grades II and III). Delay cartridges consist of a primer (an explosive charge that can be set off by percussion), an ignition charge (the delay column or delay train) that burns at a predetermined rate, a transfer charge that transfers the energy of the delay column to the main charge, and the main charge itself. Table 6 gives requirements of manganese powders.

Table 6 Requirements for manganese powder

Chemical or size requirement	Composition, min %		
	Grade I	Grade II	Grade III
Total manganese	99.5	98.0	95.0
Free metallic manganese	99.0

Zirconium. This powder is used in pyrotechnic and special ignition compositions. Its combustion behavior differs from that of aluminum in several respects. In the combustion of zirconium, the oxide--ZrO₂--a stable combustion product, dissolves in molten zirconium metal, which can react with nitrogen to form unstable intermediates. Zirconium is more easily ignited than aluminum, possibly because the oxide is a less protective coating than Al₂O₃. While aluminum melts before it ignites, zirconium particles ignite before they melt. Zirconium is highly reactive with a variety of oxidizing agents. For example, the reaction

is self-sustaining and exothermic and can be initiated at relatively low temperatures.

Table 8 gives the chemical requirements for zirconium. Particle size and particle size distribution for the two types, which are extremely important, are shown in Table 9. The average particle size requirements of type II powders are $2.5 \pm 1.0 \mu$ m for class 1, $2.0 \pm 0.3 \mu$ m for class 2, and $3.0 \pm 1.0 \mu$ m for class 3. The ignition gain percentage, which is the percent gain in weight when a sample of zirconium is ignited in a crucible over the full heat of a Meker burner for 15 min, is another critical parameter of zirconium powders. The ignition gain requirements for type II zirconium powders are 30.2 to 33.0% for classes 1, 2, and 3 and 30.0 to 33.0% for class 4.

Table 8 Chemical requirements for zirconium powder

Chemical requirement	Composition, %				
	Type I	Type II

Because of the safety problems encountered in storing and handling zirconium, special labeling and marking of containers are essential. These special labeling and marking requirements for zirconium are:

- Zirconium metal powder (minimum 25% water)
- Danger! Flammable solid. May explode if water content is 10% or below
- Keep wet in storage--dry powder may be ignited by friction, static electricity, or heat.
- Do not attempt to loosen or remove material from container with any tool.
- Keep away from heat, sparks, and open flame.
- Keep from freezing.
- In case of spillage, keep wet and remove carefully.
- In case of fire, smother with foam-type extinguisher or sand.
- Do not use carbon tetrachloride, carbon dioxide extinguishers, or water.
- Wear goggles or face shield and fire retardant clothing when handling.

Titanium. Thermal ignition of titanium-base pyrotechnics can be controlled by encapsulating the metal powders in titanium oxide. As the powder is heated, the oxide dissolves to form a reactive surface (Ref 3).

Specialty Applications of Metal Powders

Stephen Claeys, Pyron Corporation; Steven Lampman, ASM International

Fillers

Metal powders are used as fillers in various materials, such as polymers, epoxies, or other binder systems. Additives for polymers are common, but the use of iron powder in hydraulic cement dates to antiquity. It is still in use today to create hydraulic and waterproof cements, which expand on curing. An interesting extension of this application is the use of 70% iron powder mixed with 30% portland cement to create an amazingly strong filler putty. This inexpensive material can be used to repair machine bases, repair holes in concrete, and set posts and supports. The concrete used for some nuclear reactor containment vessels also has additions of iron powder to impart high density, high strength, and neutron absorbing capabilities.

Metal powders have numerous applications as fillers in polymers and adhesives. Prealloyed bronze powder is added to Teflon (i.e., DuPont de Nemours & Co., Inc., Wilmington, DE) and other plastics to provide strength and wear resistance. Many high-strength epoxy adhesives also contain fine metal particles. As with any particle strengthening system, these act to increase the crack path length and energy absorbed during crack propagation, but in addition, also improve high-temperature properties due to increased thermal conductivity and creep resistance. High-temperature silicone adhesives and sealants also contain copper powder or fibers for enhanced thermal conductivity. Silicones are also manufactured using copper powder as a catalyst.

Most inexpensive bronze "castings," especially for statues and figurines, are not cast from melted bronze, but are made in rubber molds filled with copper, bronze, or brass powders in a plastic binder.

Radar absorbing "stealth" coatings can be made with iron and other metal powder additives in a plastic binder. The radar waves become "trapped" and dissipated by repeated internal reflections and absorptions within the coating.

Metal Powder Fillers for Polymers. Metal powders are added to polymers primarily to change the appearance and/or the physical properties of the polymer. Increased demand in the automotive industry and related fields for high-performance parts that are lighter in weight than conventional metals has led to the use of polymer-based composites. A large number of these composites contain metal powders that match the metallic appearance of the components they replace.

In other applications where the physical properties of the polymers are modified for a specific end use, metal powders are used to change the insulative nature of the covalently bonded polymer or to increase electron density. Physical properties and functions that are affected in specialty polymers include:

- Electrical conductivity
- Thermal conductivity
- Electromagnetic shielding
- Anti-static surfaces

Powder metal-filled plastics are manufactured in various shapes and sizes, depending on end use. Sheet, films, rods, fibers, molded parts, and liquids are available. Metal forming operations such as compression molding, extrusion, injection molding, cold drawing, deep drawing, thermoforming, and stamping are used to produce polymers. Where a special network of metal powder is desired within the polymer, compression molding is preferred because it does not disturb the relative position of the particles. Typical polymers used in these composites include polyvinyl chloride, polymethyl methacrylate, polyethylene, polycarbonate, polyurethane, polyvinyl acetate, teflon, nylon, epoxy, and bakelite. Filler powder metal varies depending on the application, but may be made of pure metals such as copper, nickel, silver, aluminum, and iron, or alloys such as stainless steel.

Molded articles are usually made by mixing the metal and polymer powders thoroughly (in a V-mixer, for example) for sufficient time to allow the buildup of static charge on the surface of the polymer powder, which aids in attracting the smaller metal particles. To minimize shear, compression molding of the homogeneous mixture follows by applying sufficient heat and pressure to fuse the polymer particles together in the desired shape. The polymer temperature is controlled to be above the glass transition temperature, but not high enough above the melting point to cause degradation of the polymer. With ultrahigh molecular weight polyethylene (average molecular weight of 2 to 8 million), the molding temperature must be at least 50 to 70 °C (120 to 160 °F) above its melting point to guarantee maximum particle-particle fusion and minimum porosity. Generally, high molecular weights result in high polymer viscosities that require high molding temperatures. Typical molding conditions for polyvinyl chloride are 150 °C (300 °F) and 70 to 100 MPa (10 to 15 ksi). Control of pressure, temperature, and time is important to minimize porosity in the molded part. This process is particularly suited for molding thermoset polymers, such as bakelite, where the final curing occurs during the heating cycle.

Extrusion and injection molding of the metal and polymer mixture also are widely used because these processes provide continuous production and superior economics compared to compression molding. The polymer, however, experiences high shear rates in these processes, which cause metal particle segregation and orientation along the flow lines. Shear usually results in the appearance of crack-like flaw lines in the filled injection molded parts when two separate flow patterns of molten polymer merge. These flaw lines are areas with minimum density and are almost devoid of filler particles. In injection molded parts, a skin of unfilled polymer exists where the liquid polymer adheres to the cold mold surface during solidification. This surface layer may have to be removed if a conductive outer surface is desired.

Metal powders also can be dispersed in liquid polymers or solutions, such as in metallic paints containing aluminum flakes. Additionally, cast resins such as epoxy, polyesters, polyurethanes, and silicone rubber may contain metal particles in the liquid phase. Dispersion is accomplished by stirring before the viscous slurry is poured into the mold. Some segregation is expected, although viscosity of the resin can be adjusted to minimize segregation. The resin is then cured by the addition of a suitable catalyst at either ambient or elevated temperature. An added refinement of this technique calls for the orientation of nickel particles in the liquid phase by an external magnetic field, which has been reported to enhance the electrical conductivity of the composite.

Food Enrichment

Recently, the use of iron for food enrichment has been estimated at approximately 40% ferrous sulfate (dried), 50% elemental iron powder, and 10% other iron salts. Although water-soluble ferrous sulfate, which is abundant and inexpensive, may seem to be the favored iron source, ferrous sulfate and other salts are too reactive, leading to food enrichment problems such as off flavors, odors, color changes, and chemical change or reaction during the baking or cooking process. Some of these difficulties reportedly are overcome by encapsulation of the ferrous sulfate with food triglycerides, such as hydrogenated vegetable oils, but the practice is not widely used, possibly due to the added cost. Normally, the use of ferrous sulfate is limited to food products that have a short expected shelf life.

By contrast, elemental iron powder has enjoyed a 50% usage in food enrichment, mostly because of its stability in all food environments. By far, the greatest usage is in enriched flour and bread, in which the amount of iron added is approximately 37 and 29 mg/kg (17 and 13 mg/lb), respectively. Although the quantity seems small, these and other food product applications amount to a 910 metric tons/year (1000 tons/year) elemental iron powder requirement in the United

States alone. The total usage is increasing rapidly as overseas countries adopt U.S. standards. There's even a new application for enrichment of cattle feed that could be a larger market than human food enrichment.

Negative properties of elemental iron powder, although not considered serious, include its dark gray color, which has a slight graying effect on the color of flour and bread, and its higher density compared to the milled cereal grain, which may lead to segregation if incorporation is not performed carefully. Finally, the reported relative bioavailability (RBV) of the different forms of commercial elemental iron powder varies anywhere from 10 to 90% that of ferrous sulfate. The usefulness of an iron source to combat or prevent anemia is expressed in terms of RBV, in which the adsorption of the iron source is compared to that of ferrous sulfate, which has an RBV arbitrarily assigned at a value of 100. A higher RBV number indicates a better iron source. In general, higher surface area powders (i.e., sponge) have higher RBV's.

Environmental Remediation

Iron as a Supplement for Phytoplankton Growth. One of the most dramatic uses of iron powder relates to the problem of global warming (Ref 4). The crystal-clear water in much of the tropical oceans is a result of the fact that the water is poor in nutrients. In areas of the world that receive the most sunshine, phytoplankton growth is inhibited primarily by the lack of iron. This was clearly and dramatically demonstrated in a recent experiment where 500 kg of dissolved iron spread over 100 square km of Pacific ocean soaked up 350,000 kg of CO₂ by dramatically enhancing plankton growth (Ref 4). It is hoped that the effect on global CO₂ levels will be to lower them permanently by the burial on the ocean floor of the carbon containing skeletons of these plankton. Although dissolved iron was used in the experiment, iron powder has a role in the preparation of the solutions, and it has been proposed that iron powder could be employed directly if used in a low density form (i.e., sponge powder), perhaps with a biodegradable coating that would allow the particles to float near the surface of the ocean and dissolve slowly.

Toxin Removal. Hexavalent chromium, a very toxic form of the element, can be removed from soil by digging a deep trench and filling it with iron powder. The contaminated water can be pumped, or allowed to flow naturally, through this wall. Movement through the iron bed reacts the Cr(VI) to Cr(III)Fe(III) oxyhydroxide, which is more easily removed (Ref 5). Hydrocarbons in groundwater also can be effectively oxidized by the highly reactive oxygen atom catalytically liberated from hydrogen peroxide by iron powder (Ref 5).

Material Substitution

Brake Liners. When it was discovered that asbestos fibers can cause lung cancer, it became important to find a replacement material for friction applications, especially for auto brakes because of the enormous volume of use. The "metallic brakes" found on virtually all front wheel drive cars are now made with metal powders, primarily iron, but also copper. Sponge iron powders, especially hydrogen reduced, low-density versions, have been found to be not only adequate substitutes, but are far superior to asbestos in many respects. The excellent friction characteristics of sponge

powders derives from the many edges the particles present when cut in a cross section. The irregular sponge particles also have a very high green strength and lock into the binder system of the pad to a greater extent than spherical particles.

Even though the use of metals has allowed the elimination of asbestos in auto brakes, the use of copper in this application may have created its own problems. Copper levels in the San Francisco Bay have been rising in recent years, and the cause is thought to be the copper from auto brakes. As the brakes wear, the dust formed is washed into the bay by rainwater through storm drains. Copper is a potent biocide, but can be effectively removed by cementation with iron powder. There have been proposals to treat the runoff by this process.

Munitions. Concerns about lead contamination have come to the forefront lately, and this will probably become the next rallying point for environmentally driven materials substitution. Lead-containing munitions and bullets have several serious detrimental environmental aspects. Lead bullets have been banned at numerous indoor practice ranges because of lead fumes. As lead replacements, tungsten-copper and tungsten-iron composites are experiencing very rapid growth in the area of munitions, especially in the sport, hunting, and target practice sector. In sporting applications, tungsten composites can give the same performance and ballistic characteristics as lead, something the early steel replacement materials did not provide. In military applications, high tungsten composites can deliver much higher impact and penetration energies than other materials.

In target practice and training applications, powder composite bullets also can be made with various levels of frangibility in order to control the breakup of the bullet. Tungsten-copper and tungsten-iron composites have been designed to be environmentally friendly, while at the same time providing a measure of safety. The bullets are designed to have the ballistic characteristics of lead and break apart just behind the target on a backing plate, with the residue being recyclable. Some military training ammunition, used in higher volume than live ammunition, is made to break apart shortly after leaving the weapon. City police agencies also use frangible ammunition to avoid ricocheting bullets in crowded city environments.

Magnetic and Electrical Applications

Weed seeds can be separated from crop seed by dampening both with water and sprinkling with iron powder. The iron sticks to the weed seeds, which are characteristically more fibrous and wettable, followed by magnetic separation (Ref 6).

Fluid seals are created using iron powder suspended in oil, surrounded by magnetic fields that contain and control the slurry. These seals are gas tight and leak very little oil.

Magnetorheological fluids are made with suspensions of iron or ferritic stainless steel in oil. They are used in the construction of very precise and adjustable torque and braking units controlled by electromagnets.

Magnetorheological solids have been made from iron particles in an elastomeric polymer matrix. These solids change shape with the application of magnetic fields.

The National Aeronautics and Space Administration (NASA) has developed a pistonless compressor that moves fluids by the sequential magnetization of separated beds of ferritic stainless steel powder (Ref 7).

In another NASA invention, silver-filled epoxy can be used in several surge-arrestor applications. By varying the fill amount, such materials can be made to be insulators at low voltages, but switch to low resistance conductors at predetermined higher voltages, thus shunting to ground any unwanted voltage spikes (Ref 8).

- (a) Unnotched Charpy test.
- (b) Apparent hardness measures a combination of matrix hardness plus the effect of porosity. Where applicable, the matrix (converted) hardness is also given in parentheses.
- (c) Fatigue limit for 10^7 cycles from reverse-bending tests (R.R. Moore testing machines).
- (d) The suffix number represents the minimum yield strength (in ksi) for the material in the as-sintered condition.
- (e) The suffix number for the heat treated (HT) or sinter-hardened conditions represents the minimum yield strength (in ksi). Tempering temperature for most heat treated materials is 175 °C (350 °F); nickel steels are tempered at 260 °C (500 °F).
- (f) Yield strength and ultimate tensile strength are approximately the same for heat treated materials.

Appendix 2: Powder Metallurgy Standards

Table 1 Cross-index of powder metallurgy standards

Standard title	Designation ^(a)			
	ASTM	MPIF	ISO	Other
Metal powder specifications				
Aluminum Pigment, Powder and Paste, for Paint	D 962	TT-P-320B
Aluminum Powder, Flaked, Grained and Atomized	MIL-A-512A
Antimony, Powdered, Technical	MIL-A-10841B
Brass Powder (for sintering)	MIL-B-11552B
Bronze Powder, Gold	D 267	TT-P-340
Copper Powder (for use in ammunition)	JAN-C-768
Copper Powder for Use in Antifouling Paints	D 964
Iron Powder (for pyrotechnics)	MIL-I-12058A
Magnesium-Aluminum Alloy, Powdered	JAN-M-454
Magnesium Powder (for use in ammunition)	JAN-M-382A
Manganese, Powdered (for use in ammunition)	JAN-M-476A
Nickel Powder (for use in ammunition)	JAN-N-412A
Powders, Metal, Atomized (Aluminum, Magnesium, Magnesium-Aluminum)	MIL-P-14067B
Tin, Pulverized	JAN-T-458

Titanium, Powdered	MIL-T-13405
Tungsten, Powdered	MIL-T-13827
Zinc Dust (for use in pyrotechnics)	JAN-Z-365

Appendix 3: Examples of Powder Metallurgy Parts

Introduction

POWDER METALLURGY PARTS are used in a wide variety of applications for automobiles, machinery, appliances, aircraft, consumer items, electrical instruments, and other manufactured products. The parts produced by powder metallurgy (P/M) methods can also be unique and innovative. As a small sample of various applications, this appendix illustrates some typical examples of P/M parts and recent award winning parts from the annual parts competition series of the Metal Powder Industries Federation (MPIF).

Acknowledgement

The examples in this article were adapted from *Metals Handbook*, Vol 7, *Powder Metallurgy* and from *Advanced Materials & Processes* descriptions of the MPIF parts competition.

Appendix 3: Examples of Powder Metallurgy Parts

General Examples

Powder metallurgy parts are used for many types of common assembly items, such as bearings, gears, sprockets, cams, manifolds, bushings, and connector parts. Typical applications are illustrated in the following examples.

Example 1: Drive Gear for Mailhandling Machine.

A flat-belt drive gear weighing 490 g (17.3 oz), which is compacted to a density of 7.45 g/cm^3 , is shown in Fig. 1. This type of gear is used in high-speed mailhandling and inserting machines. This part, consisting of electrolytic iron preblended with 0.35% C, replaced a two-piece gear assembly made of American Iron and Steel Institute (AISI) 1030 steel, thus resulting in a total cost savings of 66%.

Fig. 1 Iron-carbon P/M drive gear. (a) Finished machined, hardened, ground part. The hub diameter is machined oversized (+0.254 mm, or +0.010 in.) to allow for final grinding. (b) P/M blank as-pressed

The powder was first compacted on a 5340 kN (600 ton) press to a density of 6.8 to 6.9 g/cm³ at a compaction pressure of 414 MPa (30 tsi). It was then presintered and repressed to a density of 7.45 g/cm³ at 965 MPa (70 tsi). After repressing, the part was sintered at 1120 °C (2050 °F) for 30 min.

As shown in Fig. 1, considerable machining (turning) of the hub was required to generate the final shape. In use, this gear rotates and a magnetic clutch rides on the machined hub. When the operator trips the cycle control on the machine, the clutch closes around the small hub diameter, and the load is transferred to the P/M gear. Pressing of a large hub ensures a uniform density in the cross-sectional area, but requires additional machining of the P/M blank.

After machining, the hub area is carbonitrided to a case depth of 0.127 mm (0.005 in.). Case hardness is 700 DPH (minimum), while core hardness is 550 DPH. To maintain a 0.025 mm (0.001 in.) diameter tolerance between the hub and the magnetic clutch, the hub diameter is ground to final dimensions. Typical properties for this P/M part are:

Tensile strength, MPa (ksi)	414-586 (60-85)
Yield strength, MPa (ksi)	365-414 (53-60)
Elongation, %	1-2
Transverse-rupture strength, MPa (ksi)	930 (135)

Example 2: Sprocket Assemblies on Agricultural Equipment.

The sprocket assemblies in Fig. 2 are parts in seed and herbicide metering equipment. The dual sprocket shown in Fig. 2(a) is made of two P/M sprockets that are staked together. This provides the flexibility to produce different gear ratios from pairs of single sprockets, rather than manufacturing a complete dual sprocket for each ratio required. The P/M staked assembly replaced a machined and welded one at a significant cost savings. The dual sprocket fits on a shaft that is fixed to the seed-metering device. A drive chain powers one of the dual sprockets to rotate the sprocket assembly and in turn drive the seed-metering device.

Fig. 2 Powder metallurgy sprocket assemblies in an agricultural planter. (a) Dual sprocket assembly. (b) Sprocket and retainer assembly

The other sprocket on the assembly drives a sprocket assembly on the herbicide/insecticide meter of the planter through use of an additional chain. This sprocket assembly (Fig. 2) is produced by compacting the P/M sprocket and then brazing the sheet metal retainer to it during sintering.

Example 3: Idler Arms.

Figure 3 illustrates a planter component that is made from two P/M parts assembled in the green state and sintered together into a single piece. This assembly is used to apply tension through a nylon roller to the chain that drives the dual sprocket assembly discussed in Example 2.

	Arm	Hub
MPIF material	F-0008-P	FC-0408-P
Carbon, %	0.61-1.00	0.60-1.00
Copper, %	...	2.00-6.00
Iron, %	97.00 min	91.00 min

Density, g/cm ³	6.1-6.5	6.1-6.4
Heat treatment	Steam blue after sintering	
Finished weight, kg (lb)	0.132 (0.30)	0.132 (0.30)

Fig. 3 Idler arm

Example 4: Eccentric Gear.

Figure 4 shows an eccentric gear for a washing machine that is made of a blend of 2% copper, 0.5% graphite, and the balance iron, which is compacted, sintered, sized, and machined. An intermediate level of graphite was chosen to produce an as-sintered part that could be sized readily to ensure an accurate gear tooth profile. Lower carbon content also improves machinability. Density of this part is 6.5 g/cm³.

Fig. 4 Eccentric gear for a washing machine made of iron alloy powder containing 2% copper and 0.5% graphite. Center hole inside diameter: approximately 19 mm (0.76 in.); eccentric outside diameter: approximately 57 mm (2.28 in.); total thickness: approximately 28.50 mm (1.14 in.); eccentric thickness: approximately 15.90 mm (0.63 in.); pitch diameter: approximately 115 mm (4.59 in.)

This gear is made from atomized powder to obtain optimum compressibility. Because this gear is a two-level part, green strength is critical to eliminate cracking at juncture. Press motion and tool design also are critical in preventing hub cracking.

Sintering is done in an endothermic atmosphere for 30 min at 1105 °C (2025 °F). Dew point is monitored to prevent carburization of the surface layers so as not to affect sizing or machining. After sintering, the part is deburred in a steel medium to facilitate sizing. Prior to sizing, the part is dipped in soluble sizing wax, which also acts as a long-term storage and rust protection medium.

Sizing enhances the tooth form and pitch diameter tolerances. After sizing, the center hole is bored for concentricity, and the outside of the hub is machined to correct any ovality. This part replaced a class 30 gray iron casting that was machined from a rough blank.

Example 5: Fourth Reduction Gears.

Lawn and garden tractors require gears that can withstand extremely high wear and heavy loading. For example, the fourth reduction gear shown in Fig. 5 is a drive gear in a six-speed transmission. A crush load of 4000 kg (8800 lb) per tooth is specified. High tooth density is required of the P/M part. To provide this feature, repressing the part to a density of 7.3 to 7.5 g/cm³ would seem to be the solution. However, the part is too large to be compacted on a 4.45 MN (500 ton)

press. To overcome this limitation, the part is compacted to three densities: 6.4 to 6.6 g/cm³ in the hub, 6.6 to 6.8 g/cm³ in the inner flange, and 6.9 to 7.0 g/cm³ in the tooth area.

MPIF material	FN-0205
Carbon, %	0.5
Nickel, %	2
Molybdenum, %	0.5
Density, g/cm³	
Tooth	7.3-7.5
Inner flange	6.6-6.8
Hub	6.4-6.6
Tooth apparent hardness, HRC	50-56
Tooth crush strength, kN (ton)	40 (4.5)
Finished weight, kg (lb)	1.042 (2.300)

Fig. 5 Fourth reduction gear

After presintering, the gear is repressed only in the tooth area to a density of 7.3 to 7.5 g/cm³. Carbon content is kept low to improve compressibility during repressing, after which the teeth are carburized.

Example 6: Bronze Clutch Lever Bearing.

A relatively large number of nonferrous P/M parts are used in automobiles, but they represent nominal weight and generally are similar to parts used in nonautomotive applications. These include bushings for radio controls, windshield

wiper motor bushings and gears, distributor bushings, and other annular parts that are similar to bushings in other applications. Figure 6 is a copper alloy P/M clutch lever bearing, which is considered a large P/M part. A considerable volume of copper metal powder has been used in the past as a journal bearing matrix material.

Fig. 6 Clutch lever bearing. Composed of 90Cu-10Sn bronze. Weight: 20 g (0.05 lb). Secondary operation: oil impregnation

Example 7: Hollow Titanium Bolts.

Figure 7 shows hollow titanium bolts produced by P/M methods. Originally, this bolt was to be manufactured from a high-strength plastic for an aerospace application. The high-temperature environment, however, made use of plastic bolt materials impractical. Because design weight was based on use of plastic, the replacement material had to maintain the light weight, with no sacrifice of strength at elevated temperatures. These requirements were met by designing and fabricating a hollow bolt with a hex shape in the head and a round bore through the remainder of the bolt. This part was made by cold isostatic pressing and sintering. Finishing included a finish cut on the outer diameter and the addition of threads.

Fig. 7 Hollow bolts. Courtesy of Imperial Clevite Technology Center

Example 8: Manifolds for Hydraulic Cam Lobe Motors.

Four-wheel drive agricultural combines have hydraulic motors on two wheels. Centrally located within the motor is a large P/M part that acts as a manifold (Fig. 8). This manifold weighs approximately 15 kg (32 lbs) and features 30 close-tolerance radial oil passages.

MPIF material	FX-2008-T
Carbon, %	0.61-1.00
Copper, %	15.00-25.00
Iron, %	69.00-84.39
Density, g/cm³	7.1-7.6
Copper infiltrate	2.7 kg (6.0 lb) wafer
Finished weight, kg (lb)	12.973 (28.60)
Leak testing	Pressurize-alternate ports with 415 kPa (60 psi) nitrogen, leakage must not exceed 75 L/min (19.8 gal/min)

Fig. 8 Hydraulic wheel motor manifold

The manifold was designed for P/M processing because the machining required with other processes would be cost prohibitive. Using P/M technology, this is not an easy part to manufacture. The tooling is complex and features a dual upper punch motion, which forms the 30 radial oil passages. Two lower punches and a stepped core rod impart a taper to the manifold.

The manifold is compacted on a 8.9 MN (1000 ton) press and is copper infiltrated during sintering to provide a final density of 7.1 to 7.6 g/cm³. Copper infiltration ensures pressure tightness and adds lubricity in operation.

Some machining is required before the manifold can be used. However, this is limited to turning the inside and outside diameters and drilling several holes. Because of the complexity of this part, cost savings are high, even at low volumes (5000 to 10,000 units).

Example 9: Power Steering Metering Pumps.

In fully hydraulic power steering, there is no mechanical connection between the steering wheel and the front wheels. The operator steers by controlling a pressurized column of oil with a power steering metering pump. This pump activates the steering valve, which in turn directs the steering motor.

The power steering metering pump in Fig. 9 consists of a cover, base, body, and two gears, all of which are made by P/M processes. Gray cast iron was considered for these parts, but it was rejected because of the capital investment required for equipment to do additional machining. Minimal machining of the P/M parts is required and is limited to lapping and machining of a cross hole. The cover, base, and body must be leakproof to perform in this pressurized hydraulic environment. This is achieved through epoxy impregnation of these parts. Pressurized nitrogen leak testing is specified for the cover, base, and body. Crush testing is specified for the gears.

	Cover	Base	Body	Gear	Gear
MPIF material	FC-0408-P	FC-0408-P	...	FC-0408-P	FC-0408-P
Carbon, %	0.60-1.00	0.60-1.00	0.8	0.60-1.00	0.60-1.00
Copper, %	2.00-6.00	2.00-6.00	2.0	2.00-6.00	2.00-6.00
Nickel, %	0.40-0.50
Manganese, %	0.25-0.35
Molybdenum, %	0.55-0.65
Iron, %	91.00 ^(a)	91.00 ^(a)	...	91.00 ^(a)	91.00 ^(a)
Density^(a), g/cm³	6.4	6.4	6.4	6.4	6.4
Apparent hardness^(a)	55 HRB	55 HRB	...	25 HRC	25 HRC
Particle hardness^(a), HRC	55	55	55
Compressive strength, MPa (ksi)	515 (75)	515 (75)	515 (75)

Crush strength, kN (ton)	26.7 (3.0)	26.7 (3.0)
Impregnation	Epoxy	Epoxy	Epoxy
Finished weight, kg (lb)	1.400 (3.10)	1.460 (3.20)	0.460 (1.00)	0.125 (0.28)	0.159 (0.35)
Leak testing	Must withstand 690 kPa (100 psi) nitrogen for 5 min without leaking				

(a) Minimum

Fig. 9 P/M parts for power steering metering pump

Appendix 3: Examples of Powder Metallurgy Parts

MPIF Parts Recognition

The Metal Powder Industries Federation holds an annual P/M Part-of-the-Year Design Competition to select outstanding powder metallurgy products in five categories: ferrous, nonferrous, stainless steel, injection molding, and overseas. The following sections briefly describe parts from recent competitions.

1995 Parts Competition

Steel differential case in Fig. 10 is a complex, five-level nickel-steel part that serves as two halves of an inter-axle differential case used in a heavy-duty tandem axle assembly on class 8 trucks. The part has a Rockwell B hardness of 85, minimum yield strength of 410 MPa (60 ksi), ultimate tensile strength of 710 MPa (100 ksi), and a fatigue limit of 270 MPa (40 ksi). The P/M case replaces a casting that required extensive machining.

Fig. 10 1995 P/M Part-of-the-Year Design Competition winners. Background: Ferrous inter-axle differential case. Foreground: Left, aluminum capstan. Center, stainless steel spacer and guide assembly; injection molded hair clipper blade. Right, rotatory compressor frame. Courtesy, MPIF

The 900 g (2 lb) halves are arc welded together to form the case, which distributes input power between the front and rear axles in the tandem. Designed to reduce both the cost and size of the assembly, the smaller case results in lower trailer bed height and increased cargo capacity. It is considered a critical application because the case must withstand rotary and thrust forces. The part was designed and fabricated by Eaton Corp. Truck Components of North America and Metal Powder Components Inc.

A multilevel aluminum capstan (Fig. 10) is part of an automatic ticket stamping machine at bus stations and subways. Use of P/M technology saved 70% compared with the cost of a machined part. Critical tolerances include concentricity and the D-shaped internal diameter. Tensile strength is 235 MPa (34 ksi), and yield strength is 230 MPa (33 ksi). Secondary operations include machining, drilling, tapping, and hard-coat anodizing. The part was made by Pennsylvania Pressed Metals Inc.

A two-piece spacer and guide assembly (Fig. 10) made of stainless steel alloy 410L is used in an automobile fuel injection system. The P/M spacer reduces cost by 25% compared with the original machined-and-welded design.

The part has a Rockwell B hardness of 43, elongation of 10%, ultimate tensile strength of 325 MPa (50 ksi), and yield strength of 200 MPa (30 ksi). During molding, a stainless steel alloy 302 guide ring is introduced into the molding tool and compacted into the part. Secondary operations include coining the fuel holes and tumbling. The spacer was made by Windfall Products Inc.

Injection-Molded Fixed Blade. A complex high-speed steel fixed blade (Fig. 10) used in a hair clipper was produced by injection molding. The fixed blade operates next to a movable blade that is made by ceramic injection molding. The P/M blade was formerly stamped out of steel, but metal injection molding reduced production time and resulted in a blade with 70 HRC hardness and improved wear resistance. The blade was made by Hitachi Metal AFT Ltd.

A copper-steel rotatory compressor frame (Fig. 10) is used in a room air conditioner. The complex part has a surface hardness of 75 HRB, a tensile strength of 300 MPa (45 ksi) and a yield strength of 160 MPa (25 ksi). The P/M

frame offers a 25% cost savings compared with other manufacturing methods. The part is made by Hitachi Powdered Metals Co. Ltd.

Power ratchet parts (Fig. 11) are made of infiltrated steel, nickel steel, and iron. Able to withstand up to 120 J (90 ft · lb) of torque, the ratchet contains eight powder-metal parts. The P/M components also provide the wear characteristics required for high-speed use over long periods of time.

Fig. 11 1995 Awards of Distinction and Award of Achievement winners. Background, left to right: eight power ratchet steel parts and integral rotor. Nonferrous timing gear and scraper. Center, Injection molded trigger guard and latching post. Center right, Stainless steel stator & rotor, and valve handle assembly. Left foreground, aluminum-beryllium heat exchanger. Center foreground, four nickel-steel disk drive parts. Courtesy, MPIF

Other fabrication methods were considered, including investment casting, stamping, forging, and machining. However, they would have cost more and were incapable of providing sufficient flatness, consistent dimensional control, fine detail in the product logo, and a quality finish. The part was made by Asco Sintering Co.

A phosphorus magnetic iron integral rotor (Fig. 11) is used in a high-speed mechanical printer and offers a 90% cost saving compared with investment casting and machining. The material has minimum yield strength of 210 MPa (30 ksi) and a Rockwell B hardness of 68. Secondary operations include drilling and tapping the side hole, coining, resin impregnation, and a dri-lube coating. The 59-tooth form is accurate to within half a degree. The part was made by Ceromet Inc.

Copper Strip. Parts are stamped from full-density spinodal copper-nickel-tin strip that replaced a beryllium-copper alloy. The strip is stamped into nonsparking, nonmagnetic, corrosion-resistant safety tools, such as knives, scrapers (Fig. 11), and spatulas. The tools are used in potentially hazardous situations where the nonsparking characteristic is vital, such as petroleum, natural gas, and chemical process industries. The P/M stamping replaced a cast and rolled alloy. The material has ultimate strength of 1035 MPa (150 ksi), yield strength of 965 MPa (140 ksi), and Rockwell C hardness of 30. The copper-nickel-tin strip is made by Ametek Inc.

An aluminum-alloy timing gear (Fig. 11) is used in an outboard motor. This marks the first time that an aluminum P/M alloy has been used in a marine timing gear application. The gear has a 5% elongation, ultimate tensile strength of 140 MPa (20 ksi), yield strength of 90 MPa (15 ksi), and a Rockwell H hardness range of 60 to 65. Secondary operations include sizing and anodizing. The part was made by Webster-Hoff Corporation.

A stainless steel rotor and stator for a pepper mill (Fig. 11) requires close inside and outside diameter tolerances. The helical design is another key dimensional feature. Combining coarse and fine cutting teeth, which have a Rockwell C hardness of 30, is also critical to the product's function. Originally designed for powder metallurgy, the parts offer significant cost savings over machining. The parts were made by Pacific Sintered Metals Co.

316 stainless steel valve handle assembly (Fig. 11) is made for a chemical process application. The powder metal assembly replaced a handle formed by plastic injection molding.

The parts must pass a 5000 h salt water test and meet a critical wall thickness specification. The P/M components have an average ultimate tensile strength of 260 MPa (40 ksi) and a yield strength of 190 MPa (30 ksi). Powder metallurgy offered more than 50% cost savings over other manufacturing techniques. The assembly was manufactured by Intech Metals Inc.

A trigger guard (Fig. 11) made from an AISI 4650 low alloy steel for a sporting rifle is a metal injection molded part. The net-shape part has ultimate tensile strength of 1650 MPa (240 ksi) and yield strength of 1480 MPa (215 ksi), and it saves more than 50% over the cost of conventional machining. The component is especially critical in terms of the multiaccess holes, logo, and self-supported arch. The trigger guard was made by Advanced Forming Technology.

A magnetic latching post (Fig. 11) is made from a 17-4 PH stainless steel for a high-density disk memory storage system. Special features of this injection molded part include a complex shape with variation in the cross-sectional area, a tapered hole that mates into a straight hole, and an unsupported bridge area with a thin slot. The part requires only a light coining operation on the unsupported area to provide the air gap that establishes the magnetic field for the latching mechanism. It has a typical Rockwell C hardness of 27, yield strength of 660 MPa (100 ksi), and ultimate tensile strength of 875 MPa (130 ksi). The part was made by Parmatech Corp.

Miniature parts (Fig. 11) used in a 1.8 in. hard disk drive are injection molded. They are complex blocks that perform multiple magnetic functions. The 1.47 g block is made of a nickel-steel alloy and is plated with nickel when used with other blocks. The parts were made by Advanced Materials Technology Pte. Ltd., Singapore.

An aluminum-beryllium substrate (Fig. 11) is used as a heat exchanger in the radar system of the U.S. Air Force F-22 twin-engine jet fighter. The part is a vacuum-brazed liquid flow-through assembly made of gas-atomized powders that are cold isostatically pressed into a billet, which is extruded into a slab and rolled into sheet. The material offers dimensional stability, low coefficient of thermal expansion, high strength and modulus, and low density. Its low coefficient of thermal expansion reduces the fatigue load on the solder joints, which increases the life of the entire avionics assembly. The part was made by Brush Wellman Inc.

1996 Parts Competition

Magnetic pole piece (Fig. 12) is a bimetallic duplex component that is an essential part of a magnetic steering assist unit for cars. The complex part is formed via a very innovative simultaneous multipowder compaction process. The inner and outer poles are made from iron-phosphorus powder, and the bridge is made of stainless steel (MPIF SS-304NI-30). A specially designed multiactuated feeder system fills the dies with the two different powders.

Fig. 12 1996 Powder Metallurgy Part-of-the-Year Competition winners: Left to right, front row: Vending machine parts and guidance system support base. Second row: sprinkler upper trip and bimetallic magnetic pole piece. Back: Planetary carrier. Courtesy, MPIF

The part must withstand a test load of 6.4 kN (1440 lb), which is applied to the hub section while supporting the stainless steel rim. More than 400,000 of these parts are produced annually. The part is made by Zenith Sintered Products Inc.

An unleaded brass upper trip (Fig. 12) is used in an agricultural sprinkler system. The complex, six-level net-shape part replaced a die casting and functions along with a P/M lower trip. Use of powder metallurgy provides a 60% cost savings and an ultimate tensile strength of 190 MPa (30 ksi), a yield strength of 110 MPa (16 ksi), a transverse rupture strength of 39 MPa (60 ksi), and an elongation of 14%. The part is made by Ceromet Inc.

A support base assembly (Fig. 12) is used for a missile guidance system. The complex SS-316L-15 three-level part provided substantial cost savings over a machined part with very tight tolerances for weight and flatness. The flatness and profile of the six support pads are held within 0.0075 mm (0.0003 in.).

The part is used in conjunction with a P/M magnetic iron pole and armature. Assembly requires extremely tight tolerances, and the thin sections demand close density control and very fragile tooling. Secondary operations include CNC milling, lapping, tapping, and plastic impregnating. The part is made by Capstan Pacific.

Vending machine parts (Fig. 12) are injection molded and are used in an electric switchbox and vending machine coin lock. The intricate stainless steel components, which have many slits and holes, replaced zinc die castings because of superior corrosion resistance and strength. The parts have a tensile strength of 520 MPa (75 ksi), a yield strength of 220 MPa (32 ksi), and a 50% elongation. The parts were made by Hitachi Metals AFT Ltd.

Brazed Planetary Carrier. A three-piece planetary carrier (Fig. 12) is used in a four-wheel drive transfer unit. The complex P/M carrier weighs 2.4 kg (5.4 lb), and it is brazed during sintering using a nickel-copper-manganese brazing alloy. The carrier has a tensile strength of 390 MPa (57 ksi), a brazed joint strength range of 390 to 490 MPa (57 to 72 ksi), and a hardness of 60 HRB. Only minor machining is required. Compared with machined cast iron, the P/M carrier offers a cost and weight savings of approximately 20%. The internal gear of this carrier works as a synchronizer with the driveshaft gear in the engine. The part is made by Sumitomo Electric Industries Inc.

Transmission Sprockets. High performance auto transmission sprockets (Fig. 13) are selectively densified ferrous parts. After compacting and sintering, the teeth and journal are selectively densified by a proprietary cold working process, and then vacuum carburized. Eight parts are used in the transmission.

Fig. 13 1996 Awards of Distinction winners. Left to right, front row: palate expander assembly, polarizing keys, hole punch. Second row, flange pulley and filter. Third row: transmission sprockets. Back: camshaft sprocket. Courtesy of MPIF

Vacuum carburizing produces a precisely controlled case on the critical journal tooth flank surfaces with minimum distortion. This provides high strength and exceptional durability for the bearing and tooth surfaces.

The parts have an ultimate tensile strength of 860 MPa (125 ksi), a yield strength of 825 MPa (120 ksi), and a tooth and journal surface hardness of more than 60 HRC. The endurance of the powder metallurgy sprockets exceeds that of induction-hardened malleable iron. The part is made by Stackpole Limited Automotive Gear Division.

A camshaft sprocket assembly (Fig. 13) made by ICM/Krebsoge, consists of a P/M steel sprocket and a timing sensor ring made from low-carbon A620 steel, which is attached to the P/M sprocket by "rollerizing" the P/M hub over the stamping flange. Inside diameter tolerances are held to 2.025 mm (0.080 in.). The sensor ring provides the magnetic pickup to tell the on-board computer the position of the camshaft in relation to the position of the crankshaft. The nickel-steel P/M sprocket has a tensile strength of 380 MPa (55 ksi), a minimum yield strength of 240 MPa (35 ksi), and a hardness range of 60 to 75 HRB.

Nickel-silver polarizing keys (Fig. 13) used in electrical rack and panel connectors on aircraft flight data recorders are thin-walled fragile parts with an ultimate tensile strength of 230 MPa (35 ksi), a yield strength of 140 MPa, (20 ksi), and a hardness of 85 HRH, and a 14% elongation.

The parts withstand a 500 connect/disconnect cycle test without measurable wear, and are also tested for electrical conductivity. The net-shape part requires no secondary operations and demonstrates a high degree of reliability. The keys can be found in almost every flight data recorder in commercial and military aircraft produced in the United States. The parts are made by Asco Sintering Corp.

Stainless steel palate expander (Fig. 13) is a complex stainless steel (MPIF SS-316NI) part for a device that expands the palates of young children with small mouths. The assembly consists of four P/M parts. Left and right P/M housings are spot welded together. Two guide pins are press-fitted and staked into left and right P/M plates along with the assembly of the adjusting screws. The orthodontic appliance may be expanded with the twist of an Allen wrench inserted into the front, a much safer procedure than that used with previous designs.

The parts have an ultimate tensile strength of 350 MPa (50 ksi) and give an estimated cost savings of 80% over other forming methods, such as machining. Secondary operations are limited to tapping and burnishing. The part is made by Precision Powdered Metal.

A foldable paper-hole punch (Fig. 13) is made by metal injection molding (MIM) of 17-4PH stainless steel. The assembly consists of two complex shapes, which have a tensile strength in the range 1100 to 1195 MPa (160 to 175 ksi), a yield strength in the range 980 to 1100 MPa (140 to 160 ksi), and hardness of 38 HRC.

The MIM powder metallurgy parts replaced machined and stamped components that required welding. MIM provided a cost savings of approximately 50%. Secondary operations are limited to reaming, grinding, and tumbling. The part is made by Metalor 2000, Israel.

A copper-steel flange pulley (Fig. 13) made by Hitachi Powdered Metals Co. is a multifunctional pulley with a sensor cam/flange that was designed especially for P/M. It has a minimum tensile strength of 390 MPa (55 ksi), a minimum yield strength of 270 MPa (40 ksi), and hardness of 55 HRB.

A metal-fiber filter (Fig. 13) is used in automotive airbag inflators. The metal-fiber filter diffuses and cools the gas that inflates the airbag. The filters take the brunt of the explosive force of the pyrotechnic fuel, which creates enough volume of extremely hot gas ($>800^{\circ}\text{C}$, or 1470°F) to fill the airbag. Besides cooling and diffusing the gas flow, the filter prevents hot particles as small as $1\text{ }\mu\text{m}$ (0.00004 in.) in diameter, and other undesirable respirables, from entering the airbag.

The sintered media can be sheared, rolled, pleated, and/or welded without cracking, splitting, or destroying its porous properties. Extremely fine metallic fibers fabricated through a bundle drawing process provide an integral, controlled-porosity medium.

The stainless steel fibers have diameters as fine as $4\text{ }\mu\text{m}$ (0.00016 in.) in a sintered web matrix combined with a stainless wire mesh. The sintered media strips are provided in a preformed, crimped condition. This facilitates handling by the customer, who flanges and roll-forms the strips to various diameters, and then welds the overlap seam. The part is made by Memtec America Corp.

1997 Parts Competition

Warm-Compacted Turbine Hub. The first automotive powertrain application fabricated through warm compaction technology is a steel torque converter turbine hub (Fig. 14). The hub is formed by means of the EI-Temp warm compaction system from powder in an 825 ton (7.3 MN) compacting press.

Fig. 14 1997 P/M Part-of-the-Year Competition winners. Left to right, foreground: Latchbolt and seven gun parts. Left to right, background: Exhaust manifold flanges, turbine hub, and a powder tool ratchet wheel set, which includes the wheel, flange, and thrust ring

The part has a minimum density of 7.2 g/cm^3 (0.26 lb/in.^3), a tensile strength of 807 MPa (117 ksi), a yield strength of 428 MPa (62 ksi), a fatigue limit of 242 MPa (35 ksi), and a 17 HRC apparent hardness.

Subjected to severe durability testing, it must withstand an internal spline torque of 1210 N · m (890 ft · lb) for one million cycles. Powder metallurgy replaced a machined and heat-treated forged part. It provided a cost savings of more than 30% and an assembly savings of more than 50%. The part is made by Chicago Powdered Metal Products.

Brass latchbolt (Fig. 14) is made to a density of 7.9 g/cm³ (0.28 lb/in.³) and has an ultimate tensile strength of 210 MPa (30 ksi). Its yield strength is 110 MPa (16 ksi), elongation is 15%, and hardness is 84 HRH.

The latchbolt is assembled with mating parts by crimping the tail section, requiring strength and ductility in the thin-walled areas. Secondary operations are limited to drilling a 2.4 mm (0.094 in.) hole, tumbling, and resin impregnation. A contour tolerance of 0.15 mm (0.006 in.) must be held. The part must pass a stringent pendulum ram test where ram blows are applied to the lock. The part is made by ASCO Sintering Company.

Automotive exhaust manifold flanges (Fig. 14) are made of stainless steel alloy 434. The manifold flange connects the manifold to the exhaust pipe that leads to the catalytic converter. The exhaust converter outlet flange connects the exhaust pipe leading from the catalytic converter to a flange welded to the manifold. The three-level manifold flange (6.9 g/cm³, or 0.24 lb/in.³) required special tooling to form the "tulip" shape.

Powder metallurgy replaced a two-piece stamped and welded assembly, which leaked exhaust fumes. The P/M part dramatically reduces exhaust leakage at the manifold/exhaust system junction. Alloy 434 P/M stainless steel has tensile properties superior to wrought 409 stainless steel at elevated temperatures, as well as improved corrosion and oxidation properties. Formed to a minimum density of 7.0 g/cm³ (0.25 lb/in.³), the exhaust converter outlet flange is supplied with two cold-headed wrought bolts, which are press-fitted into it and shipped as an assembly. Deburring is the only secondary operation performed on both parts. The components are made by SSI Technologies Inc.

Complex MIM gun parts (Fig. 14) are used for seven parts that go into .22 and .38 caliber revolvers. The frame, weighing 240 g (8.46 oz), is made from nickel-steel and has a minimum hardness of 25 to 30 HRC. The other parts are made from 4140 steel. All parts have a density of 7.6 g/cm³ (0.27 lb/in.³). The barrel must withstand heavy shock and wear. Metal injection molding technology replaced investment casting and forging to achieve better finishes and closer tolerances at more than 40% cost savings. Secondary operations include heat treating and tapping, threading and rifling the barrel, and applying a black oxide or chrome finish. Testing of the parts includes firing 1000 overload rounds. The parts are made by Taurus International Manufacturing Inc.

Warm compacted ratchet-wheel set for a new angle grinder (Fig. 14) is made to a density of more than 7.0 g/cm³ (0.25 lb/in.³), has an ultimate tensile strength of 760 MPa (110 ksi), impact strength of 22 J (16 ft · lb) and a fatigue strength of 300 MPa (40 ksi). The warm compacted thrust ring and flange are formed to a density exceeding 7.2 g/cm³ (0.26 lb/in.³) and have an ultimate tensile strength of 1100 MPa (160 ksi), an impact strength of 24 J (18 ft · lb), and a fatigue strength of 414 MPa (60 ksi). Powder metallurgy provided almost 50% cost savings and very high precision. Secondary operations include heat treating and minor machining on the wheel; the thrust ring is machined, and the flange is heat treated. The part is made by Porite Taiwan Co. Ltd.

Clutch Plates. P/M steel notch plate and pocket plate (Fig. 15) is for a new one-way clutch that revolutionizes powertrain/drivetrain designs. The P/M plates offer significant cost savings over alternative manufacturing processes. The new clutch is more economical than conventional "sprag and roller ramp" designs, and is less sensitive to vibration, unbalanced loading, and centrifugal force.

Fig. 15 1997 Award of distinction winners. Left to right, foreground: Five stainless steel mortise lock parts; three opto holders; and metal injection molded latch door, gear, and racks. Center: Metal injection molded link, receiver, and clevis; and padlock body. Background: Notch plate and pocket plate

The two-level notch plate has a minimum density of 7.0 g/cm^3 (0.25 lb/in.^3), a minimum ultimate tensile strength of 720 MPa (105 ksi), and a minimum apparent hardness in the range 20 to 25 HRC. The three-level pocket plate has a minimum density of 6.9 g/cm^3 (0.24 lb/in.^3) and a minimum ultimate tensile strength of 900 MPa (130 ksi). Both parts are heat treated, machined, and tumbled.

A Stroker load cycle and overrun test are performed on the assembly. The impact load specification is 20 cycles at 1580 J (1200 ft · lb), and the Stroker requirement is 200,000 cycles at 790 J (600 ft · lb) and 14,000 cycles at 1580 J (1200 ft · lb). The P/M clutch also withstood a maximum ultimate torque of 3950 J (3000 ft · lb), more than six times the torque that the more conventional roller ramp clutch could withstand. The P/M notch and pocket plates are assembled with four struts, four springs, and a threaded weir to form the one-way clutch. The design is patented by Epilogics Inc., and the part is made by Metal Powder Components.

Brass optical sensing part (Fig. 15) made by FMS Corp. holds a photoelectric emitter and receiver in place. The part has thin walls and four pyramid-shaped "locking ribs" located on the center bridge sections. These protrusions allow the part to be staked into a plastic molded frame.

The part is repressed and sized after sintering, then resin-impregnated, deburred, and tin plated. It has a minimum yield strength of 80 MPa (12 ksi) and a density of 8.0 g/cm^3 (0.30 lb/in.^3). The 0.635 mm (0.025 in.) wall thickness required high-precision tooling for compacting and sizing. A process capability index, C_{pk} , of 1.33 is required on critical dimensions, which include $1.3 \text{ mm} \pm 0.13 \text{ mm}$ ($0.050 \pm 0.005 \text{ in.}$) on bridge thickness and $2 \text{ mm} +0.10 \text{ mm}/-0.05 \text{ mm}$ ($0.080 + 0.004/-0.002 \text{ in.}$) on the distance from peak-to-peak on the gripping ribs.

Mortise lock parts (Fig. 15) are 304 stainless steel with a minimum density of 6.4 g/cm^3 (0.23 lb/in.^3). The stainless steel parts have a 61 HRB hardness, a yield strength of 207 MPa (30 ksi), and an ultimate tensile strength of 296 MPa (43 ksi). Brass forging, stainless casting, and zinc die casting were also considered, but could not approach the economies of powder metallurgy. The part also provides high hardness, wear resistance, and net shape. The new mortise lock design can change function and handling in the field without disassembly and extra parts, which means the lock can be installed on a door regardless of the way it is swung. The lock also contains five copper-infiltrated P/M steel parts. The parts are made by Ceromet.

Three intricate 17-4PH stainless steel parts (Fig. 15) are metal injection molded parts for a new endoscopic surgical stapler. The thin-walled parts are produced very close to their final shape.

The heat-treated parts have an ultimate tensile strength of 1180 MPa (170 ksi), a yield strength of 1100 MPa (160 ksi), a 36 HRC hardness, a 3% elongation, and a 7.5 g/cm^3 (0.26 lb/in.^3) density. The receiver has a 0.7 mm (0.028 in.) wall section, which forms a slot held to between 8.8 and 8.9 mm (0.34 to 0.35 in.) over the entire length. The clevis holds a roundness of $11.7 \text{ mm} \pm 0.05 \text{ mm}$ ($0.460 \text{ in.} \pm 0.002 \text{ in.}$) on a 0.864 mm (0.034 in.) wall section. The link holes are held to $1.19 \text{ mm} \pm 0.019 \text{ mm}$ ($0.047 \pm 0.00075 \text{ in.}$). The endoscopic linear cutter combines a 45° bilateral articulation with a 360°

rotation, providing excellent maneuverability and tissue access for endoscopic procedures, such as appendectomies and lung resections. The parts are made by PC Advanced Forming Technology.

MIM Parts for Locking Mechanism. A gear, rack, and latch door (Fig. 15) are used as a locking door unit gear mechanism for closing small battery doors in a portable terminal. The gear and latch door are made from a P/M nickel steel to a density of 7.75 g/cm^3 (0.27 lb/in.^3). They have a tensile strength range of 414 to 448 MPa (60 to 65 ksi), a yield strength of 276 to 310 MPa (40 to 45 ksi), and a 65 to 75 HRB hardness range.

The rack is made from 316L stainless steel to a density of 7.70 g/cm^3 (0.27 lb/in.^3) and has a tensile strength range of 470 to 515 MPa (68 to 75 ksi), a yield strength range of 150 to 172 MPa (22 to 25 ksi), and a 65 HRB hardness. Originally, the parts were produced from plastic and aluminum, but they failed. Metal injection molding provided a more reliable design and a cost savings of up to 50% compared to machining. The parts are made by Metalor 2000.

A net-shape steel padlock body (Fig. 15) is used in a gear-shift lever locking mechanism. Produced by Gino Olivares s.r.l., Gessate-Milan, Italy, to a density range of 6.4 to 6.6 g/cm^3 (0.23 to 0.24 lb/in.^3), the part required complex tooling. It has a 65 HRB hardness along with good ductility. Close tolerances are required in the hole and height of the part. The padlock body is

- ***P***
 - applied load; power; pressure
- **Pa**
 - pascal
- **PCE**
 - pyrometric cone equivalent
- **PDS**
 - product design specification
- **PDT**
 - product design team
- **P/F**
 - powder forging
- **pH**
 - negative logarithm of hydrogen-ion activity
- **P/M**
 - powder metallurgy
- **ppb**
 - parts per billion
- **ppba**
 - parts per billion atomic
- **ppm**

- parts per million
- **ppt**
 - parts per trillion
- **psi**
 - pounds per square inch
- **psia**
 - pounds per square inch absolute
- **psid**
 - pounds per square inch differential
- **psig**
 - pounds per square inch gage
- **PTC**
 - positive temperature coefficient
- **PVD**
 - physical vapor deposition
- **QC**
 - quality control
- **QFD**
 - quality function deployment
- **QLF**
 - quality loss function
- **r**
 - radius vector in a plane normal to the axis
- **r**
 - particle radius; radius of curvature; rate of reaction; reflectivity; spherical particle radius
- **R**
 - roentgen
- **R**
 - average particle radius; gas constant; radius; ratio of the minimum stress to the maximum stress; resistance; reliability
- **R_a**
 - surface roughness in terms of arithmetic average
- **RA**
 - reduction of area
- **rad**
 - absorbed radiation dose; radian
- **RCF**
 - rolling contact fatigue
- **RE**
 - rare earth
- **Ref**
 - reference
- **rem**
 - remainder
- **rf, RF**
 - radio frequency
- **RH**
 - relative humidity
- **rms, RMS**
 - root mean square
- **ROM**
 - rough order of magnitude; rule of mixtures
- **rpm**
 - revolutions per minute
- **RT**
 - room temperature
- **RTI**

- relative thermal index
- **s**
 - second
- **S**
 - siemens
- **S**
 - distance traveled
- **SAE**
 - Society of Automotive Engineers
- **scfm**
 - standard cubic foot per minute
- **SEM**
 - scanning electron microscopy
- **sfm**
 - surface feet per minute
- **SG**
 - standard grade
- **SI**
 - Système International d'Unités
- **sineh**
 - sine hyperbolic
- **S/N**
 - signal-to-noise (ratio)
- **S-N**
 - stress-number of cycles
- **SPC**
 - statistical process control
- **SPF**
 - superplastic forming
- **sp gr**
 - specific gravity
- **SRIM**
 - structural reaction injection molding
- **std**
 - standard
- **STEM**
 - scanning transmission electron microscopy
- **STM**
 - scanning tunneling microscopy
- **Sv**
 - sievert
- **t**
 - thickness; time
- **T**
 - Tesla; transverse direction
- **T**
 - absolute temperature; temperature; tenacity; total dispersion; transmittance
- **T_g**
 - glass transition temperature
- **T_m**
 - melt temperature
- **tan**
 - equal to ratio of the loss modulus to the storage modulus
- **TBC**
 - thermal barrier coating
- **TEM**
 - transmission electron microscopy

- **TGA**
 - thermogravimetric analysis
- **TMA**
 - thermomechanical analysis
- **TP**
 - thermoplastic
- **TQM**
 - total quality management
- **TS**
 - thermoset
- **tsi**
 - tons per square inch
- **TTT**
 - time-temperature-transformation
- **UL**
 - Underwriters' Laboratories
- **UNS**
 - Unified Numbering System
- **UTS**
 - ultimate tensile strength
- **UV**
 - ultraviolet
- **v**
 - workpiece velocity
- **V**
 - volt
- **V_f**
 - volume fraction of fiber
- **V_m**
 - volume fraction of matrix
- **V_v**
 - volume fraction of void content
- **VI**
 - viscosity index
- **vol**
 - volume
- **vol%**
 - volume percent
- **w**
 - whisker
- **W**
 - watt
- **W**
 - total radiation; width
- **wt%**
 - weight percent
- **x**
 - axial distance
- **X**
 - neck diameter
- **Y**
 - scale of microstructural segregation
- **YAG**
 - yttrium aluminum garnet
- **yr**
 - year
- **z**

- Z
 - ion charge
- \circ
 - atomic number; impedance
- $^\circ\text{C}$
 - angular measure; degree
- $^\circ\text{F}$
 - degree Celsius (centigrade)
- $^\circ$
 - degree Fahrenheit
- 0°
 - fiber direction
- 90°
 - perpendicular to fiber direction
- α
 - coefficient of thermal expansion
- γ
 - shear strain; surface energy; surface tension
- γ_b
 - interfacial energy
- γ_s
 - surface energy
- δ
 - an increment; a range; change in quantity; grain boundary width; thickness of liquid boundary
- Δ
 - an increment; a range; change in quantity
- ΔT
 - temperature difference or change
- ε
 - strain
- $\dot{\varepsilon}$
 - strain rate
- η
 - loss coefficient; viscosity
- θ
 - angle; geometrical constant
- θ_i
 - angle of incidence
- θ_r
 - angle of refraction
- κ
 - dielectric constant
- λ
 - thermal conductivity
- μ
 - friction coefficient; linear attenuation coefficient; magnetic permeability; the mean (or average) of a distribution
- $\mu\text{in.}$
 - microinch
- μm
 - micrometer (micron)
- μs
 - microsecond
- ν
 - Poisson's ratio; velocity
- π
 - pi (3.141592)
- ρ
 - density; resistivity
- σ

- Stefan-Boltzmann constant; strength; stress; tensile stress; tensile strength
- σ_a
 - applied stress
- σ_f
 - applied axial load
- Σ
 - summation of
- τ
 - shear stress
- ϕ
 - angle of internal friction; dihedral angle; porosity; power
- Φ
 - reaction rate (kinetic function); volume concentration of impurity ions
- ψ
 - damping; geometrical constant
- ω
 - frequency
- Ω
 - atomic volume; electrical conductivity; molecular volume of solute; ohm
- ∂
 - partial derivative
- $\partial\eta/\partial t$
 - kinetic function
- \rightleftharpoons
 - direction of reaction
- \div
 - divided by
- $=$
 - equals
- \approx
 - approximately equals
- \neq
 - not equal to
- \equiv
 - identical with
- $>$
 - greater than
- \gg
 - much greater than
- \geq
 - greater than or equal to
- ∞
 - infinity
- \propto
 - is proportional to; varies as
- \int
 - integral of
- $<$
 - less than
- \ll
 - much less than
- \leq
 - less than or equal to
- \pm
 - maximum deviation
- $-$
 - minus; negative ion charge
- \times
 - diameters (magnification); multiplied by

- \cdot
 - multiplied by
- $/$
 - per
- $\%$
 - percent
- $+$
 - plus; positive ion charge
- $\sqrt{\quad}$
 - square root of
- \sim
 - approximately; similar to
