Cold Isostatic Pressing. CIP uses a flexible membrane to isolate the powder from a liquid medium that is pressurized to cause densification of the powder. Typical mold materials are latex, neoprene, urethane, polyvinyl chloride, and other elastomeric compounds. Because the mold moves with the powder as it densifies, friction effects are minimized. Also, because the pressure is applied uniformly around the mold, there is no theoretical size limit. Height-to-diameter and overall size are limited by the pressure vessel size. Often a rigid mandrel is part of the tooling; and, because powder must slide along this mandrel, it is coated with a friction reducing material.

In comparison to die pressing, cold isostatic pressing can achieve more uniform densities due to minimized friction effects. Pressure vessels are typically limited to pressures of 415 MPa (60 ksi) although units with twice this capacity have been produced. Isostatic pressing equipment can be automated (i.e., dry bag CIP units), but the production rates are lower than those of die pressing. Dimensional control is generally not as tight as with die pressing due to flexible tooling. As stated, however, rigid members can be incorporated into the flexible mold assembly to produce accurate surfaces where desired.

Hot isostatic pressing (HIP) is a versatile near-net shape process that has found niches in the production of aerospace structure and engine markets, high alloy and tool steel mill shapes and individual components, titanium hardware, and monolithic and composite alloy components for the energy industry. The process fundamentals and manufacturing steps are covered in detail in the article "Hot Isostatic Pressing of Metal Powders" in this Volume.

The aim of hot isostatic pressing is a near-net shape and full density. Powder is hermetically sealed in a container that is flexible at elevated temperatures; the "canned" powder is heated within a pressurized vessel and held for a specified time. Commercially used containers include low carbon steel sheet formed into a container, stainless steel sheet, and even glass. The pressurized medium is usually an inert gas such as argon, and pressures range between 100 and 300 MPa (15 and 45 ksi). The temperature for HIP is material dependent, of course, but typical production equipment can heat parts ~1000 to 1200 °C (2000 to 2200 °F). HIP units for ceramics and carbon-base materials may heat up to 1500 °C (2700 °F). Densification mechanisms active during HIP include bulk deformation (limited amount), sintering, and creep, with the latter accounting for a significant portion of densification. Densities >98% of full density are typical, and full density is routinely achievable with care during powder sealing and strict control of time, pressure, and temperature.

The powders used in hot isostatic pressing are usually spherical in shape and very clean. The particle surfaces are free of contaminants, such as oxide films. The sphericity facilitates can loading and handling, and the particle surface cleanliness facilitates particle bonding. Powder handling and avoidance of contamination is critical to the success of the process, and considerable investment in facilities and equipment, followed up by attention to operating procedures and "good housekeeping," is required.

In comparison to hot pressing where only billet shapes are produced, hot isostatic pressing is capable of producing complex shapes. As in cold isostatic pressing, the achievable dimensional tolerances are at best near-net due to the flexible mold. Some net surfaces may be achieved if rigid members are incorporated into the mold. Figure 6 compares HIP capabilities with other compaction methods.

Fig. 6 Application areas of HIP based on part size, complexity, and level of densification three variables that dictate the P/M approach are size, density, and performance (as a percentage of wrought). This behavior corresponds to ferrous-base P/M systems, but is representative of many P/M materials. P/S, press and sinter; reP, press, sinter and repress; P/S + F, press and sinter and forge; CIP + S, cold isostatically press and sinter; HIP, hot isostatic press; HIP + F, hot isostatic press plus forge.

Powder Shaping and Consolidation Technologies

Bulk Deformation Processes

Powder Forging. In powder forging, a preform shape is cold pressed to between 75 and 85% of full density, sintered, heated to a forging temperature, and then forged in trapped dies using one blow to produce a fully dense net or near-net shape. The sintering step is optional, but it is normally included as a particle surface cleaning step (deoxidation) and to improve the workability of the porous preform. Powder forging fundamentals and general applications are presented in the article "Powder Forging and Hot Pressing" in this Volume. More detailed information is also contained in the article "Powder Forged Steel."

Normally, powder forging is performed hot (1000 to 1200 °C, or 1800 to 2200 °F, for steel powders), but it can also be conducted at warm or cold forging temperatures. Typical steel powder forging pressures are 550 to 950 MPa (40 to 70 tsi). Because the workability of a porous preform is poor, the design of the preform is critical to the process in terms of avoiding defects. Local surface tensile stresses and internal hydrostatic tension must be avoided. Nonetheless, with a correct preform shape and a well controlled process, powder forged parts have sound microstructures, good hardenability, and performance that meets or exceeds cast-wrought part performance.

There are two classes of forging practice. In repressing, the preform shape is nearly identical to the forged shape. In true forging, considerable shear deformation is involved since the preform is different in shape from the forging. The dynamic properties of toughness and fatigue resistance are higher for forged parts than for repressed parts.

Powder Extrusion. Loose powder can be containerized and extruded to full density, either with or without heat. Extrusion ratios of at least 9:1 have been shown to produce full density, and many materials are extruded to full density using much higher extrusion ratios. Extrusion at such high reductions subjects the powder particles to high levels of shear deformation and compression as they pass through the die. The result is sound particle bonding. As in hot isostatic pressing, the powder is usually hermetically sealed in a container prior to extrusion. In some alloy systems, residual air provides oxygen for selection oxidation of alloy ingredients prior to extrusion, and an oxide dispersion strengthened material is produced. In some other cases, particulates or chopped fibers may be added to the matrix powder, and extrusion produces a composite material. In still other cases, combinations of powders or powder plus wrought pieces are

extruded to produce multimetal parts, e.g., bimetallic tubing. These and other uses of extrusion are discussed in the article "Extrusion of Metal Powders" in this Volume.

Powder rolling or roll compaction of powders consolidates loose powder(s) into a porous strip as it passes through a roll gap. It is possible to produce a monolithic strip or a multilayer strip. Further processing may include sintering of the strip and additional rolling to densify the strip. Applications of this type of processing include such diverse products as clad metal for coin stock, automotive sleeve bearings, and electrode stock.

Powder Shaping and Consolidation Technologies

B. Lynn Ferguson, Deformation Control Technology, Inc.; Randall M. German, The Pennsylvania State University

Sintering

For sintering to be effective, the powder particles must be in intimate contact. For this reason, sintering is typically performed on compacted or molded powder and not on loose powder. While most powder parts are sintered during their manufacture, the densification stage of sintering may not be utilized, and in these cases the primary use of sintering is to achieve metallurgical bonding of particles. Die pressed parts typically fall into this category because dimensional control is of primary importance.

Process routings that rely on sintering specifically to achieve high densities usually fall into three categories. A very fine particle size is used so that bulk diffusion paths are minimized at the last stage of sintering, and there is a high initial surface area to drive sintering in its early stages. This is one reason for the use of ultrafine powders in injection molding where sintering is the primary mechanism for development of high property levels. A liquid phase, either permanent or transient, is present during sintering so that particle rearrangement is promoted. A high temperature is used so that local melting may accompany sintering.

Liquid Phase Sintering. The use of blended powders allows the combination of a low melting powder with a higher melting powder so that a liquid is present during sintering. This liquid can aid powder rearrangement and densification of a green compact. Cermets are typically produced by this technique. Nearly pore-free microstructures may be achieved by this technique.

Transient Liquid Phase Sintering. A subclass of liquid phase sintering is transient liquid phase sintering. Here, a blend of powders contains a lower melting point phase, as above. Only in this case, the liquid alloys with the solid phase which remains solid, and the liquid is present only for a brief period. This process is not used as the primary densification method, but it is used to achieve another increment in density. For example, it may be used in high alloy steel or tool steel production to increase the density of a green compact from 80% to >95% of full density.

High-Temperature Sintering. If the temperature of the green compact is raised to levels very close to the solidus temperature of the equilibrium diagram, small pools of liquid can form due to microsegregation of alloying elements. This small amount of liquid accelerates densification during sintering. Although this represents a somewhat extreme use of high temperature sintering, this technique is useful for a wide range of alloys, and it is used especially for tool steels and other high alloy steel components. The article "High-Temperature Sintering of Ferrous Powder Metallurgy Components" in this Volume contains more information on high-temperature sintering.

Reactive Sintering. By taking advantage of the flexibility of powder metallurgy, a blend of powders may be compacted and then sintered so that during sintering a self propagating reaction occurs (see "Combustion Synthesis of Advanced Materials" in this Volume). This reaction, if controlled properly, can densify the compact rapidly while forming the new alloy. If not controlled, the component may revert to powder!

Compaction to Higher Density

Many methods have been investigated and developed for pressing metal powders to higher densities. Most of the commercial methods involve high-temperature compaction (such as hot isostatic pressing and powder forging, as described in detail in other articles in this Section). In general, these methods are used to develop fully dense or nearly fully dense P/M products. For example, conditions for full-density iron and steel by HIP are summarized in Table 2.

Table 2 Hot isostatic pressing conditions for full-density iron and steel

Material	Pressure, MPa	Temperature, °C	Time, h
4 μm carbonyl iron	200	805	1
75 μm sponge iron	98	1000	1
70 μm low-alloy steel	150	800	1
190 μm maraging steel	210	1200	3
100 μm austenitic stainless steel	160	1150	3
120 μm martensitic stainless steel	150	1150	3
65 μm Fe-10Al-5Si	200	1000	1
80 μm tool steel	100	1100	1
165 μm iron superalloy	69	1200	3

Source: Ref 1

However, other methods besides high-temperature compaction are used to achieve higher densities in green or consolidated form. Some of these miscellaneous methods are described here. These methods are not necessarily full-density methods, and none have reached any significant commercial significance. They are described for general reference. Many experiments also have been reported that attempt to press compacts to higher densities or to produce a more uniform density and stress distribution in pressed compacts. Although none of the techniques developed has led to large-scale industrial use, they are discussed here.

Die Barrel Rotation. Rotating the die barrel while the powder is being pressed using a fine atomized aluminum powder was reported by Hammond and Schwartz (Ref 3). They lubricated the die barrel with a suspension of lithium stearate in didecyl alcohol. Annular compacts, 12.7 mm ($\frac{1}{2}$ in.) high, were pressed with outer diameters of 38 mm ($1\frac{1}{2}$ in.) and inner diameters of 25 mm (1 in.). The core rod was stationary, but the die barrel could be rotated during compression.

Compaction with a stationary and a rotating die barrel was compared. While in static compression, 20% of the applied stress was consumed in die wall friction, while only 2% of the stress was consumed when the die barrel was rotated. In addition, the pressure necessary to eject the compact from the die was reduced to approximately one half of the pressure for compacts pressed with a stationary die barrel. Similar experiments on the effect of die barrel rotation on the density of iron powder compacts were reported by Rutkowski et al. (Ref 4).

Triaxial compression by simultaneous isostatic and uniaxial compression is obtained by applying pressure to the circumference of a cylindrical specimen confined in a flexible envelope while an axial load is superimposed by a vertical piston. With this method, the level of pressure necessary to obtain a given density is less than with isostatic or uniaxial compression alone. For example, to compact an atomized iron powder (Ancor 1000) to a relative density of 85%, uniaxial compression at 540 MPa (78 ksi) or isostatic compression at 415 MPa (60 ksi) is necessary. The same density can be obtained by combining a confining (isostatic) pressure of 83 MPa (12 ksi) with a uniaxial pressure of 470 MPa (68 ksi). The principles involved in this method of compaction have been reviewed by Broese van Groenou (Ref 5).

High-Energy-Rate Compacting. The rate at which pressure is applied in compacting in a hydraulic press is slow. Compacting in certain mechanical presses is somewhat faster. The effects of the rate of pressure application in compacting were studied by Davies and Elwakil (Ref 6). They found that somewhat higher densities can be obtained for a given pressure and for a given energy input when compacts from iron powder are pressed in high-speed presses (petro-forge-presses). They also determined the effects of multiple blows during pressing.

In the fabrication of sheet metal products, techniques were developed that formed sheet metal at rates considerably higher than those obtained in fast-acting mechanical presses. This is the high-energy-rate forming technique, which generally uses explosives (see also Ref 1).

The success of high-energy-rate forming in fabricating sheet metal led to extensive experimental work on high-energy compacting of metal-powders. The most common means to achieve high velocity is by the use of explosives. In one experiment, for example, compaction was done in a rigid die with pressure applied by a projectile propelled by an explosive charge that moves through a barrel (Ref 7). In a similar experiment compressed gas actuated the projectile (Ref 8). This experiment showed that the density of copper powder is not so much a function of projectile velocity, but depends primarily on the kinetic energy of the projectile, which can be varied by proper selection of gas pressure and projectile mass (Ref 8). For copper compacts with a volume of 0.86 cm³ (0.052 in.³), relative densities of $\geq 95\%$ were obtained with energies of 150 J (110 ft · lb).

The most widely used method of explosive compacting is shown schematically in Fig. 7. The powder to be compacted is placed in a steel tube, which is closed at each end by steel plugs. The steel tube is surrounded by an explosive that is set off by a detonator located so that on detonation the tube collapses uniformly inward. Experiments by Lennon et al. (Ref 9) showed that density is a function of energy. They developed the equation:

$$D_c = D_T - \Delta D^{-(\beta E^\gamma)}$$

where D_c is the compacted density, D_T is the full density of the material, ΔD is the difference between full and compacted density, β and γ are constants, and E is the net energy absorbed by the powder. The highest relative densities obtained for iron, nickel, copper, and aluminum powders and the corresponding net energies absorbed per unit volume of compact in their experiments were:

Powder	Density ^(a) , %	Net energy, J/cm ³
Iron	98.1	261
Nickel	98.1	556
Copper	98.5	285
Aluminum	99.0	182

(a) Percent of theoretical density

This method of explosive compacting is not necessarily confined to cylindrical compacts. Cones and hollow cylinders have also been explosively compacted by this technique (Ref 10).

Fig. 7 Explosive compacting with powder contained in a steel tube

Vibratory Compacting of Powders. Vibration can be very effective in obtaining higher packed densities in powders. The relative densities of powders vibrated under carefully controlled conditions are much higher than those obtained by simply pouring the powder into the container. Therefore, much lower compaction pressures are required to reach a given density for a vibrated powder than for a poured powder. This is illustrated in Fig. 8 for a carbonyl iron powder. The density of 5.53 g/cm^3 (71% relative density), reached by compacting under a pressure of 245 MPa (35 ksi), is due to the plastic deformation of the iron powder particles, while the 5.37 g/cm^3 (69% relative density) obtained by vibrating at 167 oscillations per second is due mainly to vibratory packing. Plastic deformation during the simultaneous compacting at 2.4 MPa (0.36 ksi) is minimal. The method of consolidating powders by vibrating and simultaneous compacting is, therefore, primarily applicable to hard powders, such as refractory metal and cemented carbide powders, which can be densified relatively little by pressure application alone.

Fig. 8 Effect of powder vibration on densities of carbonyl iron compacts. ○ Obtained in static pressing. • Vibratory compacting at a frequency of 233 oscillations per second. □ Vibratory compacting at a frequency of 167 oscillations per second

Melt-spray deposition of powders encompasses a wide variety of materials and product forms. It can be used to produce monolithic shapes by build up of the spray deposition, or it can be used to form coatings by deposition of a thin layer. One of the largest applications for melt-spray deposition is welding, including hardfacing and plasma spraying techniques for coatings.

Spray forming is also a method for producing preforms by a buildup of sprayed metal powder. These preforms and billets subsequently can be consolidated into various mill shapes. Of these processes, the Osprey process, developed in Wales by Osprey Metals Ltd., and the controlled spray deposition process are in commercial use. Several other methods are being developed; plasma spray buildup has high commercial potential. Laser techniques, such as laser glazing, also have commercial potential, especially when combined with rapid solidification technologies.

Osprey Process. Facilities for production of preforms made by the Osprey process consist of induction melting equipment and a preform production unit. In the Osprey process, an alloy is melted and subjected to gas atomization under inert conditions (usually nitrogen or argon is used). The atomized droplets are collected in a mold or group of molds, in which final solidification occurs. Molds are normally copper cooled by water. High-temperature ceramics offer

other material options for molds. During solidification, welding of particles causes buildup of alloy in the mold. A preform having a density >96%, and normally >99%, of theoretical is generated by this buildup of alloy. The preform then can be consolidated to full density and formed into a mill or near-net shape part.

Alloys that have been processed by the Osprey process include stainless steels, high-speed steels, and nickel-base superalloys, although many materials appear to be compatible with the process. Alloy development has centered on high-alloy ferrous metals, Stellite alloys, superalloys, and composite materials. Because an inert atmosphere is maintained during spraying, oxygen levels similar to conventional ingot metallurgy products are attained, typically 20 to 40 ppm for superalloys. The high preform density ensures that no interconnected porosity is present in the preform, preventing internal oxidation during transfer of the material to subsequent consolidation and forming operations.

The Osprey process is used to produce a wide variety of preform shapes and sizes. Typical preform shapes are tubes, rings, cylinders, disks, or simple billets. Size is dictated by economics, with the melt facility, atomizer, and inert chamber sized for a particular product line. The largest preform size produced weighed 540 kg (1200 lb). Typical deposition rates range from 10 to 90 kg/min (20 to 200 lb/min). More information on the process is described in the article "Spray Forming" in this Volume.

The controlled spray deposition process is similar to the Osprey process in principle, but uses different machinery. Controlled spray deposition uses centrifugal atomization, while the Osprey process involves gas atomization. This process is used for production of mill shapes from high-alloy steel, which utilizes the enhanced workability of P/M workpieces. Highly alloyed metals may suffer from macrosegregation, which reduces the material workability. Elimination of segregation on a macroscale, coupled with a uniform distribution of fine carbides (2 to 3 μm range for M-2 high-speed steel), results in improved workability for P/M workpieces produced by spray deposition. These billets are processed subsequently into mill shapes and sheet products.

By atomizing liquid metal into droplets 0.5 to 1.5 mm (0.02 to 0.06 in.) in diameter, solidification rates three or more orders of magnitude higher than those of conventional ingot solidification are achieved. Impacting liquid droplets of metal onto a cooled substrate increases the solidification rate, resulting in solidification rates of 10,000 to 1,000,000 $^{\circ}\text{C/s}$ (18,000 to 1,800,000 $^{\circ}\text{F/s}$). Controlled spray deposition relies on this type of splat solidification to build up a solidified deposit that becomes a workpiece for subsequent deformation processing. As the thickness and temperature of the built-up material increases, the solidification rate decreases, but it remains much higher than that of conventional ingot solidification. Heating prior to hot working can remove any microstructural variations that may exist throughout the thickness of the built-up deposit.

Along with the metallurgical benefits of controlled spray deposition, economic advantages of direct spraying of powder into preform shapes are attained by eliminating sieving, blending, and other powder preparation steps. Also, primary compaction of powder into a green shape is eliminated. Controlled spray deposition proponents claim that these reductions in equipment needs and processing steps allow more efficient utilization of energy, compared to conventional pressing and sintering P/M technology.

Selecting a Process

Selecting the proper process for consolidating powder to produce a part requires making many decisions. Using the performance requirements as the accept-reject criteria, the wide range of possible processes can be narrowed down, but usually the designer/manufacturer still finds that several methods are possible for producing a particular part. The final selection is then usually based on the availability of equipment, the experience with particular processes, and the marketplace requirements of cost, delivery, and quantity.

Some guidelines and corollaries to these guidelines are presented here as an example of process selection decision making. These are not hard-and-fast rules for several reasons. First, the craft or skill aspect of parts making will alter these guidelines for each and every company. Second, new methods, new powders, and new equipment constantly require that any such set of guidelines be adjusted. Third, the marketplace itself dictates changes and additions to such guidelines. The reader is encouraged to take these guidelines and corollaries as a starting point, then modify and add new statements with quantified details wherever possible so that the decision making process within each organization is captured.

Guideline 1: Control of porosity is the most important aspect of a consolidation process. The size, shape, distribution, and volume fraction of pores is the singlemost important property of a powder metallurgy part. The performance of the part is directly dependent on these aspects of porosity. Therefore, the partmaker must control porosity in order to achieve a usable part, and the consolidation process is critical to controlling part porosity.

Corollary: Dynamic properties such as toughness and fatigue resistance improve dramatically as porosity is eliminated. Higher part stresses during application require higher densities. If a powder metallurgy part must compete with a wrought part, full density must be achieved in all critically stressed regions. This is especially true for applications that require high toughness or where cyclic loading is a life limiting condition.

Guideline 2a: Control of dimensions is the second most important aspect of the consolidation process. The successful implementation of parts production using powder metallurgy techniques is due to the minimization or elimination of machining operations. Therefore, the consolidation process must offer substantial control of the final part dimensions so that secondary operations are minimal.

Corollary: The use of rigid tooling provides superior control of dimensions in comparison to flexible tooling. Therefore, die pressing, injection molding, and powder forging are preferred over cold and hot isostatic pressing in terms of dimensional control. The shape of specific sections of isostatically pressed components can be better controlled by the selective use of rigid fixtures such as mandrels or pressing plates.

Corollary: The effect of friction on porosity distribution must be taken into account in order to maintain control of dimensions. Porosity gradients due to friction can cause nonuniform dimensional change during sintering. This is especially critical in die compaction where friction along vertical die walls and punch faces must be minimized through the use of admixed lubricants or die wall lubricants.

Corollary: Uniform powder loading is required to achieve a uniform dimensional change during sintering. Because the sintering rate is density dependent, a nonuniform distribution of powder will produce a nonuniform dimensional change during sintering. For injection molding, this means that the volume fraction of binder should be uniform throughout the green part. For multilevel die pressed compacts, this means that multiple pressing

motions should be used so that the proper powder distribution is achieved before consolidation starts. In die pressing there is negligible transfer of powder between cavity sections while pressure is applied.

Corollary: Prior to sintering but after debinding, injection molded parts must be supported because particle bonding at this point is simple cohesion. After ejection from the mold, an injection molded shape is held together by the binder. Prior to sintering, the binder is removed, leaving a time period when the only force holding the powder mass together is particle cohesion plus residual binder. A supporting bed of an unreactive matter such as alumina spheres may be necessary.

Guideline 2b: Ignore Guideline 2a if powder metallurgy is the only method that can be used to produce a particular material. In some cases powder metallurgy offers a way to process a unique material. In these cases, the uniqueness is the material often outweighs the economics of dimensional control so that substantial machining or secondary processing is acceptable.

Guideline 3: Metallurgical bonding of particles must be achieved during the consolidation process. After porosity, the next most important characteristic for achieving a usable part is metallurgical bonding or welding of the particles. Sintering is the most common process for accomplishing this bonding. The alternative to sintering is shear deformation of particles while under a general state of compression. In processes such as forging and extrusion, the particle deformation and local pressures are sufficiently high that strong welds develop between particles.

Corollary: Spherical particles should not be cold pressed if they are to serve a structural function. Cold pressing of spherical powders does not result in significant mechanical bonding of particles and green strength is poor. With careful handling, cold pressing of spherical powder can be accomplished, followed by sintering to achieve particle bonding; P/M filters are an example.

Corollary: The particle surface quality directly effects the strength of the particle bond. Sintering is not effective in improving mechanical properties if particle surface contaminants such as carbides or oxides block diffusion of alloy species. Therefore, sintering requires clean surfaces or it must include a surface cleaning step such as deoxidation.

Corollary: The mode of densification affects the quality of the interparticle bonding. The strength of the bond between powder particles is improved by shear deformation in comparison to repressing or isostatic compaction. Shear plus pressure breaks up surface contaminants and promotes particle bonding. As surface cleanliness is improved toward being contaminant free, there is less difference between consolidation processes involving high or low amounts of shear.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Introduction

MOST POWDERS receive at least one treatment prior to compaction. These treatments are tailored to the use of the powder and may include (a) particle size distribution adjustment through screening and/or air classifying, (b) annealing for the purpose of improving compacting properties, (c) lubricant addition for compacting grade powders, (d) mixing of different powders for premixes, and (e) blending of powders and powder mixes to homogenize their various components. These treatments are usually performed by the powder producer. The quality of these treatments can greatly affect the uniformity and consistency of sintered part properties. With increasing emphasis on zero defect manufacture, the treatments have received more attention in recent years.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Classifying/Screening

Many powder production processes yield relatively broad particle size distribution, and because of the many manufacturing variables, the distributions and average particle sizes may exhibit marked lot-to-lot variations, which contribute to the variation of important powder and sintered part properties. Classifying and screening are used to render the particle size distributions of powders more uniform with well-defined upper particle size limits. Powder producers often manufacture series of powders that differ only in particle size distribution. Such powders exhibit "graded" differences in dimensional change during sintering. For filter manufacture, classifying and screening are used to generate narrowly sized powder fractions for controlled pore size in filters and flow restrictors.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Mixtures and Segregation

Most P/M powders are multicomponent systems and, therefore, are subject to segregation. Segregation is even possible in a one-component metal powder if, for instance, coarse and fine powder particles "demix" as a result of vibration. The opportunity for powder segregation exists in processes such as shipping and the filling of hoppers and compaction dies, where individual components exhibit different flow rates due to differences in particle size, shape, density, surface roughness, and other properties.

The most widely used P/M compacting grade powders are mixtures of iron with graphite, copper, nickel, and/or molybdenum. The preferred use of powder mixtures rather than prealloyed powders is related to several factors. The most important one is that elemental powder mixtures generally possess significantly higher compressibilities than their prealloyed counterparts. Secondly, powder mixtures are usually less expensive than prealloyed powders. Finally, powder mixtures more often can be formulated to provide transient liquid phases during sintering, which can reduce sintering times and improve mechanical properties.

In most powder mixtures, the base powder typically comprises 90% or more of the powder mixture. Since the other components are present in only small amounts, and their alloying effects are powerful, it is very important that they are uniformly distributed; homogeneity of the powder must be preserved during shipping and handling at the parts producer's site until compaction is completed. Without such precautions, the properties of the sintered parts are not optimal and the standard deviation, that is, the scatter of the properties, can be quite large.

Powder Treatments and Lubrication

Mixtures and Segregation

Most P/M powders are multicomponent systems and, therefore, are subject to segregation. Segregation is even possible in a one-component metal powder if, for instance, coarse and fine powder particles "demix" as a result of vibration. The opportunity for powder segregation exists in processes such as shipping and the filling of hoppers and compaction dies, where individual components exhibit different flow rates due to differences in particle size, shape, density, surface roughness, and other properties.

The most widely used P/M compacting grade powders are mixtures of iron with graphite, copper, nickel, and/or molybdenum. The preferred use of powder mixtures rather than prealloyed powders is related to several factors. The most important one is that elemental powder mixtures generally possess significantly higher compressibilities than their prealloyed counterparts. Secondly, powder mixtures are usually less expensive than prealloyed powders. Finally, powder mixtures more often can be formulated to provide transient liquid phases during sintering, which can reduce sintering times and improve mechanical properties.

In most powder mixtures, the base powder typically comprises 90% or more of the powder mixture. Since the other components are present in only small amounts, and their alloying effects are powerful, it is very important that they are uniformly distributed; homogeneity of the powder must be preserved during shipping and handling at the parts producer's site until compaction is completed. Without such precautions, the properties of the sintered parts are not optimal and the standard deviation, that is, the scatter of the properties, can be quite large.

Stabilization of Powder Mixtures

Because of the wide use of powder mixtures and their sensitivity to demixing, much work has been done towards the stabilization of powder mixtures.

Stabilizers. A powder mixture is optimally mixed if its components approach a random (statistical) distribution free of agglomeration (Fig. 1). The quality of mixing can be measured by the number of particle contacts (in green compacts) between identical or different powder components as illustrated in Fig. 2 for iron-copper mixtures, or by the chemical analysis of appropriate samples taken from the powder mixture.

Fig. 1 Schematic representation of particle patterns in a powder mixture. (a) Ordered. (b) Agglomerated. (c) Statistical (random) distribution. (d) Demixed or segregated

Fig. 2 Effect of stabilizer on iron-iron contact formation in binary iron-copper system. Lower curve represents theoretical random mixture.

Blenders and mixers that rely mainly on gravity (tumblers) are suitable for powders that mix readily. More intense mixing is accomplished with low-shear agitated-type blenders that use ribbons, slow-speed paddles, screw-type augers, or other means of motion. Figure 3 illustrates how spherical powders mix quite readily, but also are subject to demixing or overblending. Consequently, mixing should be stopped once a near-random distribution has been achieved. The variability coefficient in Fig. 3 represents the standard deviation of the measured degree of mixing divided by the average value of the measured property. The quality of the mixture improves with decreasing variability coefficient.

Fig. 3 Effect of particle size and shape of components of 90%Fe-10%Cu mixtures on degree of blending. Quality of blending improves as variability coefficient decreases. Particle size and shape for components: (a) Cu, 200 to 300 μm ; Fe, $<63 \mu\text{m}$ of spherical particle shape. (b) Cu 200 to 315 μm ; Fe, 100 to 200 μm of

spherical particle shape. (c) Cu, 200 to 315 μm ; Fe, <63 μm of irregular particle shape. (d) Cu, 200 to 315 μm ; Fe, 100 to 200 μm of irregular particle shape

Demixing is often caused by the accumulation of electric charges, which frequently can be dissipated by the addition of a small amount of water. Surfactants and stabilizers are sometimes used to improve the flow of materials. They consist of wetting liquids and oils, which have no negative effects on the sintering process. Figure 4 shows the beneficial effect of oleic acid (dissolved in benzene) for 90%Fe-10%Al mixtures. In this example, the best mixture results from the addition of the optimized amount of a stabilizer after eight minutes of mixing, when the mixture has approached a random distribution (curved).

Fig. 4 Effect of stabilizer on degree of blending of 90%Fe-10%Al mixtures. Particle size for both components: 100 to 200 μm . Stabilizer: benzeneloleic acid. (a) Without stabilizer. (b) With 1.0% stabilizer. (c) 1.0% stabilizer added after 8 min of blending. (d) 3% stabilizer added after 8 min of blending

Diffusion-Bonded Powders. In a diffusion-bonded powder, a powder mixture is heated in a reducing atmosphere to yield a sintered powder cake, which after grinding, produces a powder that consists of agglomerates of the components of the powder. The process is controlled so that the degree of alloying among the different components is only small. This retains much of the desirable high-compressibility characteristics of the original elemental powder mixture and minimizes or eliminates the demixing tendency of such a powder. As a bonus, green strength is usually increased.

Binder-Treated Powder. In recent years powder producers have developed proprietary binders that are used in small amounts to bond fine graphite onto the coarser iron particles. Such powders reduce the dusting of a powder, and improve several important engineering properties of the sintered parts due to the more uniform concentration of carbon in the final parts.

Prealloyed Powders. Despite the widespread use of powder mixtures, the use of prealloyed powders in the structural parts industry has been increasing. In the low-alloy steel segment, nickel, molybdenum, and manganese are used as alloying elements to provide greater hardenability than is possible with admixed copper or nickel. Admixed nickel requires economically prohibitive sintering times (even at high sintering temperatures) for complete alloying. Higher alloyed powders, such as stainless steels, tool steels, and superalloys, are all prealloyed powders. The requirement of complete alloying in these alloy classes makes the elemental powder approach impractical. The problem of low

compressibility, that is, low green density and/or low green strength, is solved by high-temperature and liquid phase sintering, and through the use of special consolidation methods, such as hot isostatic pressing and extrusion.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Annealing

Although the term annealing refers to a heat treatment that renders a metal soft by the removal of strain, in P/M, the term is used more broadly and includes the softening of a powder by the removal of interstitials, particularly carbon, nitrogen, and oxygen. Powders that have been work hardened through milling; powders that contain residual amounts of carbon, oxygen, or nitrogen; and powders that contain objectionable surface oxide films are most often subjected to this type of annealing. Examples include sponge and atomized iron powders, carbonyl and electrolytic iron powders, tool steel powders, and ferritic stainless steel powders. In most cases, annealing is performed in a reducing atmosphere, which not only protects the powder against oxidation, but also removes surface and interior oxides. Annealing improves the compressibility and green strength of a powder due to the softening of the metal. Frequently, annealing also produces slightly agglomerated powders with lower apparent densities and further increases in green strength.

Powder Treatments and Lubrication

Erhard Klar, Consultant, and C.B. Thompson, OMG Americas

Lubrication

Lubrication is essential to reduce friction between the pressed compact and the rigid tool components when compacting metal powders in steel or carbide tooling. Extremely high part ejection pressures and, ultimately, seizing and excessive tool wear result without proper lubrication. In addition, the surface quality of the part is detrimentally affected. Although much work has been done with systems where the tooling itself is lubricated, these systems generally have not proved effective high-volume P/M parts production. Parts produced by isostatic compaction do not require lubrication, due to the absence of high frictional forces during this type of processing.

Compacting grade metal powders are lubricated to facilitate part ejection from the die and to minimize die wear. Lubricants can strongly affect compacting and sintering properties of a powder. For this reason, powder producers try to optimize amount, composition, and structure of a lubricant to not only reduce friction during powder compaction, but also to protect the powder against oxidation and to obtain consistent apparent density and powder flowability, proper dimensional change during sintering, and maximum and consistent mechanical properties of the sintered parts.

Although a lubricant largely evaporates and/or decomposes in the preheating zone of a sintering furnace, its interactions and reactions with the metal powder can have critical consequences. Potential problems range from lubricant segregation, burnout, and blistering to carbonization and lubricant residue interference. Lubricant performance also depends on part density, metal powder composition, and particle size.

Lubricant Selection

In the majority of P/M applications, the lubricant is premixed directly with the metal powder. Stearic acid, zinc stearate, lithium stearate, and synthetic waxes, such as Acrawax, are the most popular lubricants. Lubricant selection is based primarily on the ability of the lubricant to adhere to metal particle surfaces. The amount of lubricant added depends on many factors, including composition of the metal powder, type of tooling, compacted density, and complexity of the part. Amounts generally vary from 0.5 to 1.5 wt%.

Lithium stearate is widely used in stainless steel powders because of its beneficial effect on compressibility. Lithium stearate and zinc stearate mixtures are used in brass and nickel silver powders to produce stainfree parts. Synthetic waxes

with their low moisture and ash contents are widely used for high-density parts where ash residues are objectionable. Multicomponent lubricants permit the powder producer to adjust or influence the packing, pressing, and sintering characteristics of powder. The use of die wall rather than admixed powder lubrication is still in the development stage.

Ferrous Materials

Although lubricants are a necessary addition to compacting metal powders, they can have some critical, and often deleterious, effects on the ultimate premix. Hoeganaes Corporation (Ref 1) has made a comprehensive study of lubricants and their influence on the properties of iron premixes. Lubricant properties, such as bulk density and particle size, are very important; for example, high-bulk density and large particle size provide good flow and low stripping pressure, as illustrated in Fig. 5 and 6. To minimize premix segregation, the particle size of the lubricant must be smaller than the size of the largest particle of iron powder; for example, a 150- to 200-mesh (104- to 75- μm) lubricant should be used with 100-mesh (150- μm) iron powder.

Fig. 6 Relationship of stripping pressure and bulk density of iron powders with 1.0% zinc stearate lubricant.

Source: Ref 1

The melting point of the lubricant must be high enough to prevent melting or softening from heat developed during mixing. If this occurs, flow deteriorates, apparent density decreases, and the mix tends to agglomerate.

Higher lubricant content yields poorer flow, lower apparent density, and lower stripping pressure. Figure 7(a) shows the effect of lubricant content on apparent density of atomized stainless steel powder. The effect of increasing amounts of three lubricants on the flow of iron powder is shown in Fig. 7(b) and 8.

(a)

(b)

Mixing time of 30 min. Source: Ref 1

Stripping pressure is the initial amount of pressure required to start the ejection process of a green compact from the die after compaction. The sliding pressure is lower than the stripping pressure and can be defined as the pressure required to complete the compact ejection cycle. Both stripping and sliding pressures are dependent on the compaction pressure and type of lubricant, as shown in Fig. 9 and 10. Thus, different lubricants may be required for steel and carbide tooling materials.

Fig. 9 Effect of compaction pressure and 0.75% lubricant on stripping pressure of Ancorsteel 45P (Ancorsteel

1000B + 2.90 wt% ferro-phosphorus)

Fig. 10 Effect of compaction pressure and 0.75 wt% lubricant on the sliding pressure of Anchorsteel 45P (Anchorsteel 1000B + 2.90 wt% ferro-phosphorus)

Stripping strength can vary considerably with the type of lubricant used. When compared to parts pressed without lubricant, zinc stearate and stearic acid decrease sintered strength only slightly, as illustrated by Fig. 11 and 12. However, several lubricants, such as calcium and barium stearates, added to pure iron or to an iron and 1% graphite mixture cause significantly large decreases in sintered strength, as shown in Fig. 13. The appearance of P/M parts after sintering also can be affected by lubricants. Although the effect on iron parts is not as significant as with brass and nickel-silver powders, spotty surfaces and discoloration can be a major concern. Lubricants that vaporize completely during sintering generally leave a clean surface. Dark mottled surfaces occasionally result from zinc and calcium stearate lubricants, due to condensed zinc metal or calcium oxide deposits.

Lubricant removal, prior to the actual sinter operation, is vitally important for several reasons. Generally, this removal is accomplished during the sintering preheat operation and is referred to as "burn-off." Because of highly adverse effects of residual lubricant carbon deposits when sintering stainless steel, resulting in lowered corrosion resistance, Moyer (Ref 2) conducted an extensive study of the burn-off characteristics of common lubricants (lithium stearate, zinc stearate, Acrawax C, and Nopco Wax) in 316L powder compacts. Burn-off temperatures of 370, 425, and 480 °C (700, 800, and 900 °F) were used in both air and dissociated ammonia atmospheres. This study revealed that the waxes leave no residue at 425 °C (800 °F) or higher; the stearates, however, leave approximately 15% residue even when burned at temperatures up to 540 °C (1000 °F). Maximum lubricant burn-off is achieved at about 425 °C (800 °F). Burn-off is less controllable in

dissociated ammonia, and the amount of lubricant removed decreases as the compacting pressure is increased. Carbon burn-off is incomplete when compacts are burned off in a dissociated ammonia atmosphere.

Nonferrous Materials

Many lubricants frequently used in iron-base powder systems have not been effective in all copper-base prealloyed systems. Without lubricant system development, primarily lithium stearate, it is unlikely that brass and nickel-silver P/M parts would hold the strong market position that they do today (Ref 3). The use of lithium stearate overcame many early sintering problems and provided consistently high properties in brass P/M parts.

Lubricants such as zinc stearate, lithium stearate, stearic acid, and Acrawax have been used successfully with conventional premixed bronze materials (90%Cu-10%Sn). A recent study (Ref 4) comparing the two stearates and Acrawax revealed slightly better compressibility and lower ejection pressures with zinc stearate. Furthermore, green strength increased with decreased amounts of lubricant, and Acrawax provided superior green strength zinc and lithium stearate.

Bi-lubricant systems, such as lithium-zinc stearate, provide the advantages of high physical properties and relatively clean surface appearance. Lithium stearate and lithium-zinc stearate lubricant additions in the range of 0.5 to 0.75% are used most often in brass and nickel-silver parts. Although waxes are excellent for maintaining green strength, their use results in lower apparent densities, higher briquetting pressures, and lower sintered strengths in brass parts.

Frequently, a bi-lubricant system of zinc stearate and stearic acid at 0.75 wt% is employed for conventional bronze premix blends; these two lubricants complement each other. Stearic acid has excellent lubricating characteristics, but its spherical morphology tends to promote segregation, therefore, the irregular shape of the zinc stearate particles provides a supportive interlocking effect. Acrawax often is used alone to increase green strength, although it can lower the apparent density and retard the flow of bronze premixes.

Lubricants play a unique role in the production of copper P/M parts for high electrical conductivity applications (Ref 5). Lithium stearate allows the highest electrical conductivity among lubricated compacts, as illustrated in Fig. 14. Compacts pressed at 275 MPa (20 tsi), using a synthetic wax lubricant, have conductivities of about 74% IACS; similar compacts produced with lithium stearate exhibit conductivities of about 86%. The effect of the quantity of lubricant on electrical conductivity of copper P/M parts is shown in Fig. 15. The electrical conductivity reaches a maximum with approximately 0.6% lithium stearate in compacts pressed at 275 MPa (20 tsi) and with approximately 0.5% at 415 MPa (30 tsi).

Fig. 14 Effect of lubricant on electrical conductivity of copper P/M parts. Compacting pressure: (a) 276 MPa (20 tsi); (b) 414 MPa (30 tsi)

Fig. 15 Effect of lubricant quantity on the electrical conductivity of copper P/M parts

Synthetic organic waxes, which have low moisture and ash content, are employed in the production of aluminum P/M premixes (Ref 6). The addition of 1.5% lubricant (nominally) permits the consistent production of high-density aluminum P/M parts with fine surface quality and eliminates tool problems with seizing and cold welding. High sintered properties are achieved because these lubricants leave virtually no ash to interfere with particle bonding during sintering.

Mechanical Behavior of Metal Powders and Powder Compaction Modeling

J.R.L. Trasorras and R. Parameswaran, Federal-Mogul, Dayton, Ohio; A.C.F. Cocks, Leicester University, Leicester, England

Introduction

CONSOLIDATION OF METAL POWDER into useful products generally follows a three-step process: (1) powder transfer into a container or die, (2) powder compaction through applied force, and (3) sintering. Particular processes combine two of these steps into one. For example, hot isostatic pressing combines steps two and three through the simultaneous application of pressure and temperature in an autoclave. This article describes step two, the mechanical response of the powder to the applied compaction forces. Density of the powder transferred into the container depends on the properties of the powder and on the method of transfer, which may include tapping and vibrating. Consideration of packing density is beyond the scope of this article; however, a comprehensive review of this topic can be found in Ref 1. Proper design of compaction processes requires a description of the mechanical or thermomechanical behavior of the powder. Issues related to applications of practical interest include:

- *Compaction in rigid dies:* Density distribution in the compact, effect of tooling motion histories on density, tooling stresses and tooling deflections, stresses in the compact during ejection and fracture likelihood
- *Cold isostatic pressing:* Geometric distortion of the pressed component, effect of container dimensions and material on distortion
- *Hot isostatic pressing:* Geometric distortion of the pressed component, effect of pressure and temperature cycles on distortion, effect of container design on distortion
- *Powder forging:* Density distribution in the formed part, forging loads, and tooling stresses

Unfortunately, the complex nature of powder mechanical behavior, coupled with complex geometry and boundary conditions, precludes analytical solutions to these problems. During the late 1980s, the maturing of numerical solutions to finite strain plasticity allowed initial attempts at modeling powder compaction processes. Powder compaction modeling has not achieved widespread industrial use yet. However, many useful and encouraging results have been published, and it seems likely that during the next decade, modeling will become central to the design of compaction processes.

Formally, powder compaction modeling requires the solution of a boundary value problem--a set of partial differential equations representing:

- *Balance laws:* conservation of mass, momentum balance, and conservation of energy
- *Constitutive laws:* stress-strain relation and friction laws

The finite element method (FEM) is the numerical technique most widely used to solve these equations. Modern FEM codes incorporate constitutive models for a wide variety of materials. Some of them are suited to modeling metal powders. Furthermore, these codes also provide facilities for the user to implement a particular constitutive law.

Constitutive Models for Metal Powder Compaction

This section examines the response of powder compacts under mechanical loading histories that are typical of those experienced during the manufacture of powder metal parts. Deformation of a powder compact occurs as the result of rearrangement and plastic deformation of the particles. Frictional resistance, as particles slide over each other, can also contribute to the macroscopic response. If the packing is initially loose, then the initial stages of compaction are dominated by particle rearrangement, with little or no plastic deformation occurring between the contacting particles. If, however, the initial apparent density of the powder is relatively high, further macroscopic plastic deformation under constrained compressive stress states is dominated by plastic deformation of the particles themselves.

Knowledge of the major physical processes that occur when a powder compact is deformed can be used to guide the development of constitutive models of the compaction process. At the microlevel, the constitutive response of fully dense materials governs plastic deformation between the contacting particles. The macroscopic response can then be determined by combining the contributions from individual contacts. There are general theoretical techniques that can be employed to achieve this and determine what general statements can be made about the structure of the macroscopic constitutive laws. Micromechanical models have been developed using these techniques. It may not be appropriate to precisely follow this route, but, instead, to develop empirical constitutive laws based on observations made at the macroscopic level. The results then provide a suitable structure and general guidelines for the construction of these models. As the material approaches full density, these models should reduce to classical incompressible models. Therefore, these models serve a second purpose; they provide a starting point from which more general constitutive relationships can be developed.

Throughout the article, the response of an element of material in a particle of the compact (referred to as a "microscopic element") is identified in terms of the local stress σ_{ij} and local strain ϵ_{ij} . When evaluating the response of a powder compact, a representative "macroscopic element" of material, which contains a large number of particles but is small compared to the size of a pressed component, is identified. The response of such an element is expressed in terms of a macroscopic average stress Σ_{ij} and strain E_{ij} .

Deformation of Powder Compacts: Experimental Observations

Before examining the structure of constitutive laws for powder compaction, it is instructive to identify the major physical processes that occur within the compact as it is deformed and to determine how these are likely to influence the macroscopic behavior. When the powder is initially poured into a die or mold, the particles are arranged randomly with particles only in point contact with each other.

Consider the situation where the compact is densified hydrostatically. As the pressure is increased, plastic flow occurs in the vicinity of the contacts. As a result, the contact zones spread, the centers of the particles move closer together, and the material densifies. During the initial stages of this process, the porosity remains connected, consisting of a network of interconnected channels threading through the material. In the micromechanical models, this is referred to as stage 1 compaction. As the material is densified further, the channels pinch off, leaving a distribution of isolated pores (stage 2). Throughout this process, because of the initial random structure, the porosity is randomly distributed throughout the material, particularly during stage 1 compaction. If, however, the sample is much larger than the mean particle size, no preferential orientations or distributions of pores develop, and the structure remains macroscopically isotropic. A single

state variable can then be used to describe the structure and macroscopic response. A convenient state variable is the relative density D , which is defined as the ratio of the density of the compact to the density of the material, so that at full density $D = 1$.

In practical compaction processes, the densifying material can see complex stress states and histories. As a result, the structure that develops is no longer isotropic, and it may not be appropriate to describe this structure and the macroscopic response using a single state variable. For example, consider the case of frictionless closed-die compaction. As a cylinder is compacted along its axis, there is no straining in the transverse direction. The contact patches that develop between the deforming particles are therefore larger normal to the direction of loading than along the axis. Also, the size of these patches is different from those in a compact that has been densified hydrostatically to the same relative density. Thus, the relative density does not uniquely describe either the microstructure or the macroscopic response.

Any constitutive law that is developed needs to be validated experimentally. An examination of the types of experiments that have been performed and how the results from these tests are commonly presented follows. The analysis is based on the identification of a yield surface for the material (which is a surface in stress space within which the material responds elastically; plastic deformation can only occur for stress states on the yield surface). The size and shape of the yield surface is a function of the history of loading. The yield surface can be determined using a number of different methods. A number of samples can be prepared in the same way (for example, hydrostatically compacted to the same relative density). Each sample is then loaded along a different path in stress space until it yields. The yield surface is then formed by connecting the different yield points. Alternatively, a single specimen can be used. After compacting to the desired state, a series of probing experiments can be performed by unloading and reloading along a range of different stress paths until yield occurs. The yield surface can be mapped out in exactly the same way as before. When using this method, it is important to ensure that only a small amount of plastic straining occurs during each probe so that there is no significant change of microstructure (i.e., state) over the series of probing tests.

When examining a range of different stress states, it proves convenient to present the results in terms of global measures of stress. Two convenient quantities are the von Mises effective stress, Σ_e , and the mean (or hydrostatic) stress, Σ_m . If Σ_1 , Σ_2 , and Σ_3 are the principal stresses,

$$\Sigma_e = \sqrt{\frac{1}{2} [(\Sigma_1 - \Sigma_2)^2 + (\Sigma_2 - \Sigma_3)^2 + (\Sigma_3 - \Sigma_1)^2]} \quad (\text{Eq 1})$$

and

$$\Sigma_m = \frac{1}{3} (\Sigma_1 + \Sigma_2 + \Sigma_3) \quad (\text{Eq 2})$$

More general definitions of these stresses are provided in the following section.

Alternatively, instead of using Σ_m , the material response can be presented in terms of the hydrostatic component of stress (or pressure) $P = -\Sigma_m$. These definitions are used interchangeably throughout the article.

Many of the experimental methods used today to evaluate the behavior of metal powders have been inspired by techniques used to test soils. Most published data has been generated using such procedures. Before examining the material data in detail, it proves instructive to first examine the general features of the most common testing methods.

It is convenient to represent the yield function, as well as the stress paths during testing, in the $P - \Sigma_e$ plane. In this representation, the closer a point is to the ordinate (Σ_e axis), the more shear experienced in the material; the closer it is to the abscissa (P axis), the more hydrostatic pressure experienced. The typical powder compaction process involves stress states that have a high-pressure component, a natural consequence of the confinement of the powder in a die cavity.

Figure 1 shows a schematic representation of the load paths corresponding to the different test procedures:

- *Simple shear test:* This is marked by a complete absence of any hydrostatic load. This test has little value in the context of loose powders and can only be applied to sintered powders or porous materials.
- *Simple compression test:* This is once again a shear-dominated test, with friction at the interface of the

powder and dies assumed absent. As with the previous case, this test can realistically only be used for sintered powders or porous materials.

- *Triaxial test:* The primary advantage of this test is that a variety of stress paths can be examined through a combination of compressive stresses in axial Σ_z and radial Σ_r directions. A detailed description of this test is provided in the section "Experimental Determination of Powder Material Constitutive Properties and Functions" in this article. The effective and hydrostatic components of stress for this loading situation are given by $\Sigma_e = |\Sigma_z - \Sigma_r|$ and $P = \frac{1}{3}(2\Sigma_r + \Sigma_z)$.
- *Closed die compaction:* The state of stress in the powder in this test is possibly the best description of the actual stress state in a typical compaction. This test does not lend itself to parameter extraction procedures because friction is present at the die walls. It is possible, however, to simulate frictionless closed die compaction in a triaxial cell.
- *Hydrostatic compaction:* The state of stress during this test is one of pressure alone with shear components completely absent. This test is easy to set up and provides the compressibility of the material.

Fig. 1 Schematic representation of the load paths corresponding to the different test procedures. Source: Ref 31

All the cases illustrated in Fig. 1 involve the testing of cylindrical specimens. The inherent symmetry in the shape and loading can be exploited to simplify the analytical treatment required for the extraction of material parameters.

It should be noted that results from a particular testing procedure might be used to extract material parameters for different constitutive models. Simplifying assumptions are an essential ingredient in such determinations. For instance, friction is inevitably present in most testing procedures. However, it often becomes necessary to ignore the effects of friction in the extraction procedure, because not doing so may seriously impair the ability to obtain reasonable values for material parameters.

Kim et al. (Ref 5) cold isostatically pressed tubes of iron powder (Hoeganaes ASC 100-29) to relative densities in the range $D = 0.8$ to 0.85 . These tubes were then sintered at 1150°C for 1 h in a hydrogen atmosphere. The tubes were then tested in combined tension, Σ , and torsion, T . Typical yield surfaces obtained from these experiments are shown in Fig. 2, where the results are normalized with respect to the yield strength of the fully dense material, σ_y . The sintering process has bonded the particles, imparting significant tensile strength to the compact. A number of studies for determining the mechanical properties of powder compacts employ the same type of procedure. For example, the experimental studies of Kuhn and Downey (Ref 6) and Shima and Oyane (Ref 7), which form the basis for a widely used constitutive law for powder compaction, were performed on sintered compacts. Brown and Weber (Ref 8) demonstrated that the mechanical response of compacted and then sintered powders is very different from that of identical powders that have only been compacted. Watson and Wert (Ref 9) compacted aluminum powders hydrostatically and by using closed-die compaction. They performed uniaxial tensile and compressive tests on these samples to construct the yield surface.

Fig. 2 Yield surfaces determined by Kim et al. (Ref 5) from tension/torsion tests on sintered iron powders

Akisanya et al. (Ref 10) used the probing method to determine yield surfaces for samples of spherical powders, which were either hydrostatically compacted or compacted by simulating closed-die compaction. These tests were performed using a triaxial cell in which hydrostatic pressure and uniaxial compression could be applied independently. Yield surfaces obtained for a relative density of 0.8 are shown in Fig. 3 using the axes of $\Sigma_s = \Sigma_z - \Sigma_r$ and Σ_m . Note that in these experiments $\Sigma_r > \Sigma_z$ and thus Σ_s is negative with $\Sigma_s = -\Sigma_e$. It is important to note that the shape of the yield surfaces obtained by compacting the samples using these two different methods are significantly different from each other. Thus, the states of the materials are different even though the densities are the same.

Fig. 3 Yield surface for spherical copper powders determined by Akisanya et al. (Ref 10) for isostatically pressed and close-die compacted samples

Another convenient way of presenting experimental data is in the form of isodensity plots. These plots are constructed by loading samples proportionally (either by maintaining the stresses or the strains proportional to each other) and then determining the stress states that correspond to a given density. If the material response can be described using the relative density as the only state variable, then these surfaces would be equivalent to the yield surfaces of the material. It is evident from the results of Fig. 3 that more than one state variable is required to describe the response. However, in many practical situations, an element of material experiences near proportional loading and isodensity or similar plots provide valuable information about the constitutive behavior. Brown and Abou-Chedid (Ref 11) constructed a series of isodensity plots in $\Sigma_e - \Sigma_m$ space for spherical copper and sponge iron (Hoeganaes MH-100) powders (Fig. 4, 5). The solid symbols in these figures represent the yield strength in uniaxial compression following biaxial compression to the desired density. The major observations here are the different forms of the surface for the different powders, and the fact that the spherical powder has limited strength in uniaxial compression. These conclusions are consistent with the experiments of Akisanya et al. (Ref 10) presented in Fig. 3. The irregular powders, however, exhibit significant strength in uniaxial compression. Also, the irregular powders tested by Watson and Wert (Ref 9) had a significant yield strength when loaded in tension, while samples of spherical powder compacts can readily be broken in tension, often by hand, due to the lack of interlocking of the particles. These plots will be discussed and evaluated in the following sections. There are however, three important points to note at this stage:

- It is possible to identify a yield surface for a powder compact.
- The state of the material is a function of the prior history of loading. This influences the size and shape of the yield surface.
- The yield behavior depends on the morphology of the powder particles. Irregular particles interlock, giving tensile strength, while compacts of smooth spherical particles can be readily pulled apart.

Fig. 5 Isodensity surfaces for irregular iron powders tested by Brown and Abou-Chedid (Ref 11)

Elastoplastic Constitutive Behavior

The constitutive behavior is discussed within the framework of small deformation theory of plasticity, which allows the decomposition of the total strain into elastic and plastic components and development of relatively simple expressions for the constitutive response. In practice, large plastic straining of a body can occur during the compaction process. The general forms of expression are still applicable, provided appropriate measures of stress, strain, stress-rate, and deformation-rate for these problems are defined. At this stage, it is not necessary to precisely determine what these definitions are. All necessary information can be determined by making the simple assumption of small strains. Start by considering the response of a microscopic continuum element of material (i.e., the response of the individual particles that form the compact).

Assume that the total strain, ϵ_{ij} , a body experiences can be decomposed into elastic and plastic components, such that:

$$\epsilon_{ij} = \epsilon_{ij}^e + \epsilon_{ij}^p \quad (\text{Eq 3})$$

Where appropriate, the index notation for tensorial quantities is used to represent the constitutive response. The indices i and j can have a value in the range of 1 to 3. A repeating suffix implies summation over this range (thus, $\epsilon_{ij} = \epsilon_{11} + \epsilon_{22} + \epsilon_{33}$).

Elastic Behavior. The elastic strains depend on the current stress. For a linear elastic material,

$$\epsilon_{ij}^e = C_{ijkl} \sigma_{kl} \quad (\text{Eq 4})$$

where C_{ijkl} is the elastic compliance matrix. If the material response is isotropic, it is more convenient to decompose the strain into deviatoric, ϵ_{ij}^{ed} , and volumetric, ϵ_v^e , components, such that:

$$\epsilon_{ij}^e = \epsilon_{ij}^{ed} + \frac{1}{3} \epsilon_v^e \delta_{ij} = \frac{s_{ij}}{2G} + \frac{\sigma_m}{3K} \delta_{ij} \quad (\text{Eq 5})$$

where G is the shear modulus, K is the bulk modulus, $s_{ij} = \sigma_{ij} - \frac{1}{3} \sigma_{kk} \delta_{ij} = \sigma_{ij} - \sigma_m \delta_{ij}$ are the deviatoric components of stress, $\sigma_m = \frac{1}{3} \sigma_{kk}$ is the mean stress, and δ_{ij} is the Kronecker delta function ($\delta_{ij} = 0$ for $i \neq j$; $\delta_{ij} = 1$ for $i = j$). For a fully dense material, G and K are material constants. If the material is porous, both these moduli can be a function of the relative density of the material. This point is revisited later in the article in an examination of the constitutive response of powder compacts.

Classical Plasticity for Incompressible Materials. Central to the development of constitutive laws for plastically deforming materials is the concept of a yield surface. Here a more precise definition of ways in which the changing state of the material can be modeled is presented. The discussion is limited to classical plasticity concepts for fully dense materials, where plastic flow occurs at constant volume. Porous bodies are presented in subsequent sections.

A yield surface is shown schematically in Fig. 6 in principal plane stress space, in which there are two measures of stress σ_1 and σ_2 . Mathematically, this surface can be defined by the equation:

$$f(\sigma_{ij}) = 0 \quad (\text{Eq 6})$$

where $f(\sigma_{ij})$ is a function of stress. For example, for an isotropic incompressible material, a suitable form of this expression is:

$$f(\sigma_{ij}) = \sigma_e - \sigma_y \quad (\text{Eq 7})$$

where σ_y is the yield strength of the material in uniaxial tension and σ_e is the von Mises effective stress, given by:

$$\sigma_e = \sqrt{\frac{3}{2} s_{ij} s_{ij}} \quad (\text{Eq 8})$$

In principal plane-stress space,

$$\sigma_e = \sqrt{\sigma_1^2 + \sigma_2^2 - \sigma_1 \sigma_2} \quad (\text{Eq 9})$$

Fig. 6 Schematic of yield surface in plane-stress space, showing strain increment vector normal to the yield surface

Equation 9 then represents the von Mises ellipse shown in Fig. 6. If $f < 0$, the material response is elastic, and if $f = 0$ (i.e., if the stress state is on the yield surface), the material is able to deform plastically. The increments of plastic strain at yield are related through the associated flow rule:

$$d\epsilon_{ij}^p = \lambda \frac{\partial f}{\partial \sigma_{ij}} \quad (\text{Eq 10})$$

where λ is a plastic multiplier. This equation simply states that the strain increment vector is normal to the yield surface in stress space. Additional information is needed to determine the exact value of λ .

For the yield condition of Eq 7,

$$\frac{\partial f}{\partial \sigma_{ij}} = \frac{\partial \sigma_e}{\partial \sigma_{ij}} = \frac{\partial \sigma_e}{\partial s_{ij}} = \frac{3}{2} \frac{s_{ij}}{\sigma_e} \quad (\text{Eq 11})$$

Now,

$$d\epsilon_{ij}^p = \lambda \frac{3}{2} \frac{s_{ij}}{\sigma_e} \quad (\text{Eq 12})$$

Also,

$$d\epsilon_{ij}^p d\epsilon_{ij}^p = \lambda^2 \frac{9}{4} \frac{s_{ij}s_{ij}}{\sigma_e^2} = \frac{3}{2} \lambda^2 \quad (\text{Eq 13})$$

Thus,

$$\lambda = \sqrt{\frac{2}{3} d\epsilon_{ij}^p d\epsilon_{ij}^p} = d\epsilon_e^p \quad (\text{Eq 14})$$

where $d\epsilon_e^p$ is an effective strain increment. The volumetric component of the strain increment at yield is:

$$d\epsilon_v^p = d\epsilon_{ii}^p = \frac{3}{2} \frac{s_{ii}}{\sigma_e} = 0 \quad (\text{Eq 15})$$

which is consistent with the initial assumption of incompressibility.

This manipulation of equations is standard, but there are some important points to note:

- The effective stress, which drives the deformation, is only a function of the deviatoric stresses (i.e., it is independent of the magnitude of the mean stress).
- The strain increments at yield are proportional to the deviatoric components of stress.
- The deviatoric component of stress, and therefore the effective stress, drives changes of shape of an element.
- Volume changes are driven by the mean stress.

In the above description the magnitude of the strain increment at yield has not been determined; only the relative magnitudes of the strain components have been determined. To determine the magnitude, the evolution of the state of the material with time must be understood. In Eq 7, the state is represented in terms of the yield strength of the material. Use of a single state variable of this type implies isotropic behavior. Below, two particular forms of isotropic models are examined.

Perfect Plasticity. The simplest assumption is that the yield strength remains constant, in other words, the yield surface retains the same size and shape in stress space. The plastic strain increment $d\epsilon_{ij}^p$ can then have any value. In a structural problem, the exact value of the strain increment is determined either from the full elastoplastic response of the body or from any resulting geometry changes.

Isotropic Hardening. As the material is deformed plastically, the yield stress can increase. Consider the situation where yield strength is a function of the accumulated plastic strain ϵ_e^p :

$$\epsilon_e^p = \int_0^{\epsilon_e^p} d\epsilon_e^p \quad (\text{Eq 16})$$

that is,

$$\sigma_y = \sigma_y(\epsilon_e^p) \quad (\text{Eq 17})$$

and

$$d\sigma_y = \frac{d\sigma_y}{d\epsilon_e^p} d\epsilon_e^p = h(\sigma_y) d\epsilon_e^p \quad (\text{Eq 18})$$

where $h(\sigma_y)$ is the slope of a plot of yield strength against plastic strain in a standard uniaxial material test.

Plastic flow can only occur if the stress state is on the yield surface, in other words, plastic flow only occurs as the stress is increased from σ_{ij} to $\sigma_{ij} + d\sigma_{ij}$ if $f = 0$ throughout the increment and $(d\sigma_{ij})(\partial f / \partial \sigma_{ij}) > 0$. Then, differentiating (Eq 7) gives:

$$df = \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} + \frac{\partial f}{\partial \sigma_y} d\sigma_y = \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} - d\sigma_y = 0 \quad (\text{Eq 19})$$

Combining Eq 18 and 19 gives

$$d\epsilon_c^p = \frac{1}{h(\sigma_y)} \frac{\partial f}{\partial \sigma_{ij}} d\sigma_{ij} \quad (\text{Eq 20})$$

The individual strain increments can be obtained by combining Eq 20 with Eq 12 and 14.

In the above model, it is assumed that the material remains isotropic as it deforms plastically, so that the yield surface maintains the same shape and simply changes in size as plastic strain is accumulated. In practice, the material response can become anisotropic. One means of representing anisotropy is through the use of a kinematic hardening model, wherein the center of the yield surface in stress space is allowed to translate according to some rule. See Ref 12 for further information. As a different approach towards anisotropy, Hill (Ref 13) presents a generalized theory of plasticity that allows for a change in the shape of the yield surface, while the basic requirements of convexity and incompressibility are maintained.

There are many other types of constitutive laws that have been developed to model the response of plastically deforming materials. As in the models described here, these alternatives mainly consist of identifying a yield surface and developing appropriate laws for the expansion, translation, and change in shape of the surface as the material deforms plastically. These laws can contain many state variables, together with complex evolution laws. The choice of constitutive law depends on the type of loading histories being evaluated. If the stress history experienced by the material point is simple, then relatively simple constitutive laws adequately describe the material response. For example, for monotonic proportional loading, the kinematic and isotropic hardening models predict the same response provided they are fit to the same base data. A detailed knowledge of the shape and orientation of the entire yield surface and how these evolve with time is only required if complex loading histories are being considered. It should also be remembered that the more complex the constitutive law, the wider the range of tests that need to be devised to determine all the material parameters and the evolution equations for each of the state variables. When selecting the structure of a constitutive law, it is therefore important to first determine the type of stress history that each material point is likely to experience and to select the equations capable of capturing the major feature of the response.

In the following section, assume that the individual particles of a compact deform according to the constitutive models described in this section. This understanding provides a structure for the development of the constitutive laws for the compact.

The Structure of Constitutive Laws for Powder Material

Consider an element of a powder compact (Fig. 7), subjected to a macroscopic stress state Σ_{ij} , and experiencing strains E_{ij} . The strain can be decomposed into macroscopic elastic and plastic components, as before:

$$E_{ij} = E_{ij}^e + E_{ij}^p \quad (\text{Eq 21})$$

Assume that the elastic response is isotropic. The elastic constitutive law can then be expressed in the form of Eq 5:

$$E_{ij}^e = E_{ij}^{ed} + \frac{1}{3} E_v^e \delta_{ij} = \frac{S_{ij}}{2G} + \frac{\Sigma_m}{3K} \delta_{ij} \quad (\text{Eq 22})$$

where G and K are functions of the state of the material. Several techniques for determining the elastic moduli G and K are summarized in Table 1. It is sometimes more practical to measure Young's modulus E instead of shear modulus G . Shear modulus can be determined using $G = 3KE/9(K - E)$.

Table 1 Experimental techniques for the determination of elastic properties of powder compacts

Experimental technique	Elastic property	Comments	Reference
Triaxial test unloading	$E(D)$	Can determine E at low density (D is ~ 0.65 for atomized steel powders). Experimental apparatus is involved.	Ref 14
Resonant frequency	$E(D)$	Very accurate and repeatable. Simple experimental setup. Simple sample preparation. Commercial laboratories available that use this technique. Minimum density D is ~ 0.75 for atomized steel powders.	Ref 15
Ultrasound	$E(D)$	Higher scatter than resonant frequency. Able to determine anisotropic properties in a transverse rupture bar.	Ref 15
Hydrostatic test unloading	$K(D)$	Can determine K at low density (D is ~ 0.65 for atomized steel powders). Experimentally difficult at very high density.	Ref 14

Fig. 7 Macroscopic element of powder compact subjected to stresses Σ_{ij}

The variables E and K can be measured during the unloading of a triaxial compaction test and a hydrostatic compaction test, respectively. Another technique used to determine E is resonant frequency. The powder is compacted into a beam, typically a transverse rupture bar. The beam is excited through an impact load, and the natural vibration frequency is measured. This frequency can be used to compute E . Ultrasound has also been applied to the determination of E in compacted specimens.

Watson and Wert (Ref 9) measured the variation of G and K as a function of D for samples which had been compacted in closed die. They found that:

$$G = G_m \exp(8.15(D - 1)) \tag{Eq 23}$$

$$\chi = \chi_m \exp(5(D - 1)) \quad (\text{Eq 24})$$

with

$$K = \chi + \frac{2}{3}G \quad (\text{Eq 25})$$

and G_m and χ_m representing the shear modulus and Lamé constant for the fully dense material, respectively.

If a microscopic element deforms plastically according to any of the models described, and there are no other dissipative mechanisms operating, then it is possible to identify a yield surface in stress space:

$$F = F(\Sigma_{ij}, S_\alpha) = 0 \quad (\text{Eq 26})$$

which is a function of stress and the state of the material, described in terms of a number of state variables, S_α . Plastic flow can only occur if the stress state is on the yield surface. It can further be shown that associated flow at the micro-level guarantees associated flow at the macroscopic level, thus:

$$dE_{ij}^p = \Lambda \frac{\partial F}{\partial \Sigma_{ij}} \quad (\text{Eq 27})$$

where Λ is the macroscopic plastic multiplier.

If frictional sliding contributed to the internal dissipative processes, then it is still possible to identify a yield surface, but associated plastic flow cannot be guaranteed. Fleck (Ref 16) has examined the two extremes of frictional behavior: free sliding; and sticking, whereby sliding can only occur by shear yielding in the vicinity of a contact. In each case, there is no frictional dissipation and associated flow can be guaranteed. The yield surface for intermediate frictional conditions should lie between the yield surfaces for these two situations. Fleck (Ref 16) found that there is only a small difference between the surfaces for a given assumed state, indicating that only a small amount of energy is dissipated by shearing between the particles. Thus, even if frictional sliding occurs it will only have a small influence on the macroscopic response, and it is appropriate to assume that an associated flow rule is valid.

During compaction the stress point remains on the yield surface, therefore, following Eq 19:

$$dF = \frac{\partial F}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial F}{\partial S_\alpha} dS_\alpha = 0 \quad (\text{Eq 28})$$

In order to complete the model, evolution laws for the state variables in terms of the stress, strain, and the state of the material are needed. In the models, the state could be described in terms of suitable measures of strain, or alternatively, plastic strains can be considered the state variables. Then Eq 28 becomes:

$$dF = \frac{\partial F}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial F}{\partial E_{ij}^p} dE_{ij}^p = 0 \quad (\text{Eq 29})$$

Combining Eq 29 with Eq 27 gives

$$\Lambda = - \frac{(\partial F / \partial \Sigma_{ij}) d\Sigma_{ij}}{(\partial F / \partial E_{kl}^p) dE_{kl}^p} \quad (\text{Eq 30})$$

with the individual strain components given by (Eq 27).

To simplify constitutive models, isotropic behavior is often assumed. This consideration dictates the use of mechanical and material descriptions independent of a particular choice of coordinate system. This freedom allows one to use rotation invariant or coordinate system independent quantities in the constitutive model. For the mechanical stress or strain, which are mathematically represented as tensors of the second order, these quantities are the first and second tensor invariants.

The yield function can then be expressed as a function of $\Sigma_e = \sqrt{3/2 S_{ij} S_{ij}}$, the macroscopic von Mises effective stress in the powder aggregate, a form of the second invariant of the macroscopic stress and $\Sigma_m = \frac{1}{3} \Sigma_{kk}$, the mean stress in the powder aggregate, a form of the first invariant of the macroscopic stress. Equation 26 then assumes the form: $F = F(\Sigma_e, \Sigma_m, S_{\alpha}) = 0$.

If appropriate forms for the yield function in terms of the stress and accumulated plastic strain can be found, the above equations can be employed to determine the full constitutive response. In the following sections, different possible forms of the yield function are examined.

Yield Functions from Micromechanical Models. The section "Deformation of Powder Compacts: Experimental Observations" states the nature of the porosity changes as a material densifies. Initially, the porosity is open and distinct necks exist between the contacting particles (stage 1). At high relative densities ($D > 0.9$), the porosity is closed, which is referred to as stage 2. Different forms of micromechanical models have been developed for these two stages. In the stage 1 models, it is assumed that there is no interaction between the deformation zones that form in the vicinity of the different contacts. Analyses of the contact of two isolated bodies can then be used to obtain the appropriate contact law for a given microplasticity model. The macroscopic response is then determined by combining the contributions from each contact. Fleck et al. (Ref 16) employed a perfectly plastic microplasticity model and assumed that the material was isotropic and could be described using a single state variable, which they took to be the relative density, D . This assumption is equivalent to assuming that the material had previously been compacted isostatically to a given density. From their analysis, Fleck et al. (Ref 16) propose an approximate yield function:

$$F = \left(\frac{\sqrt{5} \Sigma_m}{3 P_y} \right)^2 + \left(\frac{5 \Sigma_e}{18 P_y} + \frac{2}{3} \right)^2 - 1 = 0 \quad (\text{Eq 31})$$

where P_y is the yield strength in hydrostatic compression;

$$P_y = 3 D^2 \frac{(D - D_0)}{(1 - D_0)} \sigma_y \quad (\text{Eq 32})$$

where D_0 is the initial dense random packing density, which is generally taken to be 0.64.

The full response can be obtained from Eq 26 to Eq 30 by noting that the densification rate is given by (neglecting elastic volume changes):

$$\dot{D} = - D \dot{E}_{kk}^p \quad (\text{Eq 33})$$

In practice, the matrix material can strain harden as the contact zones deform plastically. Fleck et al. (Ref 16) demonstrate how the effects of strain hardening can be taken into account. A more compact form of model can be obtained by rewriting Eq 31 in the form of Eq 7, that is,

$$F = \bar{\Sigma} - \sigma_y = 0 \quad (\text{Eq 34})$$

where $\bar{\Sigma}$ is an effective stress for the porous material, which is a function of the macroscopic stress and internal geometry described by D . Rearranging Eq 31 then gives:

$$\bar{\Sigma} = \left[\frac{1}{3} \Sigma_c + \sqrt{\frac{1}{4} \Sigma_c^2 + \Sigma_m^2} \right] \frac{(1 - D_0)}{3D^2 (D - D_0)} \quad (\text{Eq 35})$$

For loading conditions on the yield surface, Eq 29 becomes:

$$dF = \frac{\partial \bar{\Sigma}}{\partial \Sigma_{ij}} d\Sigma_{ij} + \frac{\partial \bar{\Sigma}}{\partial D} dD - d\sigma_y = 0 \quad (\text{Eq 36})$$

Fleck et al. (Ref 16) take σ_y to be the average yield strength in the plastically deforming material, and they define an average internal effective strain increment, $d\varepsilon_e^P$, by equating the internal and external work. Using the current terminology,

$$\Sigma_{ij} dE_{ij}^P = \bar{\Sigma} \Lambda = \sigma_y \Lambda = G(D) \sigma_y d\varepsilon_e^P \quad (\text{Eq 37})$$

where $G(D)$ is the effective volume fraction of plastically deforming material, given by Fleck (Ref 17) as:

$$G(D) = \frac{45}{\sqrt{3}} D^2 \left(\frac{D - D_0}{1 - D_0} \right)^{3/2} \quad (\text{Eq 38})$$

Combining Eq 36, 37, 33, and 18 gives:

$$\Lambda = d\bar{E} = \frac{(\partial \bar{\Sigma} / \partial \Sigma_{ij}) d\Sigma_{ij}}{D(\partial \bar{\Sigma} / \partial D)(\partial \bar{\Sigma} / \partial \Sigma_{kk}) + [h(\sigma_y) / G(D)]} \quad (\text{Eq 39})$$

where $d\bar{E}$ is a macroscopic effective plastic strain increment not to be confused with the von Mises effective strain increment, dE_e . The advantage of this form is that it separates out the effects of geometric and material hardening and it leads to a more compact expression than the relationships proposed by Fleck et al. (Ref 16).

In the development of the above model, two major assumptions were made: the strengths of the contact zones were assumed to be the same in tension and compression, and the material was assumed to be isotropic. It was demonstrated in the section "Deformation of Powder Compacts: Experimental Observations" that the strengths of the contacts are likely to be different in compression and tension, particularly for smooth particles. Also, when a compact is loaded along stress paths other than hydrostatic, the microstructure (the distribution of necks) becomes anisotropic.

Fleck (Ref 17) has proposed a model in which the tensile strength of a contact patch is less than the compressive strength by a factor η . If P_y (Eq 33) is the magnitude of the pressure required to plastically deform a compact, then the magnitude of the hydrostatic tensile stress required to initiate plastic flow is ηP_y . Fitting a quadratic to Fleck's results and adopting the form of expression presented in Eq 34, the following equation is obtained:

$$\begin{aligned} \bar{\Sigma} = & \frac{1}{\eta} \left[\frac{1}{6} \Sigma_c (1 + \eta) + \frac{1}{2} \Sigma_m (1 - \eta) \right. \\ & \left. + \sqrt{\frac{1}{36} \Sigma_c^2 (1 + 7\eta + \eta^2) + \frac{1}{4} \Sigma_m^2 (1 + \eta)^2 + \frac{1}{6} \Sigma_c \Sigma_m (1 - \eta^2)} \right] \\ & \frac{(1 - D_0)}{3D^2 (D - D_0)} \end{aligned} \quad (\text{Eq 40})$$

This expression reduces to Eq 35 when $\eta = 1$. When $\eta = 0$, it becomes:

$$\bar{\Sigma} = - \frac{4\Sigma_m^2 + \frac{5}{9}\Sigma_e^2(1 - D_0)}{4\Sigma_m + \frac{4}{3}\Sigma_e 3D^2(D - D_0)} \quad (\text{Eq 41})$$

The yield surfaces are plotted in Fig. 8 for $\eta = 0$ and 1, where they are compared with the surfaces obtained by Fleck (Ref 17). It should be noted that these surfaces have vertices where they meet the Σ_m axis. The direction of the strain increment vector is nonunique for pure hydrostatic stress states, which can lead to computational difficulties when implementing this model. In practice, this nonuniqueness has been bypassed by inserting a circular arc at the vertex to ensure a smooth continuous yield surface (Ref 19).

(b)

Fig. 8 Yield surfaces predicted by Fleck's (Ref 17) isotropic model for (a) $\eta = 0$ and (b) $\eta = 1$, compared with the prediction of Eq 41 and 35

Fleck (Ref 17) has also examined the influence of material anisotropy by relating the size and number of contacts at a given orientation to the plastic strain E_{ij}^P . The surface for frictionless closed-die compaction, normalized by the hydrostatic stress, P , required to compact the material to the same density is shown in Fig. 9 for $\eta = 0$, where it is compared with the comparable surface for hydrostatic compaction. There are a number of important points to note:

- The surface for closed-die compaction is extended in the direction of loading and contracted in the transverse direction compared to the surface for hydrostatic compaction. Thus, the yield behavior cannot be described in terms of the relative density alone.
- The vertex on the yield surface is at the loading point. Similar results are obtained for crystal plasticity theory applied to fully dense materials.
- The yield surfaces expand in a self-similar manner. Thus, the different components of stress increase in proportion to each other when the straining is proportional.
- It is not possible to obtain a closed form solution for arbitrary loading paths. Thus, the full micromechanical model is required in order to compute the constitutive response.

The predictions of this model are compared with the experimental results of Akisanya et al. (Ref 10), shown in Fig. 10 for hydrostatic and closed die compaction. It is evident that the general form of these surfaces is well represented by this model.

Fig. 9 Yield surfaces for isostatic and closed-die compaction predicted by the anisotropic model of Fleck (Ref 17)

Fig. 10 Comparison of Fleck's (Ref 17) model with the experimental results of Akisanya et al. (Ref 10)

So far only the early stages of compaction, when distinct necks exist between the particles, have been discussed. In the latter stages of compaction ($D > 0.9$), the pores are isolated. Constitutive models employed in this regime have been taken from studies originally concerned with ductile failure. In these models, the pores are assumed to remain spherical. The most widely used model is developed by Gurson (Ref 20), which predicts a yield surface given by:

$$F = \left(\frac{\Sigma_c}{D\sigma_y} \right)^2 + \frac{2(1-D)}{D^2} \cosh \left(\frac{3\Sigma_m}{2\sigma_y} \right) - \frac{2(1-D)}{D^2} - 1 = 0 \quad (\text{Eq 42})$$

This expression suffers from the same problem as Eq 31, in that the effects of material and geometric hardening are coupled. Cocks (Ref 21) proposed that a more appropriate form for the constitutive model, which does not differ significantly from that proposed by Gurson (Ref 20), is given by Eq 34, with

$$\bar{\Sigma} = \sqrt{\frac{\Sigma_c^2}{G_1(D)} + \frac{\Sigma_m^2}{G_2(D)}} \quad (\text{Eq 43})$$

where

$$G_1(D) = \frac{3D^2}{5-2D} \quad (\text{Eq 44})$$

$$G_2(D) = \left(\ln \left(\frac{1}{(1-D)^2} \right) \right)^2 \quad (\text{Eq 45})$$

Equations 36, 37, 38, and 39 for the constitutive response again apply, where, now, $G(D) = D$.

In practice, the pores do not achieve a spherical shape during the latter stages of compaction. Instead, they maintain a cusp shaped profile. Liu et al. (Ref 22) and Akisanya et al. (Ref 23) have demonstrated that bodies with cusp-shaped pores have greater compressibility than bodies with spherical pores at the same density. Qian et al. (Ref 24) have suggested how the influence of the cusp-shaped pores can be incorporated into the constitutive models for creeping materials. They still assume that the body is isotropic macroscopically. Extending their analysis to a perfectly plastic material would simply result in different definitions of $G_1(D)$ and $G_2(D)$ in Eq 43.

Under general loading situations, the expectation might be that the pores would become squashed in the main direction of compaction. Ponte Castenada (Ref 25) has examined the effect of oriented ellipsoidal-shaped pores on the constitutive response, but there have not been any studies of the influence of distorted cusp-shaped pores on the material behavior. In all the stage 2 models, it has always been assumed that the contact patches between the distorted particles are able to support tensile tractions and the contacting particles are unable to slide over each other. There has been no attempt to analyze the effect of the strength of these contacts on the constitutive response.

The yield surfaces for stage 1 and stage 2 compaction can have different shapes. In order to ensure a smooth transition, a gradual change from one shape to another is assumed to occur over a given range of relative density. Assuming a linear variation from the yield expression for stage 1 to that for stage 2 over the range D_1 to D_2 gives:

$$\bar{\Sigma} = \left(\frac{D_2 - D}{D_2 - D_1} \right) \bar{\Sigma}_1 + \left(\frac{D - D_1}{D_2 - D_1} \right) \bar{\Sigma}_2 \quad (\text{Eq 46})$$

where $\bar{\Sigma}_1$ is the effective stress for stage 1 compaction and $\bar{\Sigma}_2$ is the effective stress during stage 2. In practice, the transition is generally assumed to occur over the range $D_1 = 0.77$ to $D_2 = 0.9$.

Empirical Yield Functions. In the empirical models of powder compaction, the different form of porosity in stage 1 and stage 2 is not considered. Simple continuous expressions for the yield function are developed that satisfy the condition that the material response is incompressible when $D = 1$. The most widely used expressions are those due to Kuhn and Downey (Ref 6) and Shima and Oyane (Ref 7). These models have the same general structure as those described in the section "Yield Functions from Micromechanical Models." The yield function can again be represented in the form of Eq 34. For simplicity, a quadratic function of the von Mises effective stress, Σ_e , and mean stress, Σ_m , is assumed for $\bar{\Sigma}$. It is further assumed that the material response can be described in terms of a single state variable, the relative density, D . $\bar{\Sigma}$ can then be expressed in the form of Eq 43, where $G_1(D)$ and $G_2(D)$ are determined experimentally by assuming that the material yield strength σ_y remains constant. Shima and Oyane (Ref 7) determined these quantities by compacting samples in a closed die to a given density, sintering the samples and then performing uniaxial tensile and compressive tests to determine the yield properties. By measuring the uniaxial yield strength and Poisson's ratio, $G_1(D)$ and $G_2(D)$ could be determined at the chosen density; and by repeating these tests at different densities, the complete functions $G_1(D)$ and $G_2(D)$ could be determined. Their results for copper and iron powders are well approximated by:

$$G_1(D) = D^5 \quad (\text{Eq 47})$$

$$G_2(D) = \frac{D^5}{6.25(1-D)} \quad (\text{Eq 48})$$

The above form has been employed by a number of authors in experimental and computational studies of powder compaction. Kim and Suh (Ref 26) recognized that a material could harden as a result of shear deformation as well as a result of densification. They proposed a modified form of expression for the yield function:

$$F = \bar{\Sigma} - \kappa = 0 \quad (\text{Eq 49})$$

with

$$\bar{\Sigma} = \sqrt{\Sigma_e^2 + 1.2(1 - D)\Sigma_m^2} \quad (\text{Eq 50})$$

Here κ is the effective yield strength of the compact. The evolution law for κ is assumed to be of the form:

$$d\kappa = \beta_1 \sigma_e d\varepsilon_e + \beta_2 \sigma_m d\varepsilon_{kk} \quad (\text{Eq 51})$$

which takes into account geometric and material hardening. Now, from Eq 28 and 51, find:

$$\Lambda = \frac{(\partial \bar{\Sigma} / \partial \Sigma_e) d\Sigma_e + (\partial \bar{\Sigma} / \partial \Sigma_m) d\Sigma_m}{D (\partial \bar{\Sigma} / \partial D) (\partial \bar{\Sigma} / \partial \Sigma_m) + \beta_1 (\partial \bar{\Sigma} / \partial \Sigma_e) \Sigma_e + \beta_2 (\partial \bar{\Sigma} / \partial \Sigma_m) \Sigma_m} \quad (\text{Eq 52})$$

and the individual plastic strain increments are given by Eq 27. The yield function of Eq 49 was found to give a slightly better fit of the tension/torsion experiments of Kim et al. (Ref 5) on sintered iron compacts discussed earlier than the model of Shima and Oyane (Ref 7).

These models were validated by performing experiments on sintered compacts. The effect of the sintering process is to anneal the particles and to bond them together. As a result, the yield strength is expected to be the same in tension and compression, as observed by Shima and Oyane (Ref 7), and it is not unreasonable for a quadratic function, such as those presented in Eq 43 and 50, to adequately describe the shape of the yield surface. A consequence of this choice of yield function is that it will always predict a negative volumetric strain-rate when the mean stress is negative (i.e., compaction will always occur under net compressive stress states). In experiments on compacted, but not sintered, powders, Brown and Abou-Chedid (Ref 27) and Watson and Wert (Ref 9) observed that the volumetric strains were positive in uniaxial compression.

Based on their experimental observations, Watson and Wert (Ref 9) proposed the adoption of Drucker and Prager's (Ref 28) two part yield surface, which has been employed to model the response of soils. This surface is shown schematically in Fig. 11 and consists of a shear surface and a spherical cap. Watson and Wert (Ref 9) assumed associated flow for both surfaces (i.e., the strain-increment vector is normal to the surface). Thus, dilation occurs for stress states on the shear surface and compaction occurs if the loading point lies on the spherical cap.

Fig. 11 Schematic of Watson and Wert's (Ref 9) two surface Drucker-Prager model

Following Gurson and McCabe (Ref 29), Brown and Abou-Chedid (Ref 27) proposed a modified form of the Cam-Clay model (Ref 30, 31) to model their experiments. In this model the yield surface is represented by Eq 34, with

$$\bar{\Sigma} = \sqrt{A(D)\Sigma_e^2 + B(D)(\Sigma_m - C)^2} \quad (\text{Eq 53})$$

Brown and Abou-Chedid (Ref 27) did not propose forms for the functions $A(D)$ and $B(D)$. More detailed experiments are required to determine the exact form of these expressions.

The macroscopic effective stress of Eq 53 is similar to the quadratic forms of Eq 43 and 50, but now the elliptic surface is centered on the point $(0, C)$ in $\Sigma_e - \Sigma_m$ space. The quantity C represents the degree of cohesion between the particles. If they are perfectly bonded, $C = 0$, and the surface reduces to the symmetric expressions of Eq 43 and 50, which is appropriate for sintered materials. If the particles are smooth and the contacts are unable to support a normal tensile stress, then the value of C can be chosen so that the yield surface passes through the origin, as in the micromechanical model of Eq 41 for $\eta = 0$. Then,

$$C = -\frac{\Sigma}{(B(D))^{1/2}} \quad (\text{Eq 54})$$

and Eq 53 becomes

$$\bar{\Sigma} = -\frac{A(D)\Sigma_e^2 + B(D)\Sigma_m^2}{2(B(D))^{1/2} \Sigma_m} \quad (\text{Eq 55})$$

Equation 55 is equivalent to the most common form of Cam-Clay model used to evaluate the response of soils (Ref 31).

These last two models were derived from constitutive laws that have been developed for soils. A wide range of models have been proposed in the literature for granular materials, in which the yield surfaces are allowed to adopt different shapes, as well as being able to translate in stress space, in a similar manner to the kinematic models (Ref 31).

A Constitutive Model for Metallic Powders with Ductile Particles

Several constitutive models have been applied to the numerical simulation of powder compaction in dies. The most widely used are variations of two types of models: models with an empirical quadratic yield function (Ref 32, 33, 34, 40, and 41) and Cap models (Ref 35, 36, 38, and 39).

The main practical advantages of a model of the first type as developed in Ref 34, 36, 40, and 41 include:

- A reasonable representation of the behavior of metal powders with ductile particles under monotonic loading
- A continuous yield function that facilitates its numerical implementation
- Experimental calibration with a relatively small number of tests

Furthermore, this model has been implemented in the compaction modeling finite element code PCS (Ref 42) that is in use by several parts manufacturers in the United States. The overall strategy presented here can be employed for any of the models described in the section "Constitutive Models for Metal Powder Compaction." The only difference lies in the range of experiments that need to be performed in order to determine any unknown functions in the models.

Model Formulation

The model considered in detail here uses an empirical yield function and fits the general framework presented earlier with assumptions:

- As the powder aggregate is compacted, the particles deform plastically according to the behavior described by classical plasticity with isotropic hardening
- The powder compact displays macroscopic elastic-plastic behavior that is isotropic and independent of strain rate
- The total strain can be decomposed into elastic and plastic components
- The contributions of particle sliding to the overall deformation are negligible
- The state of the powder aggregate is represented by two state variables, the relative density, D , and the yield strength of the powder particle σ_y

Rigorously, for elastic-plastic models, a slightly different definition of the relative density D is necessary when D is used as a state variable. Earlier D was defined as the ratio of the density of powder to the density of the fully dense material. However, the plastic state of the material should not be affected by the changes in D that are due to elastic deformation. A more appropriate definition of D is the ratio of the density of unloaded powder to the density of the fully dense material, the relaxed relative density of the powder aggregate.

Following the general approach presented earlier, consider an element of a powder compact, which is subjected to a macroscopic stress state \sum_{ij} and experiences strains E_{ij} . The strain can be decomposed into macroscopic elastic and plastic components as per Eq 21:

$$E_{ij} = E_{ij}^e + E_{ij}^p \quad (\text{Eq 56})$$

Here assume that the elastic response is isotropic. The elastic constitutive law can then be expressed by Eq 22:

$$E_{ij}^e = E_{ij}^{ed} + \frac{1}{3} E_v^e \delta_{ij} = \frac{S_{ij}}{2G} + \frac{\Sigma_m}{3K} \delta_{ij} \quad (\text{Eq 57})$$

where G and K are functions of D .

An empirical yield function F of the general form of Eq 26, which is a function of the stress state and two state variables, is given by:

$$F = F(\Sigma_e, P, \sigma_y, D) = 0 \quad (\text{Eq 58})$$

where $P = -\frac{1}{3} \Sigma_{kk} = -\Sigma_m$, is the pressure, a form of the first invariant of the macroscopic stress.

The specific form of the yield function is as defined in Eq 34 and 43:

$$F = \frac{\Sigma_e^2}{G_1(D)} + \frac{P^2}{G_2(D)} - \sigma_y^2 = 0 \quad (\text{Eq 59})$$

As the powder aggregate densifies and reaches high relative density, its response will approach the incompressible plastic behavior of fully dense metals. Therefore, the function $G_1(D)$ is expected to increase monotonically with an increase in relative density and the function $G_2(D)$ is expected to decrease monotonically with an increase in relative density.

The yield functions developed by Trasorras et al. (Ref 34) involved functions $b(D)$ and $c(D)$ that are expressible in terms of the functions $G_1(D)$ and $G_2(D)$ in the following manner: $G_1(D) = c(D)$ and $G_2(D) = 3c(D)/2b(D)$.

In the following development, the yield function is cast in the form used in Ref 34.

$$F = \Sigma_e^2 + \frac{3}{2} b(D)P^2 - c(D)\sigma_y^2 = 0 \quad (\text{Eq 60})$$

The functions $b(D)$ and $c(D)$ are to be determined through experiments.

The associated flow at the macroscopic level (from Eq 27) yields:

$$\begin{aligned} dE_{ij}^p &= d\Lambda \frac{\partial F}{\partial \Sigma_{ij}} = d\Lambda \left[\frac{\partial F}{\partial \Sigma_e} \frac{\partial \Sigma_e}{\partial \Sigma_{ij}} + \frac{\partial F}{\partial P} \frac{\partial P}{\partial \Sigma_{ij}} \right] \\ &= 3d\Lambda \left[S_{ij} - \frac{1}{3} Pb(D)\delta_{ij} \right] \end{aligned} \quad (\text{Eq 61})$$

From Eq 61, the volumetric and deviatoric components of the plastic strain are given by:

$$dE_v^p = -d\Lambda \frac{\partial F}{\partial P} = -3d\Lambda Pb \quad (\text{Eq 62})$$

$$dE_e^p = d\Lambda \frac{\partial F}{\partial \Sigma_e} = 2\Sigma_e d\Lambda \quad (\text{Eq 63})$$

Eliminating $d\Lambda$ allows

$$dE_v^p \frac{\partial F}{\partial \Sigma_e} + dE_e^p \frac{\partial F}{\partial P} = 0 \quad (\text{Eq 64})$$

The conservation of mass is expressed in the form of the continuity equation (from Eq 33):

$$\dot{D} = -D \dot{E}_{kk}^p \quad (\text{Eq 65})$$

On integration, the continuity equation yields the following result for the evolution of relaxed relative density,

$$D = D_0 \exp(-E_{kk}^p) \quad (\text{Eq 66})$$

The isotropic hardening law for the powder particle (from Eq 18) is:

$$d\sigma_y = h d\varepsilon_e^p \quad (\text{Eq 67})$$

The particle hardening h may be constant (isotropic linear hardening), or may be a function of equivalent plastic strain in the particle.

If the energy dissipated by particle sliding is negligible, as assumed earlier, the external and internal plastic work of deformation can be equated (from Eq 37 with $G(D) = D$):

$$\Sigma_{ij} dE_{ij}^p = D \sigma_y d\varepsilon_e^p \quad (\text{Eq 68})$$

Application to Powder Blends

In the previous sections, the constitutive models have assumed that the powder consists of an aggregate of metal particles of a single kind. In powder compaction in dies, the powder blend will contain lubricant, and in the case of ferrous alloys, often graphite and other alloying elements as well. The theories presented here are expected to be valid for powder blends, provided that the additions to the base metal powder occupy a small volume of the total aggregate (typically a few volume percent). That being the case, the models can be used with the constraints that:

- The relative density D be defined as the ratio of the total density of the powder to the pore-free density of the powder to enforce a plastically incompressible behavior when the material reaches the pore-free density, as opposed to the density of the fully dense metal particle.
- The elastic properties, which are strongly dependent on the presence of nonmetallic constituents, be determined experimentally for the specific blend.
- The constitutive functions $b(D)$ and $c(D)$ be experimentally determined for the specific blend.

Experimental Determination of Powder Material Constitutive Properties and Functions

In this section, the experimental procedures that can be applied to determine the constitutive parameters that appear in the model of the preceding section are presented. Techniques used to determine the elastic parameters and the form of the yield function have been described in the section "Deformation of Powder Compacts: Experimental Observations."

Triaxial Tests

A brief description of the triaxial test and apparatus is presented in this section. For a more detailed treatment of the test, stemming from a soil mechanics perspective, see Ref 31. The triaxial test is important as it provides a convenient means of examining a variety of situations involving different ratios of the deviatoric and hydrostatic stress measures. A schematic of the triaxial test cell is shown in Fig. 12. The powder is placed in a container with a flexible wall, typically made of an elastomer, and immersed in a fluid under a pressure, p . Take care not to confuse this notation for the magnitude of fluid pressure with the one used elsewhere for the hydrostatic component of stress (P). A ram at the top of the apparatus provides a means of increasing the axial load on the powder while maintaining fluid pressure. Knowledge of the cell pressure as well as the applied ram load allows for the calculation of the resulting axial stress in the test sample. In addition, appropriate instrumentation on the apparatus ensures measurement of axial and radial dimensional changes. These measurements can then be translated into axial and radial strains. With the added assumption of a uniform stress state in the specimen and isotropic behavior of the material, it is reasonable to conclude that the radial and tangential strains, as well as radial and tangential stresses, are equal. Macroscopically, the stress state of the powder can be stated as:

$$\Sigma_z = - \left[\frac{F}{A} + p \left(1 - \frac{a}{A} \right) \right] \quad (\text{Eq 69})$$

$$\Sigma_r = -p \quad (\text{Eq 70})$$

Fig. 12 Triaxial compaction cell. Source: Ref 31

The quantities A and a are the areas of cross section of the specimen and ram, respectively. The strains are calculated as:

$$E_r = \ln \left(\frac{r}{r_0} \right) \quad (\text{Eq 71})$$

$$E_z = \ln \left(\frac{l}{l_0} \right) \quad (\text{Eq 72})$$

where r_0 and l_0 are, respectively, the initial radius and length of the compact, and r and l , the current values of these quantities. The deviatoric and hydrostatic components of stress reduce to:

$$\Sigma_e = \sqrt{\frac{3}{2} S_{ij} S_{ij}} = \Sigma_r - \Sigma_z \quad (\text{Eq 73})$$

$$P = -\frac{1}{3}(2\Sigma_r + \Sigma_z) \quad (\text{Eq 74})$$

In soil mechanics, triaxial tests are often performed in one of three ways, as depicted in Fig. 13. The first, the isostatic compaction test, is used to characterize soils under hydrostatic loading and to determine the elastic bulk modulus. In this test, the ram load is maintained insofar as to ensure a hydrostatic state of stress in the test specimen. The second test, the consolidated triaxial test, involves initial pressurization of the test cell followed by an increase in ram load, the cell pressure being maintained constant. The path of stress on the P - Σ_e plane has a slope of 3 as the axial load increases at constant confining pressure. This path can be verified by taking the derivatives of the expressions for P and Σ_e while keeping p constant, and then calculating the slope using the ratio of the derivatives. Finally, the overconsolidated tests are employed to help determine the shape of the yield surface on the P - Σ_e plane. The test consists of subjecting the specimen to a history of deformation under pure pressure, following this by unloading to an intermediate pressure, and subsequently increasing the ram load while maintaining cell pressure to determine a different point on the yield surface.

Fig. 13 Stress paths in isostatic compaction test, consolidated triaxial compaction test, and overconsolidated compaction test. Source: Ref 43

As presented in the section "Deformation of Powder Compacts: Experimental Observations," the size and shape of the yield surface are functions of the history of loading. Thus, if the strain history only involved hydrostatic loading, subsequent probing of the yield surface in the manner of an overconsolidated triaxial test will only identify a yield surface defined by this initial loading. A different picture will emerge if the yield surface is identified following a stress path, such as the one used in a consolidation test, followed by unloading and subsequent probing of the yield surface (Fig. 3). This is of particular importance when considering tests to be used for material parameter extraction; the best tests shall be those involving stress paths as close to the real situation as possible. In the case of compaction in dies, the compact is constrained radially. The triaxial test setup should then include control of cell pressure to ensure zero radial strain in the sample to simulate actual compaction conditions.

Calibration of Material Parameters for an Iron Powder Blend

The procedures of the previous section are applied below to the calibration of the two-state variable model introduced earlier. The data is for a powder blend comprising 99.5% by weight of Distalloy AE, 0.5% by weight of graphite, and 1% wax Hoechst micropulver. This last component is admixed as internal lubricant. Distalloy AE is a diffusion alloyed iron powder with composition 4 wt% Ni, 1.5 wt% Cu, and 0.5 wt% Mo. Particle sizes for this powder range from 20 to 180 μ

m. The apparent density of the powder is 3.04 g/cm³; the pore free density of the material is 7.33 g/cm³. The data used are from experiments reported by Pavier and Doremus (Ref 14).

Consider the yield function of the model introduced in the section "A Constitutive Model for Metallic Powders with Ductile Particles" :

$$F = \Sigma_e^2 + \frac{3}{2} b(D) P^2 - c(D) \sigma_y^2 = 0$$

To fully determine the yield function F the functions $b(D)$ and $c(D)$ must be identified. Figure 14 illustrates the yield surface for a lubricated atomized iron powder (Hoeganaes Ancorsteel 1000). The surface is plotted for different values of relative density and particle yield stress pairs. For this powder, the functions $b(D)$ and $c(D)$ were determined by Trasorras et al. (Ref 40) to be:

$$b(D) = \frac{0.13 D^{-5.6}}{(D + 0.62)^{1.35}} \quad (\text{Eq 75})$$

$$c(D) = D^6 \quad (\text{Eq 76})$$

The constitutive model has two-state variables and requires two different kinds of tests for its calibration.

Fig. 14 Yield surface for lubricated atomized iron powder (Hoeganaes Ancorsteel 1000). Surface plotted for different values of relative density and particle hardening

Triaxial Consolidation Test for $b(D)$. The state of stress in the test specimen is assumed to be uniform throughout (homogeneous). This assumption leads to the result that the radial Σ_r and tangential Σ_z stresses are equal and given by the cell pressure. If the specimen is cylindrical in shape, the components of stress in the powder aggregate can then be appropriately defined using a cylindrical coordinate system as follows:

$$[\Sigma] = \begin{bmatrix} -\Sigma_r & 0 & 0 \\ 0 & -\Sigma_r & 0 \\ 0 & 0 & -\Sigma_z \end{bmatrix} \quad (\text{Eq 77})$$

The negative signs are assigned to indicate the compressive nature of the stresses in the aggregate. The deviatoric and pressure components are then:

$$P = -\frac{1}{3}(-\Sigma_r - \Sigma_r - \Sigma_z) = \frac{1}{3}(2\Sigma_r + \Sigma_z) \quad (\text{Eq 78})$$

$$S = \Sigma + PI = \begin{bmatrix} -\frac{1}{3}\Sigma_r + \frac{1}{3}\Sigma_z & 0 & 0 \\ 0 & -\frac{1}{3}\Sigma_r + \frac{1}{3}\Sigma_z & 0 \\ 0 & 0 & \frac{2}{3}\Sigma_r - \frac{2}{3}\Sigma_z \end{bmatrix} \quad (\text{Eq 79})$$

Calculating $\Sigma_e = \frac{3}{2} \sqrt{S_{ij}S_{ij}}$, find

$$\Sigma_e^2 = \frac{3}{2} \left(\frac{2}{9} (\Sigma_z - \Sigma_r)^2 + \frac{4}{9} (\Sigma_r - \Sigma_z)^2 \right) \quad (\text{Eq 80})$$

$$\Sigma_e = \sqrt{(\Sigma_z - \Sigma_r)^2} \quad (\text{Eq 81})$$

The increment of plastic strain given by Eq 61 is:

$$\begin{aligned} \Delta E_r^p &= 3\Delta\Lambda \left[\frac{1}{3}(\Sigma_z - \Sigma_r) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \\ \Delta E_\theta^p &= 3\Delta\Lambda \left[\frac{1}{3}(\Sigma_z - \Sigma_r) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \\ \Delta E_z^p &= 3\Delta\Lambda \left[\frac{2}{3}(\Sigma_r - \Sigma_z) - \frac{1}{9}(2\Sigma_r + \Sigma_z)b(D) \right] \end{aligned} \quad (\text{Eq 82})$$

The deviatoric and volumetric components of plastic strain increment become:

$$\Delta E_v^p = 3\Delta\Lambda \left[-\frac{1}{3}(2\Sigma_r + \Sigma_z)b(D) \right] \quad (\text{Eq 83})$$

$$\Delta E_z^p - \Delta E_r^p = -3\Delta\Lambda(\Sigma_z - \Sigma_r) \quad (\text{Eq 84})$$

Eliminating $\Delta\Lambda$ obtain,

$$\frac{\Delta E_v^p}{\Delta E_z^p - \Delta E_r^p} = \frac{b(D)(2\Sigma_r + \Sigma_z)}{3(\Sigma_z - \Sigma_r)} \quad (\text{Eq 85})$$

Solving for $b(D)$,

$$b(D) = \frac{3(\Sigma_z - \Sigma_r)\Delta E_v^p}{(2\Sigma_r + \Sigma_z)(\Delta E_z^p - \Delta E_r^p)} \quad (\text{Eq 86})$$

Thus, the function $b(D)$ may be determined using data from the triaxial tests for values of axial stress Σ_z , axial plastic strain increment ΔE_z^p , and radial strain increment ΔE_r^p corresponding to a range of values of cell pressure Σ_r .

The results of applying Eq 86 to the experimental data of Pavier and Doremus (Ref 14) for the Distalloy AE blend are shown in Fig. 15. Because noise is inherently present in such information, a cursory smoothing using a moving average scheme was performed prior to computing the increments of strain. In addition, the elastic components of strain were

assumed to be negligible. For low relative densities, this assumption is reasonable. However, as plastic incompressibility is approached, the validity of the assumption must be checked. A curve fit for $b(D)$ results in the following expression:

$$b(D) = \frac{1}{2.8287} \ln \left(\frac{7.6 - 7.33D}{0.2516} \right) \quad (\text{Eq 87})$$

Fig. 15 Function $b(D)$ for an iron powder blend comprising 99.5% by weight Distalloy AE, 0.5% by weight graphite, and 1% wax Hoechst micropulver

Isostatic Compaction Test for $c(D)$. The state of stress in the isostatic compaction test is one of pure pressure, with no shear or deviatoric stress present. The isotropic test provides a convenient means of evaluating the evolution of relative density as a function of increasing cell pressure. Data are obtained by increasing cell pressure to a point before unloading the cell to determine the resulting powder relative density. Following Pavier and Doremus (Ref 14), the relation between the relative density for the powder under hydrostatic loading and the applied pressure or hydrostatic stress was determined to be:

$$P_y = \frac{37.596}{1.0364 - D} - 46.2976 \quad (\text{Eq 88})$$

where P_y is expressed in MPa and represents the pressure at yield given a value of relative density, D in the isostatic test.

It is reasonable to assume that the material is continuously yielding with load. Further, since shear stress is completely absent, Eq 60 reduces to:

$$F = \frac{3}{2} P_y (D)^2 b(D) - \sigma_y^2 c(D) = 0 \quad (\text{Eq 89})$$

If particle hardening is considered, the calculation of $c(D)$ involves the simultaneous integration of partial differential equations for the evolution of particle yield stress and the functions $b(D)$ and $c(D)$. However, for simplicity, assume the powder particles are perfectly plastic and obtain $c(D)$ from (Eq 89):

$$c(D) = \frac{3 P_y (D)^2 b(D)}{2 \sigma_y^2} \quad (\text{Eq 90})$$

Using the forms for pressure and $b(D)$ from Eq 88 and 87, and assuming a mean value of 375 MPa for particle yield stress, the function $c(D)$ is calculated and plotted in Fig. 16.

Fig. 16 Functions $b(D)$ and $c(D)$ for a iron powder blend comprising 99.5% by weight Distalloy AE, 0.5% by weight graphite, and 1% wax Hoechst micropulver

Verification of Calibrated Model. This section evaluates the accuracy of the calibration performed for functions $b(D)$ and $c(D)$ for the Distalloy AE blend considered using triaxial test data. Analysis data were generated through a finite element simulation of the triaxial tests conducted. Because hardening of the powder particles is a likely event, it is considered here. Specifically, the material of the powder particle was modeled as having a yield stress of 250 MPa with a hardening of 333 MPa. These values were obtained from data reported by Trasorras et al. (Ref 36). Figure 17 shows a comparison of the predicted powder density as it evolves during the triaxial tests against data measured by Pavier et al. (Ref 14). There is very good agreement between simulation and experiment. Figure 18 shows a plot of axial strain versus radial strain for a triaxial cell pressure of 250 MPa. The strains are measured relative to the onset of shear in the specimen, marked by an increase in axial stress over the cell pressure. Figure 19 shows a plot of axial stress versus axial strain for the same triaxial cell pressure of 250 MPa. Again, the simulations compare well with the experiments.

Numerical Modeling of Powder Compaction in Dies

In this section, practical illustrations of finite element analysis of powder compaction are presented. The first one is the compaction of a two-level component with emphasis on the effect of compaction kinematics on punch loads. The second example, the compaction of a long bushing, illustrates density predictions.

Compaction of a Two-Level Part

The model presented in the section "A Constitutive Model for Metallic Powders with Ductile Particles" is used to examine the compaction of an axisymmetric two-level component. This part was studied experimentally by Kergadallan et al. (Ref 4). The part was pressed with five different tooling motions; two of those cases, labeled as part 30 and part 34, are presented here. The compaction experiments and the finite element model are described, and numerical predictions are compared to experimental results.

Compaction Experiments. Following are the conditions of the compaction tests used to study an axisymmetric two-level component.

Part Geometry. The part is axisymmetric with a thin outer rim, a hub, and a bore. This geometry is representative of many common powder metal parts (e.g., engine camshaft timing pulleys, one-way mechanical diode clutch plates). Geometry and dimensions are shown in Fig. 20. The outer diameter is 78 mm and the overall height is 26 mm.

Fig. 20 Nominal dimensions of axisymmetric part used in compaction experiments

The powder blend is based on the diffusion alloyed iron powder, Hoeganaes Distalloy AE, as described in section "Calibration of Material Parameters for an Iron Powder Blend."

Press and Tooling. Figure 21 shows a schematic of the press and tooling. The part was pressed in a hydraulic COSMO press. The tooling consists of four moving components: an outer die and an inner core that move together, a top punch, and a lower inner punch. The tooling also includes a stationary lower outer punch. The press was instrumented with strain gauges to measure loads on tooling members (see Fig. 21) and potentiometer displacement transducers to measure tooling displacements.

Fig. 21 Schematic of hydraulic COSMO press, tooling and strain gauges for load measurement. Source: Ref 4

Initial Conditions. The fill positions of the punches are given by R_1 and R_2 as shown in Fig. 22 and Table 2. The initial density in the die cavity was estimated by assuming uniform density within the rim section and the hub section of the part, as shown schematically in Fig. 23. The initial density values (Table 2) were estimated by weighing the different sections of the part and assuming no mass transfer between the top and bottom sections.

Table 2 Initial conditions for two-level compaction experiments

Conditions	Part 30	Part 34
Rim fill (R_1), mm	54.71	55.82
Hub fill (R_2), mm	27.23	25.18
ρ_{Hub} , g/cm ³	3.51	3.63
ρ_{Rim} , g/cm ³	3.21	2.97
Mass, g	498.09	482.42

Fig. 22 Actual tooling motions for axisymmetric component with piecewise linear approximations. Source: Ref 4

Fig. 23 Estimated initial fill density distribution for parts used in compaction experiments. Source: Ref 4

Compaction Kinematics. The displacement histories for each of the moving tooling members are shown in Fig. 22. Tabulated information on punch displacements for part 30 and part 34 can be found in Ref 4. As explained later in this section, compaction of part 30 results in low density in the rim section. Also, cracks appear on the inner and outer surface of the rim. The aim of the compaction kinematics used with part 34 was to reduce the density imbalance between the hub and rim sections and to eliminate the cracks.

The Finite Element Model. The powder material model described in the section "A Constitutive Model for Metallic Powders with Ductile Particles" was implemented in the finite element code Abaqus/Standard (Ref 2) through a user-defined material subroutine. Details of the numerical implementation are beyond the scope of this article. Aravas (Ref 3) has described the numerical integration of constitutive models of this class.

Finite Element Model. An axisymmetric model of the compact was set up using four noded axisymmetric elements (Ref 2). Figure 24 shows a three-dimensional representation of the finite element mesh obtained by revolving the part about the axis of symmetry.

Fig. 24 Three-dimensional representation of the axisymmetric finite element discretization of the powder

compact

Tooling. For simplicity, the tooling components were modeled as rigid surfaces. In a more detailed model, the tooling can also be modeled assuming elastic material behavior. Tooling stresses can be computed this way. However, modeling the interfaces between the powder and the elastic tooling is numerically very intensive.

Material Model. Constant values were used for the elastic properties. A fixed value of Young's modulus (141 GPa), corresponding to the final average density, was calculated using the expression for elastic modulus determined by Pavier et al. (Ref 14). It was mentioned earlier that the elastic properties are strong functions of density. However, in an analysis such as this, severe numerical instabilities can result as a consequence of the soft elastic properties at low density. Further, the effect of elastic behavior is dominant only when the relative density approaches its pore-free value.

The friction coefficient between iron powder compacts and steel/carbide tooling varies with the normal stress (Ref 44, 45). For lubricated iron powders, the coefficient of friction varies in the range 0.1 to 0.2 for normal stresses in the range 100 to 700 MPa. For the present model, a Coulomb friction model was used and a coefficient of friction of 0.15 was assumed.

Compaction Kinematics. A piecewise linear approximation to the actual tooling motions was used as depicted in Fig. 22.

Part Fill Density. The initial fill density was set as represented schematically in Fig. 23.

Experimental and Modeling Results. Figure 25 shows the compaction forces measured for part 30. The forces exerted on the bottom and upper punches increase from the initial instant corresponding to the moment of contact between the powder and the upper punch. At instant t_{L1} (Fig. 22), the speed of the lower inner punch (LIP) is modified such that it descends at practically constant force over the rest of its travel through time t_{L2} . While the LIP is in motion, the upper punch (UP) and the lower outer punch (LOP) withstand forces that increase progressively up to their peak values. The rest of the cycle, for time $>t_{L2}$, continues while the LIP remains at a fixed position. The forces on the LOP and the UP increase rapidly to their maximum values. Compression finishes at time t_F , corresponding to the maximum displacement of the UP. The maximum loads recorded are shown in Table 3. Densities were measured in five sections of the part as shown schematically in Fig. 26. Measurements are shown in Table 4. For part 30, the hub and rim densities are approximately 7.06 g/cm^3 and 6.90 g/cm^3 .

Table 3 Measured and computed peak compaction loads

Punch	Part 30 loads, MN		Part 34 loads, MN	
	Measured	Predicted	Measured	Predicted
LIP	2.10	2.12	1.61	1.75
LOP	0.59	0.36	0.61	0.5

Table 4 Measured sectional densities

Section of Fig. 26	Density, g/cm ³	
	Part 30	Part 34
1	7.01	6.9
2	7.07	6.93
3	7.09	7.03
4	6.90	6.91

Fig. 25 Comparison of compaction tooling loads for part 30: predicted versus experimental

Fig. 26 Comparison of compaction tooling loads for part 34: predicted versus experimental

After ejection, the parts were visually inspected for cracks. Part 30 presented a distinct crack around the rim ID, 2 mm below the hub. Very fine cracks were also present on the outer surface of the rim, close to the bottom end. Although it is not possible to state exactly when the cracks were formed, it is very likely that they appeared during load removal/ejection. For part 30, the maximum loads on the inner and outer lower punches are 2.1 MN and 0.59 MN, respectively. The high load on the lower inner punch results in high punch deflection. During ejection, the elastic recovery of the lower inner punch results in tension on the rim causing cracking.

To eliminate the cracks that appeared in part 30, part 34 was pressed with higher fill in the rim section and reduced fill in the hub section (Table 2). The tool motions applied were modified to accommodate the different fill positions, otherwise they were very similar to the motions used with part 30. The forces measured are shown in Fig. 27. The peak load values are given in Table 3. The load patterns for parts 30 and 34 are similar; however, for part 34, the lower inner punch load is reduced to 1.61 MN, while the outer lower punch force increases slightly to 0.61 MN. The hub and rim densities are approximately 6.97 g/cm^3 and 6.94 g/cm^3 (Table 3). The reduced load in the lower inner punch results in lower deflection and eliminates tension during load removal/part ejection. Part 34 was defect free.

Fig. 27 Schematic of sections for density measurements for test parts

Figure 28 illustrates the compaction process as predicted by the numerical model. The deformed mesh is plotted for part 34. The model shows that there is very limited transfer of powder between the top and bottom (rim) sections of the part. This behavior is expected because the tooling motions were designed to minimize powder transfer to avoid the formation of a defect at the corner between the two sections. Figure 29 plots the evolution of density in the compact during pressing of part 34.

Fig. 28 Deformed mesh during stages of compaction of part 34

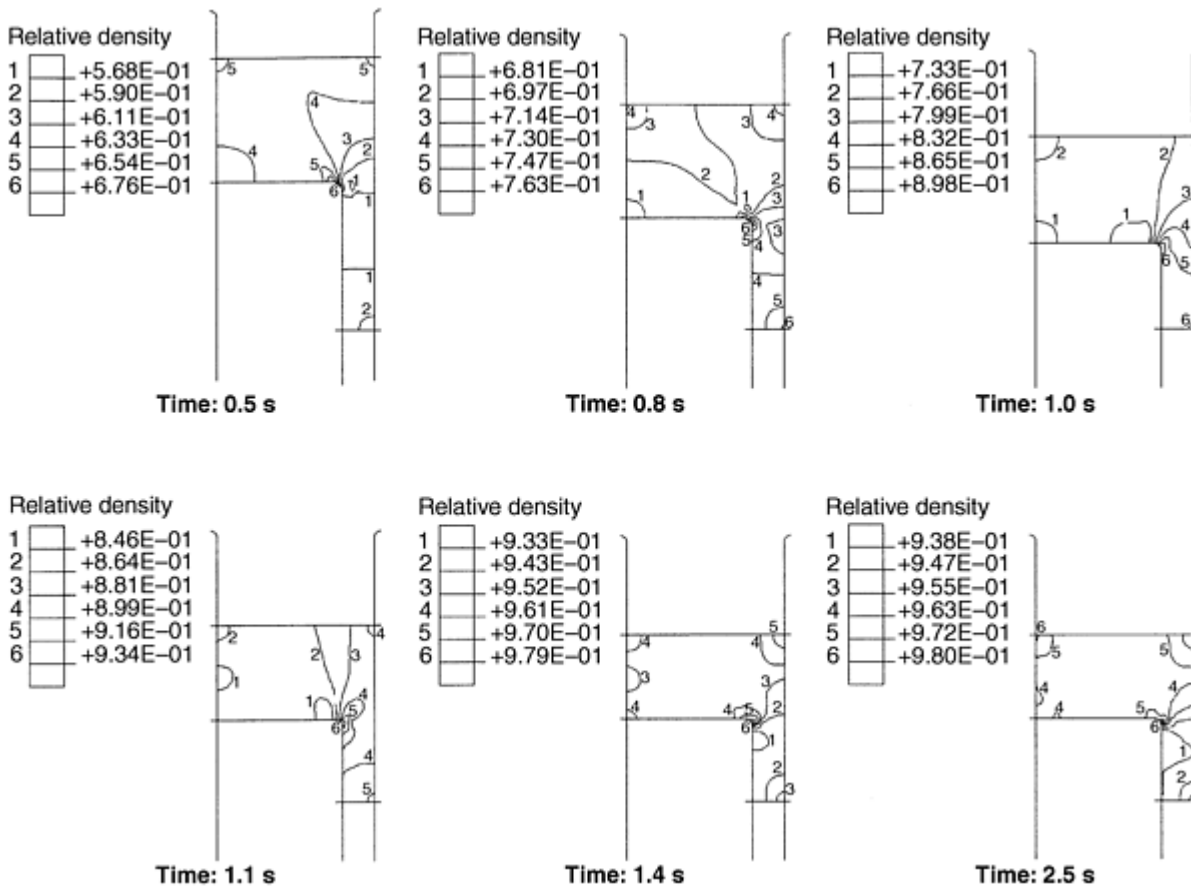

Fig. 29 Computed density fields at different stages of compaction of part 34

The loads computed for parts 30 and 34 are plotted in Fig. 26 and 27 and compared to the measured loads. There is good overall agreement between the experiments (Ref 4) and the calculations. The computed maximum load values for each punch are shown in Table 3. Again the agreement with the experiments is very good, showing that the model is capable of predicting the effects of punch kinematics and fill position on punch loads.

One observation on the nature of the load computations is pertinent. As the compact approaches its pore-free density, it becomes incompressible. Consequently, towards the end of the compaction stroke, minor variations in tool motions result in sharp changes in load. Thus, it is very important to ascertain the exact displacements of tooling members from their reference positions if accurate load predictions are sought.

Compaction of a Long Bushing

This example illustrates how the numerical model can be applied to predict density distributions. This part was studied experimentally by Trasorras et al. (Ref 40). A steel bushing was pressed in a 150 ton mechanical press. The green bushing dimensions are outside diameter (OD) = 19.05 mm, inner diameter (ID) = 12.7 mm, and height = 25.4 mm. The powder used was a blend of atomized steel powder (Ancorsteel 1000) with 0.75 wt% zinc stearate as lubricant. The punch motions comprise the following sequence. After powder filling, the top punch moves down to compact the powder, then rises and exits the die cavity. At the end of top punch motion, the die is stripped to eject the compact. Finally, the core rod is stripped. The lower punch and the die remain stationary throughout the compaction. As compaction starts, a density gradient develops in the bushing due to the friction between the compact and the tooling members. With continued top punch motion, the bushing densifies with the top always being at a higher density than the bottom. During ejection, there is some additional densification of the bottom end of the compact. Finally, the compact expands as it exits the die cavity thereby reducing the overall density. The axial density distribution in the bushing was determined by successively sectioning and weighing the compact.

Compaction of the bushing was modelled in PCS (Ref 42), a powder compaction modeling system based on the finite element code NIKE2D (Ref 46). Figure 30 shows the finite element discretization of the tooling and powder, with the punches shown at their fill position. The material model described earlier was used with the constitutive functions $b(D)$, $c(D)$, and elastic properties calibrated for the atomized iron powder. The initial apparent density of the powder was 3.2 g/cm^3 . A complete model of the tooling was used (Fig. 30) and elastic isotropic behavior was assumed. The friction between the compact and the tooling members was assumed to follow Coulomb's model with a friction coefficient of 0.2. Figure 31 compares the axial density distribution predicted by the numerical model with the experimental results. The model properly represents the densification that takes place during both compaction and ejection and the predicted final density distribution is in good agreement with the experiments. The experiments show a sharp increase of density at the powder layer in contact with the top and bottom punches. The numerical model, with the discretization level used, was not able to predict this effect.

Fig. 30 Finite element discretization of powder and tooling used in the compaction of cylindrical bushing

Fig. 31 Density distribution along axis of cylindrical bushing: FEA predictions versus experimental results

This article has examined the general structure of constitutive laws for the compaction of powder compacts and demonstrated how these material models can be used to model the response of real world components to a series of complex die operations. It identified the general structure of the constitutive law and described a number of models that have been proposed in the literature. This field is still evolving, and it is evident that there will be significant developments in this area over the next few years as a wider range of experimental studies are conducted, providing greater insights into the compaction process. At the current time, there is no universally accepted model. Therefore, a pragmatic approach and a relatively simple form of empirical model were adopted requiring, for the determination of the unknown functions, a limited range of experiments. This selection allowed an examination of the compaction of axisymmetric components in detail and a comparison of general features of the component response with practical measurements. Similar procedures could have been adopted for any of the methods described, although in general, more sophisticated experiments are required in order to determine any unknown function or coefficients, particularly if the shape of the yield function is not known, or assumed, a priori.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Introduction

POWDER METAL COMPACTING PRESSES, equipped with appropriate tooling, frequently are used for producing P/M components. Although commonly called P/M presses, use is not limited to the pressing of metal powders. Almost any alloy or mixture of materials produced in powder form can be compacted into suitable end products. The majority of components fabricated by P/M presses, in number of pieces and pounds of product produced, consists of compacted metals. Ferrous-base metals constitute the largest usage. Powder metallurgy compacting presses usually are mechanically or hydraulically driven, but they can incorporate a combination of mechanically, hydraulically, and pneumatically driven systems.

Table 1 summarizes some of the developments for P/M presses in the last 40 years. Other recent improvements in compaction technology include:

- Split-die techniques to make multilevel parts having different peripheral contours at different levels
- Punch rotation capability to facilitate production of helical gears and other helical shapes
- Higher compaction pressures by using stronger tool materials, advanced pressure control methods, and die wall lubricants
- Better process control with computerized tool motion monitoring
- Warm compaction and improved "segregation-free" powders with enhanced flow characteristics

Table 1 History of development in P/M presses

Years	Compacting press
1955-1959	Cam press, HP
1960-1964	Toggle press, MP
1965-1969	Large size HP (500 +), large size MP (500 +)
1970-1974	Multisteped MP, double die compacting press
1975-1979	Large size MP (750 +), tool holder quick change
1980-1989	NC press, multisteped HP (800 +), large size rotary press
1990-1994	Large size MP, automatic P/M manufacturing line
1995-present	Hybrid (mechanical/hydraulic) presses (800 tons)

HP, hydraulic press; MP, mechanical press; NC, numeric controlled

Compacting Press Requirements

Although P/M presses resemble stamping and forming presses, several significant differences exist. Press frames generally have straight sides. Gap-type or "C" frame presses are not suitable because the frame deflects in an arc under load, resulting in a slight out-of-alignment condition between the bed and side of the press. This arrangement produces a compacted part that is slightly out of parallel, top to bottom. Because P/M tooling clearances are generally ~ 0.025 mm/25 mm (0.001 in./1 in.) total, bending deflection can cause broken tooling or excessive tool wear.

Powder metallurgy presses apply sufficient pressure from one or both pressing directions (top and bottom) to achieve uniform density throughout the compact. Design should include provision for ejecting the part from the tooling. Pressing and ejection occur during each cycle of the press and must be accurately synchronized.

Presses need sufficient connected horsepower to compact and eject the part. In most press-working applications, the working stroke is a small portion of the total stroke of the press. In P/M presses, the working stroke during the compaction portion of the cycle is usually greater than the length of the part being produced, and the ejection portion of the cycle has a working stroke equal to or greater than the length of the part by a factor of approximately two or three. In some cases, the power required during the ejection cycle is greater than that required during compaction.

Presses should provide for adjustable die filling (the amount of loose powder in the tooling cavity). Automatic powder feeding systems that are synchronized with the compaction and ejection portion of the press cycle are desirable. Finally, P/M presses must meet federal, state, and local design and construction safety laws. Metal Powder Industries Federation (MPIF) standard 47 details safety standards for P/M presses.

Mechanical presses are available in top-drive and bottom-drive arrangements. In top-drive presses, the motor, flywheel, and gearing system are located in the crown or upper structure of the press. Presses with pressing capacities of ~ 1780 kN (200 tons) are floor mounted, requiring little or no pit. Top-drive presses with pressing capacities >1780 kN (200 tons) usually require a pit to maintain a convenient working height for the operator.

In bottom-drive presses, the drive mechanism, motor, and flywheel are located in the bed of the press. These presses usually are "pulled down"; that is, the top ram of the press is pulled downward by draw bars or tie rods. Bottom-drive presses with pressing capacities of >445 kN (50 tons) usually require pits. Top-drive and bottom-drive presses are comparable in terms of partmaking capability, reliability, and equipment cost.

Press Tonnage and Stroke Capacity. Required press capacity to produce compacts in rigid dies at a given pressure depends on the size of the part to be pressed and the desired green density of the part, which in turn is determined by requirements for mechanical and physical properties of the sintered part. Compacting pressures can be as low as 70 to 140 MPa (5 to 10 tsi) for tungsten powder compacts or as high as 550 to 830 MPa (40 to 60 tsi) for high-density steel parts.

When a part is pressed from the top and bottom simultaneously, the press should apply the required load to the upper and lower ram of the press. To eject the pressed compact, an ejection capacity must be available that is sometimes divided into the load for the breakaway stroke (which is the first 1 to 12 mm ($\frac{1}{32}$ to $\frac{1}{2}$ in.) of the ejection stroke and the load for a sustained stroke). The load for a sustained stroke is generally one-fourth to one-half of the breakaway load.

The stroke capacity of a press, or the maximum ram travel, determines the length of a part that can be pressed and ejected. In presses used for automatic compacting, the stroke capacity is related to the length available for die fill and ejection stroke.

Load Requirements. The total load required for a part is determined by the product of the pressure needed to compact the part to the required density and the projected area of the part. Compaction curves relate pressure, P , to the required density, q , and are usually obtained from compacting tests on cylindrical shapes with the height, L , equal to the diameter,

D. For thicker parts the load must be increased, by as much as 25% for a length to diameter ratio of 4 to 1, to give the required density.

Required compacting pressures can be estimated with a correction factor, k , such that (Ref 1):

$$P = P_1 (1 + k)$$

where P is the compaction pressure for a larger part and P_1 is the compaction pressure for a "standard" part (i.e., $L = D$). The correction factor is:

$$k = (0.25/3)(L/D - 1) \text{ for } L/D > 1$$
$$k = 0 \text{ for } L/D < 1$$

For parts that are not cylindrical, an equivalent L/D ratio can be used:

$$L_e/D_e = (V \cdot p)/(2 \cdot A^2)$$

where V is the part volume and A is the projected area. The press load required is then obtained by multiplying the required compaction pressure by the projected area of the part.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Mechanical Presses

In most mechanical P/M compacting presses, electric motor-driven flywheels supply the main source of energy used for compacting and ejecting the part. The flywheel normally is mounted on a high-speed shaft and rotates continuously. A clutch and a brake mounted on the flywheel shaft initiate and stop the press stroke. To initiate a press stroke, the brake is disengaged and the clutch is engaged, causing the energy stored in the rotating flywheel to transmit torque through the press gearing to the final drive or press ram.

Clutch and brake systems should be of the partial revolution type that can be engaged and disengaged at any point in the pressing cycle. The clutch usually is pneumatically engaged with a spring release, and the brake is pneumatically released with a spring set, thereby providing full stopping ability in the event of loss of air pressure. An adjustable speed device normally is supplied with electric drive motor, providing production rate adjustment as indicated by pressing and ejection conditions.

On presses that have main motor capacities up to ~ 19 kW (25 hp), the adjustable speed drive is usually of the variable-pitch pulley or traction-drive type. Above 19 kW (25 hp), direct-current or eddy-current control devices are preferred. The motor and drive must be totally enclosed to prevent contamination by metal powder dust.

Gearing systems usually are either single-reduction (Fig. 1) or double-reduction (Fig. 2) arrangements. Single-reduction gearing frequently is used in lower tonnage presses (≤ 445 kN, or 50 tons) that have stroking rates of ~ 50 strokes/min. Higher tonnage presses use double-reduction gearing and commonly have maximum stroking rates of 30 strokes/min.

Fig. 1 Single-reduction gearing systems for P/M compacting press

Fig. 2 Double-reduction gearing systems for P/M compacting press

The low-speed shaft of the press, normally called the main shaft, is linked to the press ram, causing motion of the tooling for the compacting and ejection cycles. Ram driving mechanisms can be either cam- or eccentric-driven arrangements.

Cam-driven presses generally are limited to pressing capacities ≤ 890 kN (100 tons). The main shaft of the press has two cams--one cam operates the upper ram, and the other cam operates the lower ram for compacting the part. The cam that operates the lower ram also controls the powder feed into the die and ejects the part from the die after compacting. Cams normally operate linkages that convert the main shaft rotary motion into the linear motion of the tooling.

Figure 3 shows a schematic of a cam-driven press. The cams in this type of press can be adjusted or arranged with removable sections, thus allowing cam motion to be varied to produce special motions to compact the part. Pressure can be applied either simultaneously or sequentially to the top and bottom of the compact. Anvil and rotary presses are types of cam-driven machines. These presses are described in more detail later in this article.

Fig. 3 Schematic of cam-driven compacting press

Eccentric-Driven Presses. Presses that have a final drive mechanism consisting of an eccentric or crank on the main shaft are the most widely used type of mechanical press. A connecting rod is used to convert the rotary motion of the main shaft into the reciprocating motion of the press ram. Generally, an adjustment mechanism is built into the connecting rod or press ram assembly, thus permitting the height position of the press ram to be changed with respect to the main shaft or press frame, thereby controlling the final pressing position of the ram. This adjustment mechanism can be used to control the length of the compacted part. Standard eccentric-driven presses have pressing capacities ranging from 6.7 to 7830 kN (0.75 to 880 tons).

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Hydraulic Presses

Hydraulically driven compacting presses are available with pressing capacities ranging from 445 to 11,100 kN (50 to 1250 tons) as standard production machines, although special machines with capacities $\leq 44,500$ kN (5000 tons) have been used in production. Hydraulic presses normally can produce longer parts in the direction of pressing than mechanical presses, and longer stroke hydraulic machines are less expensive compared to an equivalent stroke produced in a mechanical press. The maximum depth of powder fill in mechanical presses is ~ 180 mm (7 in.), while 380 mm (15 in.) of powder fill is common in hydraulic presses.

The maximum production rate for hydraulic presses producing a single part per stroke is ~ 650 pieces per hour. The slower speed of a hydraulic press when pressing long parts is preferable, because the longer time during pressing permits trapped air within the powder to escape through the tooling clearances.

Most hydraulic presses are considered top-drive machines because the main operating cylinder is centrally located in the top of the press. This main cylinder provides the force for compacting the part. Hydraulic presses have three distinct downward speeds:

- *Rapid advance:* Produces minimal pressing force, used for rapid closing of the die cavity
- *Medium speed:* Pressing capacities $\sim 50\%$ of full-rated capacity, used during initial compaction when lower pressing force is required

- *Slow speed:* Maximum capacity available for final compaction

Two types of hydraulic pumping systems are commonly found in P/M presses: the high-low system and the filling circuit system. The high-low system has a double-acting main cylinder. A regenerative circuit is used for rapid approach. Initially, the piston of the cylinder is activated by a high-volume, low-pressure pump; the fluid from the bottom of the cylinder is directed into the top of the cylinder in addition to the low-pressure pump volume. At medium speed, the regenerative circuit is deactivated, while the piston remains activated by the low-pressure pump. In full-tonnage press, the low-pressure pump is deactivated, and a high-pressure pump activates the piston.

The filling circuit hydraulic pumping system has a single-acting main cylinder, and ram motion is controlled by small double-acting cylinders. The ram control cylinders are smaller than the main cylinder, so only a low flow rate of fluid is needed to cause rapid movement of the ram. During approach and return cycles, however, the fluid flow rate into and out of the main cylinder is high. The main cylinder is fitted with a large two-way valve that allows fluid to flow at low pressures (usually gravity feed). During pressing, the two-way valve is closed, and high pressure from the pump is applied to the main cylinder piston.

Ejection of the part usually is accomplished by a cylinder that is centrally located in the bed of the press. The cylinder either upwardly ejects the part or pulls the die downward from the part, depending on the type of tooling used.

When pressing parts to a given thickness, positive mechanical stops are used on hydraulic presses to control downward ram movement. When pressing parts to a desired density, downward ram movement is controlled by adjustment of the pressure to the cylinder. When the part is pressed to the desired unit pressure, the press ram stops and returns to the retracted position. Some types of P/M materials, such as P/M friction materials, are always pressed to density rather than size, because uniform density provides uniform friction and wear properties.

The drive-motor horsepower on a hydraulic press is considerably larger than on an equivalent mechanical press. A mechanical press has a flywheel from which energy is taken during the pressing and ejection of the part. Energy is restored to the flywheel during the die feeding portion of the cycle. The motor on a hydraulic press must supply energy directly during the pressing and ejection portion of the cycle.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Comparison of Mechanical and Hydraulic Presses

In terms of partmaking capability, no distinct advantage is gained by using either a mechanical press or a hydraulic press. Any part can be produced to the same quality on either type of machine. However, the following parameters influence press drive selection.

Production Rate. A mechanical press produces parts at a rate one and one-half to five times that of a hydraulic press as a result of inherent design of the energy transfer systems and stroke length.

Operating cost of a hydraulic press is higher, because the total connected horsepower of a hydraulic press is one and one-half to two times that of an equivalent mechanical machine. Theoretically, the required energy to compact and eject a part is the same for a hydraulic or a mechanical press, except that the overall efficiency of a mechanical press is slightly higher than that of a hydraulic press. Also, the kilowatt usage of the larger motor on a hydraulic press is greater than that of a mechanical press during the idle portion of the machine cycle.

Machine overload protection is an inherent feature of a hydraulic press. If the hydraulic system is operating properly, the machine cannot create a force greater than the rated capacity. Consequently, overload of the machine frame is not possible, even if a double hit or operator error occurs in adjusting the machine. Misadjustment or double hits can cause a mechanical press to overload, can damage the machine, or may cause tooling overload and failure if the tooling

cannot withstand full machine capacity. Some new mechanical presses are equipped with hydraulic overload protection systems.

Equipment cost of a hydraulic press generally is one-half to three-quarters that of an equivalent mechanical press. Facility, foundation, installation, and floor space costs generally are comparable.

Die Sets. The mounting into which the tooling is installed is known as the die set. Generally, the die set must be well guided because of the close tooling clearances used. Guide bearings must be protected with boots or wipers to prevent powder particles from entering guiding surfaces. Tooling support team members should have high stiffness to minimize deflection.

The die set must be free of residual magnetism. The maximum acceptable level is ~ 2 G. To ensure press operator safety, die sets should be adequately guarded. In a complex tooling arrangement, as many as seven independent tooling members and supports are moving relative to one another during the pressing and ejection cycles.

Die sets can be classified as removable or nonremovable. Both types are used in mechanical and hydraulic presses. Nonremovable die sets are used throughout the entire tonnage requirements of available presses. Manually removable die sets are used primarily in presses with pressing capacities up to ~ 2670 kN (300 tons). Above this press size, the die set assembly is moved by a powered system, and removable die set presses with capacities of $\leq 17,800$ kN (2000 tons) are available.

The major advantage offered by nonremovable die sets is flexibility in setup and operation. Presses equipped with nonremovable die sets usually have all adjustments required for setup and operation built into the press and die set, including:

- *Part length adjustment:* Any dimensions of the part in the direction of pressing can be quickly changed during production.
- *Part weight:* Material weight in any level of the part can be changed easily during production.
- *Tooling length adjustment:* Adjustments are provided to accommodate shortening of punch length due to sharpening or refacing.

Another advantage of nonremovable die sets is the greater space available for tooling, compared to the removable type. This space provides more freedom in tooling design. However, presses incorporating nonremovable die sets must be shut down during tooling changes or maintenance. Tooling change and setup time generally is from 1 to 4 hours--but sometimes substantially longer, depending on the complexity of tooling.

Nonremovable die sets are well suited for developing new P/M parts, because press and tooling adjustments can be made quickly to achieve the desired weight, density, and part dimension. Adjustment features of nonremovable die sets make them desirable on long production runs, where changes in powder quality among lots require frequent tooling adjustment to maintain part quality.

Users of removable die sets normally have two or more die sets per press. Tooling can be set up in a spare die outside the press. Removable die sets normally can be changed in less than 30 min, so loss of production time is minimal. On small presses where the die set is also small, the die set is restricted to a given set of tools and is considered semidurable tooling.

One disadvantage of many removable die sets is that pressing is controlled by pairs of pressing blocks made of hardened tool steel, such as D-2. The height of the pressing block controls the height of the part. If the part length dimension is changed due to design, or if the tooling length is changed due to repair, the pressing blocks must be changed accordingly. Removable die sets are ideally suited for shorter production runs. On newer presses with removable die sets, complete powder adjustment is available, even when the die set is outside the machine.

Part Classification

The Metal Powder Industries Federation has classified P/M parts according to complexity. Class I parts are the least complex, and class IV parts are the most complex. To better understand the types of commercially available P/M compacting presses, and their advantages and limitations, an understanding of P/M part classification and tooling systems used to produce parts is necessary. Part thickness and number of distinct levels perpendicular to the direction of powder pressing determine classification--not the contour of the part.

Class I parts are single-level parts that are pressed from one direction, top or bottom, and that have a slight density variation within the part in the direction of pressing (Fig. 4a). The highest part density is at the surface in contact with the moving punch, and the lowest density is at the opposite surface. Parts with a finished thickness of ~ 7.5 mm (0.3 in.) can be produced by this method without significant density variation.

Thin cams

(a) Class I parts

Compound gears

Splined bushings

Links

(b) Class IV parts

Fig. 4 Basic geometries of (a) MPIF class I (simple) and (b) MPIF class IV (complex) parts

Class II parts are single-level parts of any thickness pressed from both top and bottom. The lowest density region of these parts is near the center, with higher density at the top and bottom surfaces.

Class III parts have two levels, are of any thickness, and are pressed from both top and bottom. Individual punches are required for each of the levels to control powder fill and density.

Class IV parts are multilevel parts of any thickness, pressed from both top and bottom (Fig. 4b). Individual punches are required for each level to control powder fill and density.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Shape of Rigid Tooling

Rigid tool compaction differs from roll compaction, isostatic compaction, hot isostatic pressing, and injection molding in that a quantity of powder (fill) is confined in a rigid die cavity at ambient temperature. The die cavity is entered by one or more punches, which apply compaction pressure to the fill powder. As a result of the compaction pressure, the fill powder densifies, develops green strength, and assumes the exact shape of the die cavity and punch faces. Following the pressure cycle, the shaped powder fill, now a piece part, is ejected (stripped) from the die cavity.

The physical size of parts made in rigid tool compaction systems is a function of press tonnage capacity, fill depth, and also the length of a green powder fill that can be effectively compacted in terms of a maximum density variance. Parts vary in size from those weighing ~ 1 g (0.035 oz) that are made in presses with capacities as small as 35 kN (4 tons) to those weighing 10 kg (22 lb) that are made in presses with capacities of 8900 kN (100 tons).

Rigid tools must also be constructed oversize, with exact linear dimensions, to compensate for the final volume change. Although theoretical computations are useful, most successful rigid tool sets are based on shrinkage allowances developed from existing tooling and the dimensional histograms developed for particular powders. However, shrinkage allowances can be complex depending on subsequent sintering and binder additives. For example, some metallic powders, such as the carbide and tool steel types, and some gas and centrifugally atomized specialty powders, such as spray-dried tungsten carbide, do not develop significant green strength, because their individual particles are predominantly spherical or they lack plasticity. To compact such powders in rigid tool systems, wax or wax-stearate binders are added, which can occupy up to 20 vol% of the green compacted shape. The development of full metallic properties during sintering also requires a volume shrinkage.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Powder Fill

The important consideration in P/M part production is the fill ratio required to produce parts to a density that is compatible with end use requirements. The fill ratios must remain constant for a given part to maintain dimensional reproducibility. Parts can be of single-level or multilevel design.

Single-level parts, designated as class I by the Metal Powder Industries Federation (MPIF), present the least difficulty to the tool designer, regardless of the size or part configuration. The main consideration is designing a die that is long enough guidance for the lower punch (usually 25 mm, or 1 in.) and providing adequate fill depth for compacting the powder to the required density. This challenge, coupled with the primary mechanical consideration of locating the center of mass in the press center, provides the best potential for producing a uniform quality part. Figure 4(a) shows basic geometries of MPIF class I parts.

Multilevel parts, with industry classifications II through IV, present two additional complications to the tool designer: powder fill and part ejection. Because metal powders tend to compact in vertical columns and generate little hydraulic flow, the tool designer must create fill levels in the tools that compensate for the thickness variations present in the final

part configuration. Uniform density, neutral axis of compaction, and part ejection should be considered to determine the need to vary fill levels and the manner in which these variations are achieved. Excessive density variations contribute to green cracks and sintered distortion.

A common method of varying fill levels is by using multiple lower punches, which are timed to react to one another either through the use of springs or air, or by mounting on separate press platens. Other methods are less effective, because punches are not adjustable and are fixed on one of the tool members, such as the die or core rod.

Fixed levels are commonly referred to as die chokes, core rod steps, or splash pockets (Fig. 5). Fixed fills are sensitive to the apparent density of the material being compacted. In operations that control compacting pressure, such as in hydraulic pressing, fixed fills cause dimensional variations in part thickness. Because mechanical presses are set to operate to a fixed position relative to the die, the variation created by the apparent density of the powder causes overdensification or underdensification, resulting in a corresponding oversize or undersize peripheral area on the part. Green expansion occurs as a part is stripped from the die. Ideally, the part returns to die size through shrinkage during sintering.

Fig. 5 Methods of achieving fixed fill levels. (a) Fixed fill on an upper level using a step die. (b) Fixed fill using a splash pocket to permit a projection feature on an upper punch. (c) Stepped core rod forming an internal shoulder

When a part has more than one level in the compacting direction, the step height should be limited to one-quarter of the overall height for a single punch (Fig. 6a). If a larger step is required, multiple punches should be considered (Fig. 6b).

Fig. 6 Two-level compaction. (a) Single lower punch when $h \leq H/4$. (b) Double lower punches when $h > H/4$.

Fill Height. The fill height is the depth of the loose powder required to give the required part thickness after compaction. The value is determined by the compressibility of the loose powder at the required density. The fill height, h_f , is obtained by multiplying the finished part height by the compression ratio of the powder:

$$h_f = tk_r$$

In this equation, t is the part thickness, k_r is the compression ratio, and $k_r = q/q_a$, where q is the part required compaction density and q_a is the apparent density of the loose powder. If the fill height is greater than the maximum fill height that can be accommodated in the press selected on the basis of the compacting load required, a larger capacity machine should be selected, which has the required fill height capacity.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Tooling Systems

High-production P/M compacting presses are available as standard production machines in a wide range of pressing capacities and production rate capabilities. Presses are designed to produce parts of a specific classification, as discussed previously.

Single-action tooling systems generally are limited to production of class I parts. During the compacting cycle, the die, core rod, and one of the punches (usually the lower punch) remain stationary. Compacting is performed by the moving punch, which is driven by the action of the press. One or more core rods may form any through holes in the part.

During ejection, the upper punch moves away from the formed part, and the part is ejected from the die by the lower punch. The core rod (Fig. 7) is stationary, and the part is ejected from the die and core rod simultaneously. On some presses, the core rod is arranged so that it is free to move upward (float) with the part as it is ejected. The compacted part experiences slight elastic expansion on ejection from the die, which causes the part to free itself from the core rod. The core rod is then free to move downward to the fill position. This floating core rod arrangement reduces ejection forces and core rod wear.

Fig. 7 Compacting sequence utilizing single-action tooling. Dashed line indicates motion of lower punch.

Double-action tooling systems primarily are used to produce class I and II parts. Force is applied to the top and bottom of the part simultaneously, because the punches have the same travel rate. The die and core rod are stationary. Densification takes place from the top and bottom, with the lowest density region near the center of the part. Although the

core rod is fixed in this system, it can be arranged in a floating position. Figure 8 shows the compacting sequence of a double-action tooling system.

Fig. 8 Compacting sequence utilizing double-action tooling. Dashed line indicates motion of component parts.

Floating die tooling systems are similar to double-action arrangements. As shown in Fig. 9, the die is mounted on a yielding mechanism (springs). However, pneumatic or hydraulic cylinders usually are used, because they offer an easily adjustable resisting force. As the upper punch enters the die and starts to compact the powder, friction between the powder and die wall causes the die to move down. This has the same effect as an upward-moving lower punch. After pressing, the die moves upward to the fill position, and the upward-moving lower punch ejects the part. The core rod can be fixed or floating.

Fig. 9 Compacting sequence utilizing floating die tooling. Dashed lines indicate motion of component parts.

Withdrawal tooling systems use the floating die principle, except that the punch forming the bottommost level of the part remains stationary and that the die motion is press activated rather than friction activated. The die and other lower tooling members, including auxiliary lower punches and core rods, move downward from the time pressing begins until ejection is complete.

Figure 10 shows the compacting sequence in a multiple-motion withdrawal tooling system. During compaction, all elements of the tooling system except the stationary punch move downward. The die is mounted on the top press member of the platen and is supported by pneumatic or hydraulic cylinders. Auxiliary punches are mounted on additional platens, which are similarly supported and have positive pressing stops. The stops control the finished length of each of the levels within the compacted part. Before ejection, these stops are released or disengaged so that the platens can be moved further downward. During ejection, the upper punch moves upward, away from the compact, while the die and lower punches move sequentially downward until all tool members are level with the top of the stationary punch. The compact is fully supported by the tooling members during ejection, resting on the stationary punch as the die and lower punches are lowered to release it.

Fig. 10 Compacting sequence utilizing floating die withdrawal double-action tooling. Dashed lines indicate motion of component parts.

The core rod can be provided with pressing position stops to allow a part to be produced with blind or counterbored holes. The core rod is held stationary until the part is free of all other tooling members before moving downward to the ejection position.

At this point in the machine cycle, the feeder moves across the die, pushing the compacted part from the die area and covering the die cavity. The die and auxiliary lower punches move upward to their respective fill positions. The core rod then moves upward, displacing the excess powder into the partially empty feed shoe. The feeder retracts, wipes the top fill level, and readies the press for the next cycle.

Powder Metallurgy Presses and Tooling

Types of Presses

Anvil presses generally are limited to compaction of class I parts in a single direction. Anvil presses do not have an upper punch; a moveable, solid, flat block seals the top of the die. Compacting is done by the lower punch, which, after the anvil is released and moved, moves farther to eject the compact from the die.

Anvil presses are available with pressing capacities ranging from 6.7 to 310 kN (0.75 to 35 tons), with maximum depth of fill ranging from 1 to 75 mm (0.040 to 3 in.). Multiple-cavity pressing frequently is used in anvil presses, with possible production rates of >100,000 pieces per hour. Some anvil presses can be converted to double action, using an upper punch entry system. Anvil presses usually are mechanically driven. Figure 11 shows a schematic of an anvil press operation.

Fig. 11 Compacting sequence utilizing sliding anvil single-action tooling. Dashed line indicates motion of component parts.

Rotary presses generally are limited to compaction of single-level class II parts, although some class III parts, such as flanged bushings, are produced. Rotary machines are available with pressing capacities ranging from 36 to 590 kN (4 to 66 tons), with a depth of fill up to 75 mm (3 in.). Production rates of >60,000 pieces per hour are possible, depending on machine size and the number of tooling stations. Rotary presses are mechanically driven.

Single-Punch Opposing Ram Presses. Like rotary presses, these machines are limited to production of class II and some class III P/M parts. These presses are available in top- and bottom-drive models, with pressing capacities ranging from 36 to 980 kN (4 to 100 tons) and with a maximum depth of fill up to 100 mm (4 in.).

Production rates of up to 3000 parts per hour are possible using mechanical presses with single-cavity tooling, although production rates of 900 to 1800 pieces per hour are more common. Hydraulic presses produce ~900 pieces per hour. Ejection of the part is accomplished by the lower punch moving upward. Mechanical and hydraulic presses are available.

Single-punch withdrawal presses have essentially the same partmaking capabilities as the single-punch opposing ram system in terms of pressing capacity, depth of fill, and production rate. The major difference is that floating dies are used to achieve top and bottom pressing. The die is moved downward to eject the part.

Multiple-motion die set presses can be designed to produce the most complex P/M parts. These presses use floating die and withdrawal tooling methods. Machines are available with either bottom- or top-drive arrangements. Pressing capacities range from 27 to 7830 kN (3 to 880 tons), with a maximum depth fill of 180 mm (7 in.). Production rates vary from more than 6000 pieces per hour on smaller machines to 1800 pieces per hour for 1960 kN (220 ton) presses.

In addition to producing complex parts, the removable die set (tool holder) minimizes press downtime for part changeover if the die set for the next part to be produced is set up outside the press and is ready for installation. Pressing position for

each level being produced by a separate tooling member is controlled by fixed-height tooling blocks (stop blocks), which usually are ground to the proper height to produce a given dimension on the part. A small adjustment in the block mounting member allows for minor changes to part dimension. Full range adjustments are available on more recent presses.

Multiple-motion adjustable stop presses have the same partmaking capability as multiple-motion die set presses and use the same tooling methods. Pressing capacities range from 980 to 7340 kN (110 to 825 tons), with a maximum depth of fill of 150 mm (6 in.). These presses do not incorporate removable die sets; however, press stop positions are adjustable, and a change in any dimension of the part in the direction of pressing is easily accomplished.

Powder Metallurgy Presses and Tooling

Advanced Tool Motions

A common limitation of some rigid tooling systems is that part features not perpendicular to the direction of pressing cannot be compacted and stripped. Frequently, it is cost effective to form features such as cross holes and threads by machining. Other nonperpendicular features, notably helix shapes and hidden flanges, can be formed using complex tool motions. Another type of advanced tooling system permits production of complex shapes with magnetic orientation of the microstructure.

Helical shapes, typically helical spur gears, are produced in rigid compaction tool sets with punch rotation capability. In a simple system, a helical form lower punch is engaged in a die with a matching gear form. In such a system, the lower punch remains engaged in the die at all times, as is common practice for all rigid tool systems, so that indexing rotation of the punch to the die is avoided. The die acts as a guide. Rotation is carried out on a thrust bearing, which rests on the punch platen that supports the lower punch. An upper punch is not required, because the top of the die cavity is closed by an upper anvil, which does not enter the die cavity. Central core rods, with or without additional features such as splines and key forms, are commonly operated in this helical tool system.

Helical gears made in this manner are limited to helix angles of $\sim 25^\circ$ and a thickness of 32 mm ($1\frac{1}{4}$ in.) due to fill limitations along the helix tooth form. More complex helical gear tooling systems have been developed for routine production using helical upper punches, driven by follower cams for indexed die entry, with inner and outer lower helical punches for stepped helical gears.

Split Die Systems. Another rigid tooling system that avoids some through-cavity limitations is known as the split die, or "double die," system. It enables the compaction of parts with completely asymmetric upper and lower sections in the pressing direction. Figure 12 shows typical tool motions in split die compaction. This system requires two die-holding platens to carry the upper and lower die. Each platen is controlled and moved independently.

Step 1

Step 2

Step 3

Step 4

Fig. 12 Split die compaction sequence

Wet magnetic compaction (Fig. 13) has enjoyed wide usage in the production of magnetically oriented ferrite shapes. In this production process, a feed shoe is not required. Instead, the die cavity is injected with an aqueous slip (slurry) that has a high concentration of ferrite powder, with the addition of green binders as required. Typically, the die filling pressure is 35 MPa (5000 psi). By using an aqueous slip, many of the gravity die fill problems, such as attainment of uniform powder density and filling the areas that are difficult for the powder to reach, are avoided.

Fig. 13 Wet magnetic compaction. (a) Force-time diagram for magnet presses. (b) Schematic of press tool for chamber-filling method designed for withdrawal operation

Following die fill injection, an orienting magnetic field is applied to the slip, resulting in magnetic polarization of the individual ferrite particles, which remain mobile at this point. The optimal orientation of the ferrite particles directly

determines the quality of the finished permanent magnet. After magnetic orientation, the main pressing load is applied, densifying the ferrite mass and causing the suspending aqueous carrier to be expelled through drainage ports. The compact is imparted with the precision shape and dimensions of both the upper and lower dies, plus any core rods that may be inserted. The cycle is completed by separation of the press platens and ejection of the compacted ferrite shape.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Tooling Design

Traditionally, P/M tooling was designed on the basis of production experience. In simple parts, such as single-level class I and II parts, these determinations proved successful. As state-of-the-art materials and presses advanced to the production of complex, multilevel parts, the "cut-and-try" method of tool design became obsolete. The high cost of complex tooling and adapters, plus downtime to redesign and rebuild tooling, requires the partmaking system, including the press, to be carefully analyzed in terms of load, stress, and deflection.

Tooling layout is required to design a suitable set of tools and to determine the physical dimensions (length and thickness) of tooling members. A preliminary layout helps to determine fill, pressing, and ejection positions and to eliminate interference at these positions.

The die space drawing supplied with every compacting press, which usually starts with the ejection position, is the basis of the tooling assembly layout. Generally, tooling members are never closer than in the ejection position, which constitutes the minimum space available to contain all components and their adapters.

Die Design. Dies are commonly constructed by using inserts that are held in the die case by shrink fitting. The amount of interference between the insert and the die case depends on the inside and outside diameter of each member and on the compacting pressure used. The powder can be considered a fluid in a closed container that transmits the compacting pressure in all directions; therefore, the die must be designed as though it were a pressure vessel with internal pressure.

In actual practice, radial pressure on the die walls due to compacting rarely exceeds 50% of the compacting pressure. The interference fit of the die case and die insert should be such that the stress on the insert always remains in compression for round dies. However, for shaped dies such as gears, cams, and levers, the use of finite element analysis is the best method for accurately determining stress and deflection.

In P/M tooling, the die normally controls the outer peripheral shape and size of the piece part. Typically, it is constructed from materials such as tungsten carbide or high alloy tool steels, such as T15, D2, CPM-10V, or CPM-15V with high hardness and good wear resistance. Dies are usually constructed in one or more sections and compressed into a retaining ring made of a low-alloy steel, such as AISI 4340 or 6150.

Considerations in die design and material selection include initial tool cost, shear strength of the die material, and die shape. A large die may require tungsten carbide, which costs ten times as much as tool steel materials. Tungsten carbide may be the best material for a set of gear tools with a relatively steep helical angle. Sectional die construction may be required for specific shapes such as sharp corners or projections into the die cavity.

Die Wall Thickness. An exact calculation of the stress on die walls is almost impossible from a practical point of view because stress distributions in the compact are extremely complicated and include variables such as part shape, particle size distribution, and other factors that affect transmission of compressive stress in the lateral direction (Ref 2). The vertical axial load can exert a horizontal force after a certain degree of consolidation has been attained. For example, when a simple shape is compacted at 400 MPa, as much as 120 MPa pressure can be exerted radially against the die walls.

If for purposes of simplification, the internal pressure is considered strictly hydrostatic in nature and the confined material is an incompressible liquid, then the die wall thickness for a cylindrical die could be determined by using Lamé's formula:

$$D = d \sqrt{(S + p)/(S - p)}$$

where S is the maximum allowable fiber stress for the material of the die, D is the outer diameter of the die, d is the compact diameter, and p is the radial stress acting on the die wall. This is a simplification because during metal powder compaction the pressure is not hydrostatic and the material is not incompressible. Initially, the powder is compressed with a consequent reduction in the vertical height of the space filled by the powder. The compressed material begins to resemble a solid after a certain degree of compaction has been reached.

Poisson's ratio is 0.3 for fully dense and isotropic steel. While this wrought form value cannot apply to powder metal, it is assumed to be applicable in the fully compacted condition. Thus, the Poisson's ratio is introduced into the previous equation, and the following modified Lamé's formula is used for estimating the die wall thickness for metal powder compaction.

$$D = d \sqrt{(S + \mu p)/(S - \mu p)}$$

where μ = Poisson's ratio = 0.3. This formula, however, does not take into consideration that the internal pressure acting over the length of the compact is balanced by the strength of the die having a larger length. The formula does address the friction at the tooling/powder interfaces resulting in nonuniform pressure distribution in the compact.

Generally speaking, the formula produces more conservative results than are necessary. The interference fit between the shrink ring and the die insert should be such that the stress on the insert always remains compressive for round dies. For shaped dies such as those used for production of gears and cams, the use of finite element analysis is the best method for accurately determining the stress and deflection.

Core Rods. Basically, the core rod is an extension of the die that controls the inner peripheral shape and size of the piece part. Tungsten carbide and M2 or M4 high-speed steels are the most common materials used for core rods. Primary factors in materials selection include wear resistance and hardness, which enable the core rod to resist the high compressive force exerted during compaction and the abrasive action sustained during part ejection. Core rods >25 mm (1 in.) in diameter or area are held to a base by mechanical means, such as a screw, while smaller core rods are held by means of silver solder or braze.

Punches can perform the function of a die or a core rod and carry the full load of the compressive force required to compact the P/M part. Wear resistance and toughness are the most important factors in materials selection. The most commonly used materials are A2, D2, S7, and H13 tool steels. Dimensional control, especially in areas such as concentricity and hole-to-hole location, depends on the amount of clearance that can be maintained between the punches, die, and core rods. Clearance should be calculated for each specific range and size of part. It is important to note that thermal size changes occur during operation, primarily because of the friction created by stripping the compacted part and the speed of the pressing cycle.

Punch Component Stress. Compacting powder causes compressive stress in the punch. This stress must be below the yield strength of the punch material. Calculation of buckling stability should be made for long, thin-walled punches.

Figure 14 shows the effect of axial compressive force on a tubular punch. A tubular punch is subjected to internal pressure during compacting of multilevel parts. In this case, the resulting circumferential tensile stress in the punch wall should be calculated. If the stress and accompanying deflection is excessive, tooling clearances should be designed so that when the outer punch wall expands, it is supported by the die wall before the stress reaches the yield limit (Fig. 15).

Fig. 14 Effect of compressive stress on tubular punch

Fig. 15 Tensile stresses in a tubular punch during compacting. Large arrows indicate action of powder on walls of punch.

During ejection, the punch is subjected to compressive stresses by resisting the stripping action of the die and to tensile stresses from the stripping action of punch. These stresses normally are lower than compacting stresses. Components of the punch subjected to stress include the punch clamp ring and bolts, which should resist the ejection of the punch without permanent deformation. Punch adapters are subjected to bending loads that create a tensile stress around the center hole during compacting. This stress should not exceed the fatigue limit of the adapter material.

Tubular adapters must have sufficient cross-sectional area to withstand the pressing load without permanent deformation. A stepped core rod, or a core rod forming a blind hole, must not buckle during compacting. The base of the core rod must resist, without permanent deformation, whatever ejection loads are imposed on the core rod.

The core rod clamp ring and retaining bolts should be sized to withstand the ejection force on the core rod without permanent deformation. The core rod adapter generally is strong enough to resist both pressing and ejection loads, due to the size of the adapter when space is provided for clamp ring fasteners.

Deflection Analysis. Pressing of P/M parts at pressures >690 MPa (50 tsi) presents unique considerations for size and tolerance in multilevel parts. A variety of tool members should be utilized to establish proper fill ratios, and deflection and springback can occur. Deflection occurs because of the column loading effect on the compacting tools during the briquetting cycle. For column load consideration, the bottom section of the lower punch is considered fixed, while the top section or working end of the lower punch can be considered free to rotate. The amount of deflection on the tool member will be determined by the column slenderness ratio of the punch and the adapter. When the column load is released after the press goes through the bottom dead center compaction point, the deflected punches will return to their original lengths, if their elastic material property limits have not been exceeded. This return movement is generally called springback and can be deleterious to the green part, depending on the fragileness of the green part section geometry involved.

Deflection can be minimized by strengthening the various tool members through changes in physical size or shape and/or by changes in material selection. The most common method of minimizing deflection effects is to equalize deflection using tool members and adapters that are designed to match the deflection characteristics of the most critical member. The ability of the tool designer to find the proper balance is paramount for production of crack-free parts.

When designing tools for production of parts other than single-level class I or II parts, deflection analysis of the tooling, tooling adapters, and press is desirable. These members are essentially stiff springs, each with a different spring rate or modulus. When the compacting load is applied, the parts deflect. When the load is released, they return to their original length. If the press contains two or more separate lower punches, the total deflection of each punch and the supporting members must be the same. Otherwise, the compacted part will move with the punch that has the greatest total deflection, leaving a portion of the part unsupported. This condition is likely to cause cracking during part ejection.

A punch under load normally is in pure compression and therefore will follow Hooke's law. If the punch has varying cross-sectional areas, each length having the same cross-sectional area is calculated individually. The total punch compression is the sum of these calculations. For a long, thin-walled punch, local buckling of the punch wall under load should be investigated. Compression of punches and their supporting members may be calculated using the equation given in Fig. 16.

Fig. 16 Punch compression. P is total punch load, L is length, Y is deflection, A is area of punch, and E is Young's modulus.

Adapter Bending. The adapter, on which the punch is mounted, usually is a flat plate with the punch and the load positioned at the center, around a hole through which either another punch or a core rod passes. This plate, if supported at the outer edge, is subjected to the pressing load around the center hole. Two forms of deflection--bending and shearing--occur in this area. Adapter deflection is linearly proportional to force. Calculated adapter stress should be compared with the allowable adapter material stress to evaluate design suitability.

Press Deflection. Like the tooling and support, the press is subject to deflection. This tendency is considerably less than that of punch compression or adapter bending, but it must be considered in total tool design. Data regarding press deflection should be obtained from the press manufacturer. Deflection is linearly proportional to the amount of force exerted:

$$Y = C \times W$$

where C is the equipment constant, W is pressing force, and Y is deflection.

Powder Metallurgy Presses and Tooling

Revised by John Porter, Cincinnati Incorporated

Tool Materials

Dies. In the most common type of die construction, wear-resistant inserts or liners are held in place by clamping or shrink fitting. The amount of interference between the insert and the die case depends on the inside and outside diameter of each member and on the compacting pressure used. The powder can be considered a fluid in a closed container that transmits the compacting pressure in all directions; therefore, the die must be designed as though it were a pressure vessel with internal pressure.

In actual practice, radial pressure on the die walls due to compacting rarely exceeds 50% of compacting pressure. The interference fit of the die case and die insert should be such that the stress on the insert always remains in compression for round dies. However, for shaped dies, such as gears, cams, and levers, finite element analysis is the best method for accurately determining stress and deflection.

Die inserts for compaction of carbide, ceramic, or ferrite powder most frequently are the medium- or coarse-grain 94WC-6Co grades of cemented carbide. Cemented tungsten carbide containing 12 to 16% Co can be used to make inserts for compacting metal powders in medium-to-long production runs.

The elastic moduli of carbides are considerably higher than those of steels, a fact that should be considered when designing composite steel and carbide die assemblies. Because carbide will deflect only 33 to 40% as much as steel, the steel portion generally should be designed with enough stiffness to support three times the expected loading in order to match the deflection of the carbide. The shrink-fit allowance should be ~ 1.0 mm/m (0.0010 in./in.). Shrink rings and similar supporting parts of the tooling can be made from medium-carbon alloy steel, such as AISI/SAE 4340 or 6150, quenched and tempered to ~ 42 to 46 HRC. It is especially important that supporting parts for carbide tools provide sufficient support; otherwise, the carbide tools are likely to break in service.

Cemented carbides are relatively expensive, and shaping of parts to the required form must be done either by electrical discharge machining or by specialized methods of grinding.

Wear-resistant tool steel inserts are sometimes used instead of carbide inserts. Tool steel inserts are tougher and easier to fabricate than carbide inserts. Powder metallurgy tool steels such as CPM 10V, Vanadis 4, and Vanadis 10 are frequently chosen for medium-to-long production runs because they have wear resistance approaching that of carbides. Other wear-resistant tool steels, usually D2 or D3 or a high-speed steel such as M2 or M4, have been used for short-run applications. Tool steel inserts generally are heat treated to a working hardness of 62 to 64 HRC. For increased wear resistance, a nitrided case may be specified for dies made of CPM 10V, Vanadis V, Vanadis 10, or D2. For certain part designs, a solid die rather than an insert die is a more practical choice; an air-hardening 5% Cr tool steel such as A2 is generally used for such applications.

Punches. The stresses imposed on punches during service are such that toughness is a much more important material requirement than wear resistance, although wear resistance cannot be ignored. Type A2, and sometimes the shock-resisting type S7, are preferred for punches. Wear-resisting grades such as D2 and CPM 10V often lack the required toughness, particularly for solid punches. In type A2, which is deep hardening upon air quenching, an as-quenched hardness of 60 HRC can be developed in the center of a section 125 mm (5 in.) square, even though a solid punch this large would seldom be used. In contrast, for type S7 the maximum section size in which such hardness can be obtained is 65 mm ($2\frac{1}{2}$ in.) square. If sections >125 mm (5 in.) square are required, type A2 should be oil quenched from the austenitizing temperature to ~ 540 °C (1000 °F), then air quenched to 65 °C (150 °F) before tempering. S7 can be carburized or nitrided for added wear resistance.

For applications in which A2 or S7 punch faces become severely abraded, a more wear-resistant grade, such as CPM 10V, D2, D3, or M2, should be considered. Cemented carbide punches and core rods employ a higher cobalt grade ($\sim 11\%$ Co) with a hardness of ~ 90 HRA. They can be made of solid carbide or a composite that uses tungsten carbide in the wear areas. More recently, fine-grain carbides with 10 wt% Co have also been employed in these applications.

Core Rods. Both toughness and wear resistance are important criteria in the selection of core-rod materials, but generally the primary consideration is wear resistance. Tungsten carbide and high-speed steels (M-grades) are the most common materials for core rods. For particularly abrasive conditions, CPM 10V has been used successfully, as have D2, M2, and A2 tool steels that have been nitrided or coated with tungsten carbide. Crucible P/M (CPM) tool steel CPM 15V has recently become popular for these applications.

Tooling support adapters normally are made from medium-carbon alloy steel, such as AISI/SAE 4140 or 6150, heat treated to a hardness sufficient to resist brinelling of the punches into the adapter surface without failing due to fatigue. Adapters should be heat treated to a minimum hardness of 28 to 32 HRC to reduce damage to critical mounting surfaces during handling.

Punch clamp rings normally are not highly stressed members, but they should be made from a heat-treatable steel to prevent damage during handling. Heat treating of the clamp ring is optional.

Operational Factors. Die working surfaces and core rods should be polished or lapped to a mirror-like surface finish, and final polishing should be done in a direction parallel to the axis of the tool. The faces and lands of the punches should also be given a fine finish. An exceptionally smooth surface finish reduces friction, thereby reducing some of the load on the tooling. It also makes it easier to eject the compacts, and it eliminates minute scratches and other stress raisers that could lead to premature fatigue failure.

Hard chromium plating is sometimes recommended to improve the life of tool steel punches and core rods, particularly when abrasive powders are involved. Some users claim that nitrided or chromium-plated die parts have up to ten times the wear resistance of untreated tool steel die parts; others claim that chromium plating is not very effective. Both nitrided and chromium-plated die parts are subject to chipping or flaking, especially at sharp edges. When this is a problem, a diffused surface layer such as that produced by chromizing may prove to be an effective alternative.

Tooling Clearances and Design

As in many other manufacturing operations, process variables (e.g., the type of materials being processed, the density of the part being produced, the amount and type of powder or die lubrication, and production rate) dictate operating conditions. Density and production rate greatly affect tool clearances during a continuous production run in which tooling temperature increases as compacted density and/or production rate increases. Temperature variations and corresponding dimensional changes within the various tooling members must be considered.

Standard tooling clearance is 0.016 mm/25 mm (0.0006 in./1 in.) on the diameter total. Minimum clearance should be used initially, because materials can always be removed from the punch or die to provide additional clearance as needed. In addition, the clearances must be smaller than the size of the powder particles to prevent their entrapment. Smaller clearances will also help reduce possible variations in the dimensions of the parts. The density of the compact produced and the production rate have a great influence on the determination of clearances. Compacting loads will be higher for increased densities. These, as well as higher production rates, increase the tooling temperature. As the temperature increases, dimensional changes occur in the tooling members. For this reason, the clearances must be sufficiently large to prevent seizure of the tools.

A representative value for the clearances between die walls and punches is 0.005 to 0.008 mm for precision parts and an upper limit of 0.013 mm for other parts. Minimum possible clearance should be used initially, because it can be increased as needed by removing material from the punch or the die.

The expansion ("pop out" or "springback") of the compact upon ejection makes it essential that the top edge of the die cavity be properly rounded or flared to allow the compact to make a smooth transition during ejection. Provision of a shallow chamfer is a more practical solution in the case of gears.

Die cavities and punch faces should be lapped and polished to a very high degree of surface finish, preferably $<0.25 \mu\text{m}$.

Shapes and Features. A shape or feature can be die compacted provided that it can be ejected from the tooling and the tools that form the feature have sufficient strength to withstand the repeated compaction loads. Due to the vertical closure of the tooling and the lack of tool motions perpendicular to the pressing direction, part removal from the tools controls many features. Examples of features that cannot be accommodated in die compaction, and therefore require secondary machining operations, include undercuts, reverse taper (larger on bottom than on top), annular grooves, and threads. The following guidelines provide assistance with many possible features in die compaction. Further details are provided in Ref 3.

Wall Thickness. Minimum wall thickness is governed by overall part size and shape. For parts of any appreciable length, walls should be not $<1.5 \text{ mm}$ (0.060 in.) thick. A maximum length-to-wall thickness ratio of 8 to 1 should be followed to ensure reasonable density uniformity and adequate tool life. Separate tool members (punches) should be used to provide density uniformity and proper ejection.

Steps. Simple steps or level changes not exceeding 15% of the overall part height (H) can be formed by face contours in the punches. A draft of 5° or more is needed to release this contour from the punch face during ejection. Features such as countersinks and counterbores can be similarly formed. This tooling method, as compared to multiple punches, will result in slight density variations from level to level. However, this approach offers the simplest tooling, lower-cost tooling, and closer axial tolerances than multiple punches.

Spherical Shapes. Complete spheres cannot normally be made because the punches would have to feather to zero width (Fig. 17). Spherical parts require a flat area around a major diameter to allow the punch to terminate in a flat section (Fig. 17). Parts that must fit into ball sockets are repressed after sintering to remove the flats.

Fig. 17 Proper design of spherical shapes in P/M parts. Source: Ref 3

Taper and Draft. Draft is not generally required or desired on straight-through parts. While tapered side walls can be produced where required, the tools may demand a short straight surface (A in Fig. 18) at the end of the taper to prevent the punch from running into the taper in the die wall or on the core rod.

Fig. 18 Tapered hole design for P/M parts. Source: Ref 3

Holes. Through holes in the pressing direction are produced with core rods extending through the punches. Round holes require the least expensive tooling, but many other shapes, such as splines, keys, keyways, D-shapes, squares, and so forth

can readily be produced. Blind holes, blind steps in holes, and tapered holes, are also readily pressed. For very large parts, lightening holes are added to reduce weight and the area of compacted surface.

Flanges. A small flange, step, or overhang can be produced by a shelf or step in the die. Separate lower punches are used if the amount of overhang becomes too great to permit ejection without breaking the flange.

Alphanumeric Characters. Numbers, lettering, logos, and other characters can be pressed into surfaces oriented perpendicular to the pressing direction. Recessed lettering is preferred because raised letters are fragile, easily damaged in the green compact, and prevent stacking of parts for sintering.

Chamfers, Radii, and Bevels. Chamfers are preferred rather than radii on part edges to prevent burring. It is common practice to add a 0.25 mm (0.010 in.) flat at a 45° chamfer; lower chamfer angles may not require the tooling flat.

Hubs and Bosses. Hubs or bosses that provide for drive or alignment rigidity in gears, sprockets, and cams can be readily produced. However, the design should ensure the maximum permissible material between the outside diameter of the hub and the root diameter gear or sprocket features.

Other Features. Additional information on these and other features (slots, grooves, knurls, studs, fillets, countersinks, etc.) can be found in Ref 3. Because shape complexity is a recognized limitation of die compaction, multipiece assembly is a useful alternative, especially where extensive machining would be required. Pulleys, spools, and sprockets have been produced using sinter bonding, brazing, and welding techniques.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Introduction

INJECTION MOLDING is widely recognized as a manufacturing approach that can form complicated shapes from plastics. Since the 1920s, there has been a progressive evolution of injection molding from strict use on plastics to use with metal and ceramic powders. This new technology, known as powder injection molding (PIM), combines the productivity of injection molding with the ability to fabricate metals and ceramics. Thus, complicated shapes emerge from materials capable of operating at high temperature, or from materials that have desirable electrical, thermal, optical, or magnetic properties not available with polymers.

Much interest exists in PIM because of five key features: low production costs, shape complexity, tight tolerances, applicability to several materials, and high final properties. Many successful applications rely on particular combinations of these attributes. Examples include orthodontic brackets for straightening teeth, porous filters for treating hot waste water, magnets for controlling computer disk drives, small gears for electric hand tools and toothbrushes, cleats on sporting shoes, surgical tools such as scalpels, electrical connectors, handgun components, eyeglass and wristwatch components, golf clubs, and microwave filters for high-frequency microelectronics.

The technology has undergone widespread commercialization since the 1980s and today is practiced in many variants, reflecting different combinations of powders, binders, molding techniques, debinding routes, and sintering furnaces. An outline of the core production sequence is given in Fig. 1. In this simple form, four steps are required: formation of the feedstock, molding into the tooling, binder removal, and sintering.

Fig. 1 Flow chart for the major activities making up the powder injection molding process. Processing tends to divide the operations into four major segments.

As schematically illustrated in Fig. 2, the first step in the production sequence is to combine a small quantity of a polymer with the powder to form a feedstock. A thermoplastic polymer is selected to provide flow upon heating in the molding machine. Feedstock for the process is formulated by mixing small powders and thermoplastic binders to form pellets that easily flow in a molding machine. Today there are several suppliers of these precompounded feedstock pellets in a wide variety of compositions. These feedstock pellets are molded into tooling that defines the shape. Once the polymer is heated the mixture can flow by viscous flow. After molding, the binder is removed (debinding) and the remaining powder structure is sintered. These last two steps can be combined into a single thermal cycle because significant shrinkage is associated with sintering. The sintered product may be further densified, heat treated, coined, plated, or machined to complete the fabrication process. Most important, the sintered component has the precision of plastic injection molding in materials that deliver properties unattainable from polymers.

Fig. 2 A flow sketch of the powder injection molding process, showing the fabrication of a component from the original binder and powder, which are combined to form feedstock, then molded, debound, and sinter densified to produce the final component

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Materials and Equipment

Feedstock. PIM begins with the mixing of selected powders and binders. The particles are small to aid sintering, usually between 0.1 and 20 μm with near-spherical shapes. For example, a 5 μm carbonyl iron powder is widely used in the PIM process, as is a -16 μm gas-atomized stainless steel powder. Most common engineering alloys are used,

including various steels, tool steels, and stainless steels. Likewise, ceramics, refractory metals, and cemented carbides are processed in a similar manner. The binder is based on a common thermoplastic such as wax or polyethylene or wax-polypropylene, but food-grade polymers, polyacetal, cellulose, gels, silanes, water, and various inorganic substances are also in use. Usually the binder system consists of two or three components. An example binder, which is molten at 150 °C, consists of 65% paraffin wax, 30% polypropylene, and 5% stearic acid. A typical binder content is near 40 vol% of the mixture; for steel that corresponds to about 6 wt% binder. A few other binder systems are:

- 90% polyacetal, 10% polyethylene
- 69% paraffin wax, 20% polypropylene, 10% carnauba wax, 1% stearic acid
- 75% peanut oil, 25% polyethylene
- 50% carnauba wax, 50% polyethylene
- 55% paraffin wax, 35% polyethylene, 10% stearic acid

Feedstock is a term for the mixture of powder and binder. Many types of powders can be used, but great differences exist in mixing and molding, especially if the particle shape is nonspherical. The formulation of a successful feedstock balances several considerations. Sufficient binder is needed to fill all voids between particles and to lubricate particle sliding during molding. A viscosity similar to that of toothpaste is generally most desirable. Mixing is best achieved using a continuous twin screw compounder. Actually the viscosity depends on several factors. At too high a powder-to-binder ratio there is a high viscosity and insufficient binder to fill all void space between the particles. Consequently, it is hard to mold such a feedstock. Alternatively, too much binder is undesirable because component shape is lost during debinding. Inhomogeneities in the feedstock lead to defects in molding; thus, a high shear is required in mixing to force the binder among all particles. Consequently, special mixing practices are required to compound feedstock for most applications. The final step in feedstock preparation is to form pellets that are easily transported to the molding machine. Figure 3 shows both worms and pellets formed for molding. An important evolution in the technology has been the preparation of feedstock by major chemical companies, removing some of the licensing and technological barriers, allowing rapid growth in the field. Table 1 details the composition of a few common injection molding feedstocks, showing the binder, powder, and formulation details.

Table 1 Examples of powder injection molding feedstock

Powder	Binder, wt%	Solids loading, vol %	Density, g/cm ³	Molding temperature, °C	Viscosity, Pa · s	Strength, MPa
4 μm Fe	60PW-40PE	58	4.90	120	35	5
4 μm Fe	55PW-45PP-5SA	61	5.12	150	19	22
4 μm Fe-2Ni	90PA-10PE	58	4.52	180	190	20
2.5 μm Mo	60PW-35PP-5SA	58	5.97	113	200	7
10 μm stainless	55PW-45PP-5SA	67	5.60	130	100	15
15 μm stainless	90PA-10PE	62	5.33	190	80	20
12 μm tool steel	90PA-10PE	62	5.33	190	180	20
8 μm W	65PW-30PP-5SA	56	11.22	142	...	5

Fig. 3 Feedstock pellets and worms for molding

Pelletized feedstock is injection molded into the desired shape by heating it in the molding machine and hot ramming it under pressure into the tool cavity. By virtue of the binder, the feedstock becomes low enough in viscosity that it can flow into the die cavity under pressure. Cooling channels in the die extract heat and solidify the polymer to preserve the molded shape. The shaping equipment is the same as that used for plastic injection molding. It consists of a die filled through a sprue, runner, and gate from a heated barrel. Most popular is molding in a reciprocating screw machine. Here the screw in the barrel stirs the feedstock while it is melting and acts as a plunger to generate the pressure needed to fill the die. In the actual molding stroke, the molten feedstock is rammed forward to fill the cold die in a split second. Molding pressures depend on several parameters, but might be 60 MPa or more. Pressure is maintained on the feedstock during cooling until the gate freezes to reduce the formation of sink marks and shrinkage voids. After cooling in the die, the component is ejected and the cycle is repeated.

Tooling. The tool materials used in PIM are similar to those encountered in many metal working, plastic injection molding, and powder metallurgy operations. Table 2 identifies some of the common tooling materials. The tool material choice depends on the anticipated number of molding cycles and the required wear resistance. On the one hand, machining difficulty and material costs need to be considered. For molding tools, P-20 is the most common material, because of the combination of strength and cost. Yet wear concerns with PIM make the selection of higher-hardness tool steels most common. Rapid prototype tool materials, including epoxy, have been used in pilot production. Soft alloys of aluminum, zinc, or bismuth are used during tool development because of easy machining. Cemented carbides are useful where wear is a primary concern, but tool fabrication is expensive and tool damage is a problem because of the low toughness. Material cost varies by a factor of ten between these materials. Tool steels are best because of the combined strength, toughness, hardness, and machinability.

Table 2 Construction materials for injection molding tools

Material	Composition	Hardness, HRC	Suggested applications
420 stainless	Fe-14Cr-1Si-1Mn-0.3C	50	Corrosion-resistant cavities, cores, inserts
440C stainless	Fe-18Cr-1Si-1Mn-1C	57	Wear-resistant, small inserts, cavities, cores
H13 tool	Fe-5Cr-1.5Mo-1Si-1V-0.4Mn-0.4C	50	Larger or intricate cavities, high toughness, low wear
M2 tool	Fe-6W-5Mo-4Cr-2V-0.3Mn-0.8C	61	Core and ejector pins
P20 steel	Fe-1.7Cr-0.8Mn-0.5Mo-0.4V-0.35C	30	General purpose, hot runner, large cavities
Cemented carbide	WC-10Co	80	High wear, compressively loaded small inserts

Tool fabrication occurs in a machining center via progressive removal of material from an initially oversized block of material. Most machining is computerized, but there is still the necessity to hand-finish critical components or dimensions in the tool set. A final surface roughness of 0.2 μm (8 $\mu\text{in.}$) is typical, but smoother finishes are used in selected applications. The desired tool hardness is typically more than 30 HRC, which is satisfied by many heat-treated stainless steels or tool steels. Under normal conditions, an injection molding tool set can mold up to one million parts. With soft tool materials like aluminum, the life is less, at 1,000 to 10,000 cycles.

The tool set has the cavity and further consists of the pathway for filling the cavity with ejectors for extracting the component from the cavity. In most instances, the tool set consists of a single cavity. This cavity captures the component shape, and it is oversized to allow for component shrinkage during sintering. Around the cavity are several tool parts needed for opening and closing the cavity, ejecting the component, aligning the die sections, moving inserts, cooling the component, and locating the sprue, runner, and gate. Figure 4 is a sketch of a molding tool set with ejector pins, ejector plate, and keyed slides to ensure proper closure of internal die components. Many operations use a three-plate mold for automated removal of the gate on mold opening.

Fig. 4 A sketch of the tool set for powder injection molding, showing major components

A primary concern in designing injection molding tooling is component shrinkage. On a volume basis, the typical feedstock contains 60% solid and 40% binder. To attain the desired final component properties, the linear shrinkage during sintering may be 15%. The shrinkage in dimensions is known as the shrinkage factor Y , calculated from the solids loading, Φ , and the sintered fractional density, ρ/ρ_T :

$$Y = 1 - \left(\frac{\Phi}{\rho/\rho_T} \right)^{1/3} \quad (\text{Eq 1})$$

where ρ is the final density and ρ_T is the theoretical density for the material. This assumes isotropic shrinkage in sintering. For example, if a 13.8 mm dimension shrinks to 12 mm, then the shrinkage factor is 0.13 or 13%, calculated as the change in a dimension divided by the original dimension. Because the target is the final component size, each dimension of the tool cavity is oversized to accommodate shrinkage. If the desired final dimension is L_f at a fractional density ρ/ρ_T from a feedstock with a fractional solids content of Φ , then the initial dimension of the tooling is given in terms of the tool cavity expansion factor, Z :

$$Z = \frac{1}{1 - Y} \quad (\text{Eq 2})$$

As an example, if the shrinkage factor Y is 0.15 (15% shrinkage), then the tool expansion factor Z is 1.1764. Thus, to obtain a 12 mm final dimension requires a tool dimension of 14.11 mm (12×1.1764). Note that the shrinkage from 14.11 mm to 12 mm is 2.11 mm, so the measured shrinkage factor is $2.1 \div 14.11$ mm, or 0.15 (15%).

At the end of the runner is the gate leading into the die cavity. It is a small opening designed to freeze before the cavity, runner, or sprue freezes. A solidified gate allows removal of the pressure at the machine while the mass in the cavity cools. Gates are usually near 3 mm in diameter. Actual gate size is determined by two factors: the filling shear strain rate and the section thickness. For the gate to freeze before the compact requires a thickness between 10 and 50% of the compact thickness.

In the typical tool set, the feedstock flow path is from the molding machine nozzle into the sprue, along the runner, through the gate, and into the mold cavity, as evident in the test geometry shown in Fig. 5. This five-step geometry has two gates fed by the runner system from the sprue. This flow path is surrounded by various clamping plates, alignment and locating pins, and ejector components. Alignment of the components and their proper sequencing and smooth motions are important to successful PIM. Most of the tool components are available as premachined packages, so only the cavity needs to be custom machined. Also, within this geometry are the cooling or heating networks designed to control mold temperature. One key advantage of injection molding is the ability to fabricate complex shapes that cannot be produced by alternative techniques. Accordingly, complex tool designs are a necessary aspect of injection molding.

Fig. 5 A five-step test geometry with dual gates attached runner and sprue

The number of cavities in the tool set depends on the number of components to be fabricated, the shot capacity of the molding machine, tool fabrication costs, and the available clamping force. Tool sets with up to 40 cavities have been used for high-volume production. Most injection-molded steel components are generated in tool sets with 1 to 16 cavities. A single cavity tool set is satisfactory for low production quantities, below about 200,000 parts. As higher productivity is required, more cavities may be justified, because production increases are gained without the purchase of new molding machines. As the number of cavities increases, the cost of manufacturing the tool set increases, but the net production cost per component decreases. Because tool cost is distributed over the production quantity, there is a minimum total cost that depends on the total production quantity increases.

After molding, the component is cooled in the die cavity. Cooling causes the binder to contract and this results in a progressively lower pressure, eventually allowing ejection of the part. The ejection force depends on the component shape and feedstock. To accomplish ejection, pins in the die body move forward with the ejector plate and push the component from the cavity. If inserts, internal cores, or threads are put into the shape, these must be retracted (possibly by motorized motions) to allow free ejection. Sometimes core pins, inserts, or other features are placed in the cavity before filling and these items become encapsulated in the part, ejecting out on each cycle. Ejector pins blemish the component, because they concentrate ejection force on a soft material. Some of the blemishes associated with molding include ejector pin marks, parting lines, and gate impressions.

For ejection, pins move from flush positions on the tool walls and push against the component to extract it from the cavity. To build in undercuts or holes perpendicular to the molding direction, the tooling must contain side-actuated cores or inserts. Using rotating cores to create threads or rifling patterns without a parting line is also possible. Unlike die compaction, in injection molding it is possible to design into the tooling perpendicular holes, undercuts, and indents using side cores that are mechanically actuated on mold opening and closing. A tool set can contain several such cores, which may be actuated using hydraulic pistons, electric motors, or mechanical motions.

Molding Machines. The three most common molding machines are reciprocating screw, hydraulic plunger, and pneumatic. Table 3 summarizes the attributes of a few such molding machines. Pneumatic machines simply apply gas pressure to move heated feedstock into the mold. They are inexpensive and effective for small components where internal flaws are not objectionable. However, voids form because the feedstock is under low pressure that fails to compensate for shrinkage on cooling. In a hydraulic molding machine, a plunger rams heated feedstock into the mold. Excess pressure is generated to compensate for the volume contraction normally encountered by feedstock cooling. This pressurization is important to forming defect-free compacts, but the control systems usually are not suitable for forming complicated shapes.

Table 3 Sample attributes of powder injection molding machines

Attribute	Low pressure	Moderate tonnage	Intermediate tonnage	High tonnage
Type	Pneumatic	Reciprocating screw	Reciprocating screw	Reciprocating screw
Clamping force, ton	0.7	25	75	200
Clamp type	Pneumatic	Hydraulic	Toggle	Hydraulic
Platen size, mm	480	260	530	900
Drive motor, kW	2	5.5	15	30
Screw diameter, mm	None	18	28	50
Injection volume, cm³	3000	35	70	350
Fill rate, cm³/s	0.5	46	66	100
Injection stroke, cm	...	9	11	14
Plastication capacity, kg/h	...	12	20	40
Screw speed, mm/s	...	110	300	110
Molding pressure, MPa	0.5	190	230	200
Shortest cycle time, s	4.8	2	1.2	3.6
Maximum temperature, °C	150	200	200	200
Control	Open-loop	Adaptive	Closed-loop	Adaptive

High-volume injection molding uses a horizontal reciprocating screw located inside a heated barrel. The screw is designed to compress and transport the feedstock to the die, and it becomes a plunger during mold filling. Figure 6 is a typical layout of a horizontal machine and Fig. 7 is a picture of a contemporary molding machine with vision system, robot, process controller, and data acquisition computer. The tooling is clamped in the center of the machine. The

granulated or pelletized powder-binder feedstock is placed in the hopper for metering into the injection barrel. This is the beginning of the molding operation.

Fig. 6 Overview of a horizontal injection molding machine and key components

Fig. 7 Picture of a research injection molding machine with attached vision system, robot, data acquisition computer, and control computer

The heart of molding lies with the motions of the reciprocating screw. This needs to be wear resistant to withstand abrasion by the particles. It has a helical pitch, the design of which is adjusted for the viscosity of the feedstock, but generally it consists of gradual section changes along its length. Screw rotation is controlled via a hydraulic motor and heat is supplied by external heaters on the barrel.

An important role of the screw rotation is to de-air the feedstock and prepare the next charge for injection. This is termed *metering*, where the screw rotates to pressurize feedstock to the nozzle. During metering the screw acts as a mixer to ensure uniform powder-binder distribution and uniform heating. The screw has a check ring behind the tip that acts as a valve that allows feedstock flow into the front of the barrel. This ring seals on the screw during mold filling and forces molten feedstock to flow into the die cavity through the nozzle at the end of the barrel. Effectively, the screw becomes a plunger during mold filling. Control of the screw rotation, displacement, and pressure is important to the fabrication of precise components by injection molding.

During the molding cycle, the screw initially rotates, compressing the feedstock. Then, during the injection step, the screw moves forward, closing the check ring, and the shot is injected into the mold. A closed-loop control system with a

quick response servohydraulic valve is required for screw position and pressure control. During the fill stroke, the volume of feedstock injected into the mold depends on the cross-sectional area of the screw and on the stroke length. A typical screw diameter is 22 mm, but it might range from 15 to 40 mm (0.6 to 1.6 in.), depending on the machine capacity.

Feedstock flow in molding depends on the applied pressure and viscosity. For a cylindrical runner, the volumetric feedstock flow rate, Q , varies with the runner diameter, D , to the fourth power according to Poiseuille's equation:

$$Q = \frac{P \pi D^4}{128 \eta L} \quad (\text{Eq 3})$$

where P is the applied pressure on the feedstock, L is the runner length, and η is the feedstock viscosity. The rate of mold filling is very sensitive to the injection pressure and runner diameter. Usually a high feedstock flow rate is needed in order to fill the die before the feedstock cools.

The barrel holds the rotating screw and is surrounded by heaters that control the mixture temperature. There are often multiple heater zones to ensure temperature control during mold filling. Because cold feedstock is abrasive, the first heater zone is geared to rapidly heat the feedstock, and subsequent zones might be at lower temperatures. The materials used in constructing the screw and barrel are critical to long service without contamination. Hard materials and close tolerances are required to reduce abrasive wear. Tool steels containing vanadium carbide and boride-clad tool steels prove most durable. Similarly, other machine components in the flow path can exhibit considerable wear, resulting in a loss of machine control.

All of the molding steps are controlled by a computer that might even correct errors during molding. Besides the molding machine, coordination is required with the peripheral operations needed in automation schemes. For example, robots are used to stage the compacts for debinding. Other automation features include conveyor systems, parts and tooling storage with automated retrieval, and continuous feedstock preparation and component debinding steps.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Process Description

Molding Cycles. A typical sequence for the injection pressure and screw position are shown in Fig. 8. Prior to filling, the screw rotates in the barrel and the external heaters bring the feedstock to temperature. The dwell time for the feedstock in the barrel must be sufficient to ensure thorough and uniform heating. Then, during molding, the screw plunges forward in a split second. This is traced by the screw displacement curve in Fig. 8. Three pressure curves are included to show that pressure is high at the source (hydraulic pressure) and lags at the cavity. The rapid rise in hydraulic pressure induces feedstock flow into the mold. Once the cavity is filled, the gate freezes and there is little effect of hydraulic pressure on the cavity pressure. The nozzle pressure is intermediate between these two.

Fig. 8 Plots of the screw position and pressures involved in molding

Moldability is a measure of the ease by which a feedstock can be shaped to a given specification. A high moldability is desired from a feedstock. In practice, several combinations of temperature, fill rate, and pressure exist that produce defect-free components. This pressure is generated by the forward motion of the screw in the barrel as a plunger. A low pressure gives incomplete packing with cavities or sink marks on the compact surface. Excessive packing pressure causes the compact to stick in the die, resulting in severe ejection problems.

To compensate for the flow resistance and pressure gradients in the molding system, the screw position and hydraulic system pressure vary during molding in a coordinated manner. Friction along the flow path decreases pressure. After mold filling, pressure is held during the packing stage. The objective is to compensate for the thermal contraction of the feedstock during cooling. Finally, when the binder has sufficiently cooled to hold the component shape and withstand the ejection forces, the die is opened and the component is ejected. The ejector motion can be from the hydraulic system or a separate mechanical motion.

The time for molding relates to the cavity size, filling time, and cooling time. It can be as short as 5 s or as long as 1 min. Initial feedstock flow requires that the molding temperature be higher than the softening point of the binder. This is usually between 50 and 200 °C (122 to 392 °F). A low temperature results in short shots (incomplete mold filling), while a high temperature degrades the binder or causes flashing or powder-binder separation, and requires prolonged cooling. Molding pressure affects the mold filling rate and is usually limited by the machine design. Once the component has cooled, the final step is component ejection. Short shots occur if either the molding temperature or pressure is too low. At the higher pressures and temperatures the components stick to the die walls or open the die along the parting line, giving flash. Voids are captured in a part if the feedstock shoots across the cavity without pushing out all of the air. This is termed *jetting* and is very undesirable. Jetting occurs with too high a fill rate, so most molding machines are programmed for a fill rate that prevents jetting.

Table 4 gives the range of molding conditions and one example of a specific component and its molding conditions. That component is a steel trigger guard for a rifle formed from carbonyl iron powder and a binder based on paraffin wax, polypropylene, and stearic acid. Once the component is molded, the polymer binder phase is extracted and the compact is sintered to near-full density. These steps are covered in the sintering articles in this Volume.

Table 4 Typical powder injection molding parameters

Parameter	Typical range	Trigger
Barrel temperature, °C	100-200	160
Nozzle temperature, °C	80-200	180
Mold temperature, °C	20-100	40
Screw rotation speed, rpm	35-70	35
Peak injection pressure, MPa	0.1-130	20
Packing pressure, MPa	0-10	8
Fill time, s	0.2-3	0.6
Packing time, s	2-60	3
Cooling time, s	18-45	20
Cycle time, s	8-360	37

Densification. Usually the binder is removed from the component prior to sinter densification. A wide array of options exist for binder extraction. Thermal debinding is the easiest to envision. The component is slowly heated to decompose the binder. As illustrated by Table 5, many variants exist. There are some differences in component precision and debinding rates. For this tabulation, the measured rates are compared on an equivalent basis of 5 μ m steel powder and 10 mm section thickness. The most popular approach is to immerse the component in a solvent that dissolves some binder, leaving some polymer behind to hold the particles in place for subsequent handling. The remaining binder is thermally extracted as part of the sintering cycle. Newer binders are water soluble, so the debinding solvent is water. Major growth is occurring in the use of catalytic phase erosion for debinding. Most of the binder is attacked by a catalytic vapor, and the residual binder is removed during heating to the sintering temperature. This can now be performed as a continuous process at the beginning of sintering. Debinding is highly variable as to binder system, technique, and section thickness. Solvent and catalytic debinding ensure the best dimensional control, because the binder is kept rigid during extraction. For these techniques penetration rates of 1 to 2 mm/h are common.

Table 5 Comparison of debinding techniques and times

Binder system	Debinding technique	Conditions	Time
Wax-polypropylene	Oxidation	Slow heat 150 °C, hold, heat to 600 °C in air	60 h
Wax-polyethylene	Wicking	Slow heat to 250 °C, hold, heat to 750 °C in hydrogen	4 h
Wax-polymer	Supercritical	Heat in freon vapor at 10 °C/min to 600 °C under 10 MPa pressure	6 h
Wax-polyethylene	Vacuum extraction	Slow heat while passing low-pressure gas over compacts, heat to sintering temperature	36 h
Water-gel	Vacuum sublime or freeze dry	Hold in vacuum to extract water vapor from ice	8 h
Oil-polymer	Solvent immersion	Hold in ethylene dichloride at 50 °C	6 h
Water-gel	Air drying	Hold at 60 °C	10 h
Polyacetal-polyethylene	Catalytic debind	Heat in nitric acid vapor at 135 °C	4 h

Note: Section thickness, 10 mm; particle size, 5 μ m; solids loading, 60 vol%

The next step is sintering, which can be incorporated directly into a thermal debinding cycle. Sintering bonds the particles together, leading to densification. Often sintering serves the dual role of densification and chemical homogenization. In the latter process, mixed powders are molded and sintering causes them to form homogeneous alloys by long-range atomic motion. Usually sintering shrinkage is uniform and isotropic, so the molded component is oversized to deliver the desired final dimensions. For metals, sintering is performed in a protective atmosphere or vacuum at a peak temperature that causes rapid elimination of the pores that were previously filled with binder. Steels and stainless steels are sintered at 1120 to 1350 °C range for 30 to 120 min, with shrinkages of 12 to 18%. Table 6 details some common sintering cycles, giving the initial green density, heating rate, maximum temperature, hold time, sintering atmosphere, support material, and final density. If the powder structure is formed homogeneously, then sintering is uniform and final dimensions can be held to close tolerances.

Table 6 Sample sintering cycles for powder injection molding materials

Material	$D, \mu\text{m}$	$\rho_G, \%$	$dT/dt, ^\circ\text{C}/\text{min}$	$T, ^\circ\text{C}$	t, min	Atmosphere	Support	$\rho_s, \%$

D , particle size; ρ_G , green density; dT/dt , heating rate; T , sintering temperature; t , time; ρ_s , sintered density

After sintering, the component has excellent strength, with properties near or even superior to those available from other processing routes. Final densification can be assisted by both hot and cold deformation, including hot isostatic pressing. Other post-sintering steps include coining, drilling, reaming, machining, plating, passivation, and heat treatment. Options in heat treatment include tempering, precipitation hardening, nitriding, and carburization.

A typical PIM component is a trigger guard for a sporting shotgun, the curved piece that surrounds the trigger below the barrel. It is fabricated from a low-alloy iron-nickel steel, usually with a final weight of 40 g. A mixture of 5 μm Fe and 8 μm Ni powders are used. These are combined with wax and polyethylene to form feedstock that can be molded at 58 vol% solids. During molding, the nozzle temperature in the molding machine is 175 $^\circ\text{C}$ with a die temperature of 40 $^\circ\text{C}$. The maximum pressure applied during mold filling is 20 MPa and a pressure of 8 MPa is held on the feedstock during cooling. The mold filling time is rapid (about 0.5 s), but the mold cooling time is 18 s, with a total cycle time of 37 s between parts.

Powder Injection Molding

Randall M. German, The Pennsylvania State University

Advantages and Limitations

Process Attributes. As emphasized already, PIM can produce a range of components from powders. A main attraction is the economical production of complex parts from high-performance materials. Because of the high final density, the PIM products are often superior to those produced by other powder fabrication routes. Most materials are available, including all common ceramics and alloys: steel, stainless steel, tool steel, silicon nitride, cemented carbide, silicon carbide, copper, tungsten heavy alloys, nickel-base alloys, alumina, cobalt-base alloys, and composites that include tungsten-copper and molybdenum-copper.

Besides the primary advantages of shape complexity, low cost, and high performance, several other attributes are worthy of notice. Producing both internal and external threads in the molded component is possible, thereby avoiding post-sintering machining. Also, waffle patterns and insignias can be molded directly into the component. Furthermore, the surface finish is typically good.

PIM vs. Die Compaction. Some confusion exists about the difference between PIM and traditional die compaction. The latter process is widely employed in forming powders into squat (low-height) shapes that can be ejected from compression tooling. Die compaction usually employs high forming pressures but gives less shape complexity. Most

important, uniaxial die compaction results in density gradients in the compact, unlike PIM, which is hydrostatic. Density gradients result in distortion during sintering. Consequently, components fabricated from pressed powder are either sintered at lower temperatures, where sintering shrinkage is avoided, or machined after sintering. Otherwise, dimensional scatter becomes unacceptably large. Because of forming pressure gradients, sintering temperature differences, and differing performance levels, PIM and traditional powder compaction are usually not applied to the same structures. The PIM approach is suited for complex shapes sintered to near-full density, while die compaction is suited to simple shapes, sintered at lower temperatures to lower performance levels. The low porosity in PIM materials gives a high strength, toughness, ductility, conductivity, magnetic response, and so on.

Advantages. Besides the traditional materials, PIM can also produce specialty materials such as nickel superalloys, intermetallics, precious metals, refractory metals, and ceramic-fiber reinforced ceramic composites. Co-molding is another possibility, where two materials are combined to make a laminated structure. Such components can be joined in the green condition. This option has merit for creating corrosion barriers, wear surfaces, electrical interconnections, or high-toughness structures.

For the producer, injection molding is a desirable option because of manufacturing ease, including process control, flexibility, and automation. Inherently, injection molding is associated with large production volumes. Various components are produced at rates approaching 100,000 per day. On the other hand, small production runs are possible, with as few as 5000 parts per year being economical. This flexibility fits well with the current desires for quick response in manufacturing.

As with all technologies, the essence centers on economics. Powder injection molding is cost advantageous for the more complex shapes. The largest advantage comes from the elimination of the secondary operations, such as grinding, machining, drilling, or boring, that typically are required for precision components. Also, since the feedstock material (runners, sprues, and damaged moldings) can be recycled, material use is nearly 100%. This is especially important for costly raw materials such as refractory metals, specialty ceramics, and precious metals.

Process Limitations. Generally, PIM is viable for all shapes that can be formed by plastic injection molding. Still, for shapes with simple or axial-symmetric geometries, it is not competitive with traditional screw machining or die compaction and sintering.

In some cases another limitation is the component size. Large components require more powder (a large expense in some compositions), and large molding and sintering devices, which are more expensive and difficult to control. Small components with simple geometries can be more economically produced by standard machining, die compaction, or casting techniques.

Debinding is a key problem with PIM because the time for binder removal depends on the section thickness. Consequently, various manufacturers have set upper limits on section thicknesses, ranging from 10 to 50 mm. On the other hand, PIM has been used to form section thicknesses less than 0.5 mm. In practice, dimensional tolerances are typically within 0.3% of a target, although holding tighter tolerances on critical dimensions is possible. For better dimensional control, machining or coining is required after sintering. Density gradients can result from uneven filling, thickness variations, or direction changes during molding, and they often cause component warpage in sintering. Thus, manufacturers minimize changes in section thickness and if possible hold the variation in thickness within a factor of two. However, 10- to 100-fold section thickness changes are possible. Maximum sizes depend on several factors, including tool costs, powder costs, and equipment capacities. Typically, the largest dimension is below 100 mm, with the total component volume being below 100 cm³. However, much larger components are in production.

The small particles used in PIM are more expensive than larger powders or wrought materials. This becomes a barrier to large component fabrication, because powder cost becomes a larger fraction of the production cost. On the other hand, as consumption increases, the powder cost continues to decline.

Substantial problems facing the technology are the lack of knowledge on the part of end users, missing property data, and the shortage of personnel trained in the basic process. These problems are acute with the ceramic materials because of the high sensitivity of ceramics to microstructural flaws induced during molding. Further, a lack of design guidelines has inhibited PIM from being adapted as a replacement for other production routes. These problems are being addressed via seminars and educational literature. However, the many process variants create initial confusion.

Powder Injection Molding

Design Guide

Certain component characteristics are best suited to PIM. Early identification of a match with these characteristics ensures technical and economic success. The considerations involve the materials, properties, component size and shape, tolerances, production costs, production quantity, and delivery schedule. Powder injection molding is best applied to the fabrication of complex, small components, especially those that would otherwise require multiple assembly or forming operations in alternative production routes. Further advantages occur when the material is expensive or difficult to process by alternative techniques. However, the shape complexity that can be produced is limited. Various shapes require secondary machining operations or complicated tooling that increase the manufacturing expense.

Tolerances are another concern. Precise tolerances prove difficult to achieve; production variations on a dimension are $\pm 0.1\%$ for special cases, and $\pm 0.3\%$ is more typical. Besides dimensional variability, successful component design must allow for noncritical placement of the parting line, ejector pin marks, and gate. It is also desirable to include a slight draft or taper of 0.5 to 2° to assist in ejection from the mold. Because precision tooling is expensive, the production quantity must justify the initial tooling cost. These factors need to be evaluated early to ensure feasibility. Greatest success is attained by early discussions of the manufacturing approach so that features can be incorporated that will aid PIM processing.

To emphasize the contemporary fabrication range, Table 7 summarizes the minimum, maximum, and typical features. Some explanation is in order. Components are characterized by the geometric aspects, including the largest dimension and the wall thickness. For PIM, the wall thickness is usually small, and it might be less than 10% of the largest dimension. Further, the variation in thickness over the part is usually small. The blades of scissors are an example where the length is much greater than the thickness, and the thickness is not highly variable. It is thickness that determines debinding time and is the main limitation of PIM.

Table 7 General criteria for powder injection molding

Attribute	Minimum	Maximum	Typical
Thickness, mm	0.2	25	10
Thickness variation	None	100×	2×
Longest dimension, mm	2	1,000	100
Tolerances, % (standard deviation)	0.03	2	0.3
Number of dimensional specifications	20	1,000	100
Mass, g	0.02	20,000	40
Material	Simple element	Composites	Alloys
Properties	Unimportant	Highest attainable	Handbook
Cost per part, \$	0.20	400	2
Production quantity per year	200	20,000,000	150,000

Another gage of PIM candidates is through the information content, which is akin to the number of dimensions on the engineering drawing. A simple shape, like a flat washer for a bolt, has only a few features, while a microcomputer circuit has many millions of features; both would be poor applications for PIM. Common PIM successes involve several dimensions in the 20 to 40 g range--a wristwatch case is one example that matches well with the technology. The typical mass is low, and similar attributes are evident in components for electronic packaging, computer disk drives, surgical tools, and firearms. On the other hand, metal, ceramic, and carbide bodies have been fabricated that are several kilograms in mass and up to 1 m in maximum length. These are somewhat lower-precision structures used in electric power turbines, steel mills, and furnace construction. The general production limit for precise components is 250 g, although several special processes have evolved to produce precise components as large as 1 kg.

Only in a few instances are mechanical or physical properties unimportant, such as in jewelry and wristwatch cases. More typically the goal is to attain near-handbook properties for the selected material. Likewise, only rarely are properties

pushed to the limits for any material. In these cases secondary hot isostatic pressing or other treatments might be employed to ensure maximum properties. From a cost consideration, typical prices are moderate, but that assumes a high production volume to justify the cost of tool construction, and dimensional tolerances that are compatible with the inherent process variability. Thus, a general processing window exists that proves most feasible. The typical parts are small enough to be held in a hand, but can be as small as the tip of a pencil. This implies that very large objects are difficult or expensive to produce by PIM, as contrasted with other forming technologies.

Geometric Considerations. In a simple sense, if a shape can be formed from plastic, then PIM is viable. Tables 7 and 8 provide general quantitative and qualitative component design guidelines.

Table 8 Nominal powder injection molding component design guidelines

<p>Restrictions</p> <ul style="list-style-type: none"> • No inside closed cavities • Corner radius greater than 0.075 mm • Smallest hole diameter 0.1 mm • Weight range 0.02 g to 20 kg • No undercuts on internal bores • 2° draft on long parts • Minimum thickness 0.2 mm
<p>Desirable features</p> <ul style="list-style-type: none"> • Gradual section thickness changes • Weight less than 100 g • Assemblies in one piece • Small aspect ratio geometries • Largest dimension below 100 mm • Wall thickness less than 10 mm • Flat surfaces for support
<p>Allowed design features</p> <ul style="list-style-type: none"> • Holes at angles to one another • Stiffening ribs • Protrusions and studs • D-shaped and keyed holes • Hexagonal, square, blind, and flat bottom holes • Knurled and waffle surfaces • External or internal threads • Part number or identification in die

The particle size is a dictate for the minimum section thickness. The powder size needs to be less than one-tenth of the smallest thickness. Particle size limits the sharpness of all corners, because the minimum particle radius is the edge radius, but more typically several particles are needed to fill out the dimension. A conceptual limit on an edge radius is 0.05 mm and a corner radius is 0.1 mm.

Table 8 also lists options in the design or production of PIM compacts. These options include square holes, flat-bottomed holes, knurled surfaces, faces, twists, curls, helical geometries, and external or internal threads. Although these features are not needed to make a PIM compact viable, they are possible and add to the design flexibility. Certain attributes, such as component size and mass, will increase as experience and manufacturing optimization occur. Already components up

to 10 kg and 1,000 mm maximum length have been fabricated by PIM. These require special efforts and are not routine products. With respect to changes in the section thickness, a ratio of 2 is typical; however, compacts have been successfully fabricated with thickness changes of 100:1.

Component design has a great influence on the success of PIM. Identification of injection molding as a production process in the design stage allows changes that increase the ease and lower the manufacturing cost. Possible design shifts that give essentially the same functional features are sketched in Fig. 9. Two alternatives are shown in each case. Both alternatives achieve the same design objectives, but one is better aligned with the specifics of the PIM approach.

Fig. 9 Recommended designs for powder injection molding components and suggestions for improved processing

Table 9 summarizes the minimum and typical tolerances possible in PIM processing without secondary operations. Generally, the ability to hold tolerances increases with production experience. With little effort, dimensional tolerances can be held within 0.5% (one standard deviation). A controlled process with solvent, wicking, or catalytic debinding allows dimensions to be held with a deviation of 0.3% or less, and critical dimensions can be held within 0.1%. With newer binder systems and integrated process controls these values can be improved to 0.05%. In the production of jet engine ceramic casting cores, the mass ranges from 10 to 1200 g and part lengths range from 2 to 50 cm. These cores are produced with final dimensional scatter of $\pm 0.05\%$ on length (one standard deviation) in production quantities over

50,000 per week. Larger dimensions exhibit more scatter. Fortunately, the component density can be held within $\pm 1\%$ and weight variation to $\pm 0.1\%$.

Table 9 Typical standard deviation of powder injection molding production components

Feature	Best possible	Typical
Angle	0.1°	2°
Density	0.2%	1%
Weight	0.1%	0.4%
Dimension	0.05%	0.3%
Absolute dimension	0.04 mm	0.1 mm
Hole diameter	0.04%	0.1%
Hole location	0.1%	0.3%
Flatness	0.1%	0.2%
Parallelism	0.2%	0.3%
Roundness	0.3%	0.3%
Perpendicularity	0.1% or 0.1°	0.2% or 0.3°
Average roughness	0.4 μm	10 μm

Powder Injection Molding

Materials and Applications

The availabilities of small powders that match the needed characteristics for molding determine the production materials used in PIM. Most of the classic engineering materials are available except aluminum, glass, lead, and tin. Typically ferrous alloys and alumina-base ceramics are used most often. For the stainless steels, the 316L composition is used frequently, because of its combined strength and corrosion resistance. Another favorite is 17-4 PH stainless steel, which is precipitation hardenable. Other compositions with more chromium are available, and for easier sintering, two-phase compositions that have high levels of molybdenum (up to 6%), chromium (up to 22%), or silicon (up to 3%) are preferred. These are sometimes called duplex stainless steels, because of the two-phase final microstructure. Stainless steels, iron-nickel compositions, and alumina are the materials most often used. Figures 10, 11, 12, 13, and 14 show a few examples of PIM components.

Fig. 14 Some wear components formed by powder injection molding out of cemented carbides

Properties. The properties attainable with PIM are generally equivalent to those possible via other production techniques. Although many PIM components are selected for thermal, optical, or wear applications, the bulk of the property evaluation has focused on mechanical properties. A few sample mechanical properties of PIM materials are given in Table 10. However, there is considerable variability. For example, there have been several reports on 316L stainless steel formed by PIM. Sintered densities ranged from 93 to 100% of theoretical, with a reported mean yield strength of 220 MPa, but a range from 170 to 345 MPa. The lowest strength occurred with the lowest density. Likewise, a range from 18 to 81% elongation has been reported, with a mean of 45% and a standard deviation of 17%. The scatter reflects variations between vendors, especially in controlling impurities such as carbon, oxygen, and nitrogen during debinding and sintering. These same impurities degrade corrosion resistance.

Table 10 Selected mechanical properties of powder injection molding metals and alloys

Material	Composition, wt%	Density, %	Yield strength, MPa	Ultimate tensile strength, MPa	Elongation, %	Hardness
4140 (HT)	Fe-1Cr-0.4C	93	1240	1380	2	40 HRC
4640 steel (HT)	Fe-2Ni-1Mo-0.4C	97	1400	2000	3	30 HRC
Iron-copper steel	Fe-2Cu-0.8C	95	...	700	10	92 HRB
Iron-chromium steel	Fe-1Cr-0.5C	94	...	600	10	90 HRB
Iron-nickel	Fe-50Ni	96	170	420	20	50 HRB
Iron-nickel steel (HT)	Fe-2Ni-0.5C	94	1230	1230	1	45 HRC
Iron-silicon	Fe-3Si	99	345	520	25	85 HRB
Kovar or F15	Fe-29Ni-17Co	98	350	520	42	60 HRB
Stainless 17-4 PH (HT)	Fe-16Cr-4Ni-4Cu	96	965	1140	12	35 HRC
Stainless 316L	Fe-17Cr-12Ni-2Mo-2Mn	96	220	510	45	75 HRB
Stainless 420 (HT)	Fe-13Cr-1Mn-1Si	92	690	1440	6	47 HRC

Tool steel	Fe-6W-5Mo-4Cr-2V-1C	99	...	2000	0	66 HRC
Tungsten heavy alloy	W-4Ni-1Fe	99	650	1000	20	50 HRA

HT, heat treated

In the Fe-2Ni steels, when the carbon level is almost zero the sintered yield strength is about 190 MPa and the fracture elongation is 30%. When the carbon level is increased to 0.5%, the heat-treated material has a yield strength of 1230 MPa with 1% fracture elongation. These dramatic shifts in strength and ductility are due to the retained carbon. For ductile

systems, the strength will typically have a standard deviation of 20 MPa and the elongation will have a standard deviation of approximately 1%.

The dynamic properties, such as fatigue and impact toughness, depend on the pore structure. In the case where the final pores are small and spherical, there is competitive resistance to crack propagation. Unfortunately, dynamic properties are not commonly tested. Early reports gave fatigue endurance strengths of 219 MPa for Fe-7Ni, 237 MPa for Fe-7Ni-0.5C, 575 MPa for 4640 steel, and 517 MPa for 17-4 PH stainless steel. Improved fatigue strength comes with case hardening. Hot tensile tests on PIM 316L stainless steel have shown a steady decline in strength as temperature increases, with yield strengths of 258, 177, 121, 71, and 62 MPa at temperatures of 180, 300, 500, 700, and 900 °C. The ductility remained fairly high, over 25% up to 900 °C.

Impact toughness tends to be low when measured with pre-notched samples, largely because of residual porosity effects on cracking. Fracture toughness has been evaluated for only a few PIM materials, but these are similar to more conventional processing routes.

Corrosion resistance of the PIM stainless steels is a concern. When properly processed without contamination, the PIM products are corrosion resistant, and they are often superior to wrought materials for thin sections. Corrosion is highly dependent on impurities, density, and final thermal cycles. However, as a simple generalization, often the sintered corrosion properties match or exceed the typical properties observed with alternative processing routes.

The soft magnetic characteristics are of interest for the ferrous systems such as iron, Fe-2Ni, Fe-3Si, Fe-0.45P, Fe-0.6P, and Fe-50Ni. Of these, the Fe-50Ni alloy has the most attractive combination of high magnetization and low coercive force. Experience shows considerable variability in the coercive force. Part of this variation is directly due to differences in sintered density, but impurity control is also a major factor. Like corrosion and strength, the magnetic characteristics are sensitive to contaminants in the compacts.

Economics. Cost is the critical parameter in determining the feasibility of PIM production. It depends on many factors, not the least being the initial tooling cost. Other factors include the number of cavities in the tool set, production quantity, powder cost, details of the fabrication steps, surface roughness, packaging requirements, labor rates, and required tolerances. The best applications for PIM involve high production quantities of complex parts formed from materials that are difficult to fabricate. A desirable production quantity is more than 50,000 per year, although at quantities over approximately 100,000 per year the tooling cost per compact is not significantly less, because of needed tooling refinishing. For production of 250,000 per year or more, the use of multiple cavity tooling is typical, and up to 16 cavities are typical. New products are planned to reach production rates of 300,000 to 500,000 per day. Current industry growth rates are near 22% per year, after reaching sustained rates of 32% per year through the 1990s.

Binder-Assisted Extrusion

David E. Alman and Jeffrey A. Hawk, U.S. Department of Energy, Albany Research Center

Introduction

BINDER-ASSISTED EXTRUSION is a plastic forming process in which a highly viscous feedstock, that is, a powder mixed with a binder and other rheology modifiers (also termed the paste), is forced through a die to form a shaped product. The binder-assisted extrusion process is used commercially to produce ceramic parts, such as furnace tubes, bricks, insulators, pipes, tiles, tubular capacitors, catalyst supports, magnets, heat exchangers, wires, and springs (Ref 1, 2, 3, 4, 5, 6, 7, 8). However, binder-assisted extrusion has also been used to fabricate metals and high-temperature superconductors (Ref 9, 10), as well as being a technique for aligning reinforcement in the processing of advanced composites (Ref 11, 12, 13). Depending on the powders being shaped, the extrusion process can be performed at room temperature with the utilization of a solvent-based binder, or at elevated temperatures with a plastic binder system.

The basic principles of binder-assisted extrusion are similar to powder injection molding (PIM) in that both processes consist of four very similar steps: (1) feedstock or paste preparation; (2) product shape forming (powder extrusion in one case, powder injection in the other); (3) binder removal; and (4) the consolidation step, that is, sintering. During the feedstock/paste preparation stage, the powders are mixed with the constituents of the binder to obtain the proper flow characteristics. Feedstock preparation may consist of several steps (e.g., dry mixing, wet mixing, and high-shear mixing) to remove agglomerations, to produce a uniform mixture, and to coat the powder particles with the binder. During the forming step, the feedstock/paste is extruded through the appropriately shaped die. At this point in the process, the part must possess enough structural integrity to be manipulated while maintaining its shape. In the finishing step the part is cut to size, dried, and thermally processed. Table 1 summarizes the steps generally followed in making a part using the binder-assisted extrusion process. Knowledge and control of each step in the process are crucial to the production of a sound part.

Table 1 Stages of binder-assisted extrusion

Processing stage	Purpose	Potential difficulties
Dry mixing	Uniformly mix all solid components	Regions of poorly mixed solids
Wet mixing (for solvent-based binders systems)	Uniformly distribute particles in liquid	Air entrapment; liquid rheology may prevent mixing; adherence to surfaces
High-shear mixing	Break down agglomerates; ensure binder surrounds individual powder particle	Binder--powder separation; incomplete deagglomeration
Degassing	Remove entrapped gas	Hard to achieve in some equipment
Extrusion	Shape feedstock	Binder--powder separation; excessive pressure drop; lamination flow defects between confluent streams; surface defects
Extrudate handling and cutting	Remove product from extruder and cut to desired length	Damage to weak product; surface damage; closure of internal holes during cutting
Binder removal	Remove binder; aid shape retention	Dry cracks from solvent-based binder system; incomplete binder burnout resulting in residual contaminates in product
Sintering	Generate strength in product; remove porosity	Temporary weakness in extrudate

Adapted from Ref 6

Binder-assisted extrusion differs from PIM in that the extrusion usually consists of a constant cross section. Although parts with complicated cross sections can be produced, a selection of which is shown in Fig. 1.

Fig. 1 Schematic of typical cross sections produced by binder-assisted extrusion. Source: Ref 2

Binder-assisted extrusion and its derivatives have many advantages and some important disadvantages when compared to other powder processing techniques, for example, powder compaction in dies, isostatic pressing, slip and tape casting, and so forth. According to Benbow and Bridgwater (Ref 6), the primary advantages of using the binder-assisted extrusion processes include:

- The formation of complicated cross sections
- The small amount of binder/liquid added to the solids
- The ability to shape very hard powders
- A uniform density distribution
- The construction of long, thin sections
- Competitive capital and operating costs relative to other processes

The disadvantages include:

- The final structure is dependent on the powder properties.
- The strength is not imparted during the extrusion process itself.
- Structural defects may be introduced.
- Structure or strength are not generally adjustable by changing the extrusion conditions.
- Binder and rheology modifiers can adversely affect product properties, and the rate at which the binder and rheology modifiers can be removed from the extrudate is slow.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Introduction

As raw materials and processing methods continue to improve, more high-performance components requiring heat treatment are being converted to powder metallurgy due to its net-shape capability and cost effectiveness. Powder metallurgy parts sintered to net shape after compaction typically contain a minimum of approximately 10% residual internal porosity in traditional press-and-sinter methods. With warm compaction, minimum residual porosity can be lowered to approximately 5%.

Unlike wrought steels, where hardening response is controlled primarily by chemical composition and grain size, P/M hardenability is significantly influenced by this interconnecting porosity, which makes the structure permeable to gases and fluids.

Because P/M processing can provide net-shape capability, the hardening process becomes much more critical when compared to near-net-shape wrought components where finish machining is usually applied after the harden-and-temper operations. With powder metallurgy, dimensional shrinkage normally occurs upon quenching and tempering. With simple shapes this shrinkage is predictable and can be accommodated in the compaction tool design.

However, as the P/M components become more complex in shape, such as the typical multilevel parts in production today, variations in porosity from one level to another can cause significant distortion in the part upon heat treating, which can affect the function or fit of the part in an assembly. When this occurs, a finish machining operation is usually required, which detracts from the cost benefit of powder metallurgy.

This permeability also influences the hardenability of the material. The interconnected porosity acts as an insulator and reduces the thermal conductivity of the material. When rapidly quenched from the austenite range, this permeability retards the cooling rate, resulting in mixed microstructure and inconsistent hardness measurements. These variations increase with part-shape complexity.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Effect of Porosity on Material Properties

Powder metallurgy materials are unique due to their permeable nature. This permeability reduces the theoretical density of the base metal, it changes the thermal conductivity as mentioned earlier, and it also affects other physical properties such as ferromagnetism and elastic modulus. Mechanical properties such as tensile strength, fatigue strength, and impact resistance are directly influenced by porosity.

Due to this influence, the hardenability of a P/M ferrous alloy is reduced in direct proportion with an increase in porosity. This is illustrated in Fig. 1, where the results of a series of Jominy tests on sintered carbon steel test bars are compared with a wrought steel of similar composition. The P/M specimens were prepared from atomized iron powder mixed with 0.90% graphite, compacted and sintered to various density levels ranging from 6.0 to 7.1 g/cm³. These correspond to porosity levels

ranging from 9 to 24%. The sintered bars along with a bar machined from wrought SAE 1080 steel having a composition similar to the P/M material, were austenitized at 870 °C (1600 °F) for 30 min in a neutral atmosphere. There were then water quenched in a Jominy fixture as described in ASTM A 255. Hardness readings were taken every 2.5 mm (0.10 in.) from the quenched end and plotted as shown in Fig. 1. This illustrates two important features of P/M heat treatment. Not only is hardenability directly affected by porosity through its influence on thermal conductivity, but there is also an important secondary effect because porosity also reduces the true hardness measurement of the material. A Rockwell or Brinell hardness measurement on a sintered material is referred to as apparent hardness due to the lower resistance to penetration of the indenter caused by the porosity.

Fig. 1 Comparison of water quench Jominy tests (ASTM A 255) of sintered carbon steel test bars (density ranging from 6.0 to 7.1 g/cm³) with wrought C-1080 steel with similar composition

A more practical effect of porosity is the limitation of the quenching medium to oil. Quenching in water or liquid salts can degrade the material because these entrained fluids can initiate internal corrosion. With the advent of gas pressure quench vacuum furnaces, P/M alloy steels with sufficient hardenability can be hardened without this problem of liquid entrapment.

Influence of Porosity on Case Depth

In P/M steel parts with interconnected porosity, case-hardening processes such as carburizing, carbonitriding, and nitrocarburizing become much more sensitive to process control due to the rapid penetration of the atmosphere gases. These high-carbon-potential atmospheres diffuse into the internal pore surfaces at the same rate as the external surfaces of the part, causing very rapid carburizing to a significant depth below the surface and a consequent loss of a sharp case/core transition zone.

The micrographs in Fig. 2 show microstructures of P/M test specimens that were carburized at 865 °C (1590 °F) for 30 min. The test bars were processed to attain increasing density levels ranging from 7.0 to 7.7 g/cm³ sintered density.

Fig. 2 Microstructures of heat treated P/M test specimens carburized for 30 min at 865 °C (1590 °F) to density levels and case depths of: (a) 7.72 g/cm³ and 0.23 mm (0.004 in.) (b) 7.45 g/cm³, and 0.46 mm (0.018 in.) (c) 7.34 g/cm³ and 0.6 mm (0.024 in.) (d) 7.08 g/cm³ and 1.25 mm (0.050 in.)

As shown, increasing density was accompanied by a proportional decrease in carbon penetration. At 7.2 g/cm³, the interconnected pores begin to close off, thereby preventing the atmosphere gases from penetrating into the internal volume of the material. Plotting case depth versus density (Fig. 3) shows that for optimal control of case-hardening processes P/M parts should be specified at 7.2 g/cm³ or higher.

Fig. 3 Effect of increasing density on case depth for F-0000 P/M iron and FL-4400 P/M steel carburized at 865 °C (1590 °F) for 3 h and 30 min, respectively, with 0.95% carbon potential, 80 °C (175 °F) oil temperature, and 150 °C (300 °F) temper. Test bars for FL-4400 are shown in Fig. 2

The primary purpose of case hardening low-carbon steels is to provide a hard, wear-resistant surface while maintaining a tough, resilient core. This combination imparts optimal properties for gears and other highly stressed components. When carbon penetration is uncontrolled, such components can exhibit extreme embrittlement and dimensional distortion upon quenching.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Influence of Alloy Content on P/M Hardenability

Increasing the carbon content of a steel increases tensile strength and hardness in proportion with the added carbon. In P/M steels, this ratio is reached at the eutectoid composition of 0.8% C. Increasing carbon content above this level allows carbide networks to form at grain boundaries and along pore channels, causing embrittlement and loss of strength.

When selecting a P/M alloy for subsequent heat treatment to improve strength, carbon content of the sintered material becomes the most critical variable. This is controlled by the graphite addition to the powder blend and the atmosphere control during the sintering operation. Hardenability is determined by part mass, density, and alloy content. The requirement for maximum strength improvement is a microstructure that is predominantly martensite at the surface, but contains sufficient transformation products in the core to provide a measure of toughness.

Figure 4 shows the influence of carbon content on the tensile strength of an iron-phosphorus (0.45 wt%) specimen sintered to 6.8 g/cm³ density and subsequently reheated to 845 °C (1550 °F) for 15 min in a sealed quench furnace containing an endothermic atmosphere with a 0.85 C potential. The tensile specimens, which were machined from bars, were then oil quenched and tempered at 175 °C (350 °F) for 2 h.

Fig. 4 Influence of carbon content on strength of iron-phosphorus alloy at 6.8 g/cm³ sinter density

As shown, sintered strength continues to increase with carbon content, but reaches its peak strength after hardening at approximately 0.40 to 0.50% C content. Also, elongation, which is reduced by the transformation stresses, is also decreased by increasing carbon levels in the material. To ensure strength improvement after hardening, the core microstructure should contain no more than 70% martensite, the remainder being a mixture of bainite and unresolved pearlite that can improve impact and fatigue resistance.

As alloying elements such as nickel, molybdenum, chromium, and copper are added, the optimal carbon content is lowered. In sintered steels, the most common alloying elements are copper and nickel.

Copper Content. Additions of copper increase both apparent hardness and tensile strength in the sintered condition. Upon hardening, it increases surface hardness, but loses toughness and strength due to its embrittling influence. This relationship between copper content and combined carbon is illustrated in Fig. 5. In the plain Fe-C compositions, peak strength occurs near the eutectoid composition in the as-sintered condition at approximately 0.65% C in the hardened-and-tempered condition. By adding copper to the sintered-steel composition, strength is significantly increased with increasing copper up to approximately 5% Cu. Upon heat treatment, however, optimal strength is found at lower carbon levels as the copper content is increased.

Fig. 5 Influence of copper and carbon content on strength of hardened P/M steel at 6.8% g/cm³

Nickel Content. Nickel increases tensile properties in sintered steels, but to a lesser degree than does copper. However, it provides significant strength improvement after heat treatment. This is due in part to the heterogeneous nature of nickel alloy steels made from blended elemental powders. Copper forms a liquid phase at the conventional sinter temperature of 1120 °C (2050 °F) and combines with the iron to form a solid solution that provides a considerable increase in strength and hardness. Nickel, having a much higher melting point, combines with iron by solid-state diffusion. This produces a duplex microstructure consisting of partially alloyed iron surrounded by nickel-rich islands. Upon quenching, the matrix transforms to martensite, but the nickel-rich areas remain austenitic, resulting in a strengthened matrix with some retention of toughness and ductility.

By alloying with both nickel and copper, the hardenability of a P/M steel can be substantially improved, as shown in Fig. 6. Here Jominy bars were pressed to a 6.7 g/cm³ density with increasing amounts of copper and nickel additions. Carbon content was kept at 0.5% C. After sintering, all bars were austenitized at 850 °C (1560 °F) for 2 h before quenching. A dramatic increase in surface hardness was seen with a 2.5% Cu addition. Adding nickel produces a small increase in surface hardness, but a significant increase in depth of hardness. Many components that require optimal hardness and hardenability contain both copper and nickel additions.

Prealloy/Diffusion Alloyed Irons

Prealloyed irons are completely alloyed with hardenability agents such as manganese, nickel, molybdenum, and chromium to provide improved dynamic properties upon densification and heat treatment.

Diffusion alloyed irons are produced by coreducing the iron oxide with the oxides of these elements to provide partial alloying. The advantage of partial alloying compared to prealloying is improved compressibility, allowing for higher green density at a given compaction pressure.

In rotating bending fatigue (RBF) testing, as well as in component testing, it has been found that these alloys provide improved fatigue strength at higher densities than the preblended steel compositions. These alloys are frequently specified for highly stressed components where fatigue strength and impact resistance are required.

Figure 7 shows the improvement in fatigue strength compared to tensile strength at two density levels after hardening. As shown, the fatigue strength improvement is most pronounced with increased density and combination of a prealloy with elemental nickel to form a composite microstructure of tempered martensite and nickel-rich austenite.

Fig. 7 Influence of alloy content on fatigue strength of heat treated low-alloy steels

The process route taken to make a component also is a significant factor in developing optimal properties. Table 1 shows the comparison of properties attained from an FL-4405 alloy by a single press sinter (SPS), a double press double sinter (DPDS), and a DPDS coupled with a high temperature sinter (HTS). As shown, HTS combined with high density provides a substantial increase in static and dynamic properties after heat treatment.

Table 1 Influence of density and sinter cycle on heat treat properties for 0.85 Mo-0, 13 Mn-0.40C alloy

Sinter cycle	Density g/cm ³	Sinter temperature		Atmosphere	Sintered ultimate tensile strength		Heat treated ^(a) ultimate tensile strength		Charpy impact		Apparent hardness, HRC	Microhardness,		Carbon content, %

(a) Heat treat: carburize at 900 °C (1650 °F) for 2 h, oil quench and temper 175 °C (350 °F) for 2 h

Preblended, prealloyed, and diffusion alloyed powders are being used in high-density components that are highly stressed during service. The component shape and process requirements usually dictate which type of powder is specified. If secondary machining is required, a less hardenable alloy may be necessary for improved machinability. All of these process requirements need to be considered to make the part cost effectively. The heat treatment must also be included in this analysis. These considerations need to be determined prior to design and manufacture of hard tooling. Dimensional change varies depending on the base powder type and composition as well as density and process conditions.

Figure 8 shows the dimensional changes occurring in three powder types at a given density with different graphite additions. Here, the transverse rupture bars of each material were sintered together at 1130 °C (2070 °F) for 30 min in N₂10%H₂ atmosphere then quenched from 870 °C (1600 °F) in a fast oil and temperature at 180 °C (350 °F) for 1 h. As shown, significant variation can occur, depending on type of powder and the extent of additives. It is very difficult to change powder compositions once tooling has been developed and maintain part tolerances.

Fig. 8 Effect of carbon and heat treatment on size change. Density: 7.0 g/cm³. TR, transverse rupture

Heat Treating Processes Applied To P/M Parts

The majority of P/M parts heat treated today are neutral hardened and tempered. This treatment was used to develop the properties shown in MPIF standard 35 (Ref 6). These steels are hardened primarily for wear resistance and improved core strength. They contain 0.5 to 0.8% C and usually have densities exceeding 6.8 g/cm³. Most production P/M parts are normally hardened in batch-type sealed quench furnaces (rather than continuous belt furnaces) because they are net-shaped parts and should not touch or impinge upon one another during the heating cycle. This would tend to cause distortion and soft spots. The most widely used atmosphere for heat treating is endothermic gas with both methane and air additions to control carbon potential. Due to the rapid penetration of atmosphere into the interconnecting porosity, carbon diffusion is quite rapid and short cycle times at relatively low process temperatures are normally specified.

Medium- to high-density parts (6.8 to 7.2 g/cm³) are better suited for batch-type sealed quench furnaces where the temperature profile can be easily controlled. With this equipment, parts can be loaded into the basket in the arrangement that best minimizes distortion. Also, control of carbon potential is more precise in batch equipment. The one drawback to a batch furnace is the longer transfer time to the quench. Many of the newer furnace designs have automated internal handling equipment to transfer the hot load to the quench. This can prolong the time to quench, causing a loss of temperature, and subsequent surface hardness.

When quenching for maximum hardenability, a fast oil is recommended. Quench oils with a General Motors quenchometer rating of 10 s or less is considered fast. Load size is also a critical factor in attaining uniform hardness. Most sealed quench furnaces are designed to quench 0.5 kg of steel per gallon of quench oil. For P/M parts, it is recommended that 11.5 to 15 L (3 to 4 gal) of quench oil be used to quench 0.5 kg of sintered steel. Overloading is probably the most common problem in attaining uniform heat treated properties.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Carburizing/Carbonitriding

These two case-hardening treatments are most commonly specified for applications that must withstand high-cycle loading and surface scuffing. Here, the need for high surface hardness combined with a relatively soft ductile core area to provide toughness. Most of the highly loaded gear applications require one or the other of these treatments.

In P/M applications, these treatments are used on high-density prealloy or partially alloyed steels where the combined carbon content is less than 0.5% C. Parts with porosity levels higher than 10% are not recommended for case hardening due to the rapid penetration of carbon and the difficult control of carbon potential in the furnace.

In wrought steel, case-hardening treatments are characterized by a uniform surface hardness and an effective case depth. This is usually defined as the depth at which a 50 HRC hardness is measured. Microhardness measurements can accurately show the hardness profile in a wrought steel section, but can be erratic when used on P/M steels where subsurface porosity can influence the hardness reading. It is recommended that at least three readings be taken at each depth level below the surface and averaged to determine effective case depth. Figure 9 shows the influence of porosity on carbon penetration and effective case depth during the vacuum carburizing of an iron-copper alloy at three density levels.

Fig. 9 Influence of porosity on carbon penetration and effective case depth during vacuum carburizing of an iron-carbon alloy at three density levels

Carbonitriding differs from carburizing in that it provides both carbon and free nitrogen for diffusion. This is accomplished by the addition of anhydrous ammonia (≤ 2 vol%) to the furnace atmosphere. Nitrogen diffuses into the steel simultaneously with carbon, retarding the critical cooling rate on quenching, which leads to a more complete transformation to martensite. This produces a more consistent surface hardness profile, thereby improving the wear resistance of the P/M material.

Process temperatures for carbonitriding are usually lower than those required for carburizing. This provides improved control of dimensions and less distortion of the part compared to carburizing. Care must be taken when adding ammonia; however, because excessive nitrogen diffusion into internal porosity can result in embrittlement and loss of strength.

Carbonitriding is a shallow-case treatment. Case depths greater than 0.5 mm (0.02 in.) deep are seldom specified. For this reason, cycle times are relatively short, usually 30 to 45 min depending on process temperature, case depth requirements, and density. Carburizing is the first part of the cycle followed by addition of ammonia. Process temperature is usually approximately 870 °C (1600 °F) depending on P/M composition and density.

As in neutral hardening, carbon control is a critical aspect of the treatment. Normally, carbon potentials of 1.0 to 1.2% are specified to maintain the carbon profile in the part. The usual (wrought) method is to keep carbon potential 0.85% to 0.95% C (to reduce the likelihood of producing mixed phases and retained austenite). In P/M parts, however, it may be difficult to maintain a uniform carbon content at the surface due to rapid penetration of gas through porosity. Decarburization can result if the effect of porosity is not adequately considered.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Tempering

Tempering is a postquench thermal treatment designed to reduce the stress imposed on a part by rapid quenching and martensite transformation. This stress, if not relieved, can increase the brittleness and notch sensitivity of the part, making it

more prone to fracture. This stress is increased with increasing density level in the part. All parts with density levels above 6.7 g/cm³ should be tempered after hardening. Recommended tempering temperatures for P/M parts range from 150 to 200 °C (300 to 400 °F). Above this range, entrained quench oil can ignite, creating a hazardous condition in the furnace. Tempering above 200 °C (390 °F) results in improved toughness and fatigue properties in the hardened part, at the expense of tensile strength and impact resistance; however, the tempering furnace would need to be specially adapted to handle the high volume of smoke generated by the volatilization of the quench oil. Tempering is also used to reduce the effects of retained austenite that can occur in alloy steels when rapidly quenched. This constituent has been shown to influence dimensional change and hardness of the material. Freezing by cryogenic treatment (below -100 °C, or -148 °F) for several hours transforms the retained austenite to martensite. This is usually followed by a second temper at 200 °C (390 °F) to stress relieve the newly formed martensite. Figure 10 shows the influence of tempering temperature on impact resistance of FL4205 alloy after hardening.

Fig. 10 Effect of density and tempering on impact energy

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Induction Hardening

Spur gears, bevel gears, splined hubs, and cams are ideal components to utilized P/M production techniques. These parts usually require hard, wear-resistant surfaces in some areas, with retention of the ductility of the sintered matrix in the remainder of the part. Induction hardening is commonly specified for these applications. The process can be placed in an automated machining line to reduce handling and be a cost-effective hardening treatment when high volumes of parts are being produced. Because the inductance of P/M materials is typically reduced due to porosity, a higher power setting is normally required to reach a given depth of hardening compared to that used for a wrought material of similar composition. Furthermore, because the heat rapidly dissipates, a rapid transfer to the quench is mandatory.

As with wrought steels, the response to hardening by induction is dependent on combined carbon content, alloy content, and surface decarburization. This latter variable can be a major concern with P/M parts. Conventional belt-type sintering furnaces (depending on their construction) can allow decarburization to occur as the parts leave the hot zone and cool slowly through

the 1100 to 800 °C (2010 to 1470 °F) temperature range. Newer designs are now able to compensate for this problem by installation of controlled cooling through the transformation range.

In most instances, induction-heated P/M parts are quenched in a water-based solution containing some type of rust preventative to forestall internal corrosion. In those applications where induction hardening is considered, densities above 90% should be specified. With a decrease in density, the resistivity of the steel increases and magnetic permeability decreases. For this reason, integral quench coils using a high-velocity spray quench are generally used to attain maximum surface hardness in the P/M part.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Nitrocarburizing

This process is rapidly gaining in popularity as an alternative treatment for P/M parts. Gaseous ferritic nitrocarburizing (FNC) is a surface treatment where both nitrogen and carbon are diffused into the surface of low-carbon steel parts under controlled conditions. To this extent the process resembles carbonitriding. It differs primarily in lower process temperature (570 to 630 °C, or 1060 to 1165 °F) and in atmosphere composition. As in carbonitriding (780 to 870 °C, or 1435 to 1600 °F), anhydrous ammonia is used as a source of nitrogen. Carbonitriding uses endothermic gas as a base with NH₃ addition for nitrogen. Nitrocarburizing, on the other hand, uses the NH₃ as the base gas and adds various hydrocarbons as the source for carbon. This process can be applied using various types of equipment, such as batch-type integral quench furnaces, pit-type furnaces, and plasma vacuum furnaces.

At the nitrocarburizing temperature range, no austenite transformation occurs, thereby significantly reducing the distortion that can occur on components that get oil quenched. Nitrogen and carbon are diffused into the surface of the steel part in sufficient concentration to form a thin layer of iron nitride on the surface, which appear as a white layer under metallographic examination. This white layer provides high hardness and lubricity for improved wear resistance. When applied properly, it can reduce the coefficient of friction of the steel surface to one-half its normal untreated value.

Because FNC is a diffusion process, its application to P/M parts is dependent on density. If the nitride compound is allowed to penetrate and form on an internal pore surface to any significant extent, a volume expansion as well as embrittlement can occur. For this reason, density of P/M parts should be 92% of the pore-free density. Because it requires warm compaction and/or additional re-pressing operations to reach this density level, a lower cost option would include steam treating prior to nitrocarburizing. This patented process can proceed in a conventional manner. The nitride layer, as mentioned before, improves the resistance of the part surface to adhesive wear. A subsequent oxidation process that can be applied during the nitrocarburizing cycle can also provide exceptional corrosion resistance as well as wear resistance.

A process that provides improved dimensional control is plasma nitrocarburizing. In this process, parts are processed in a vacuum chamber using a combination of direct and indirect plasma heating. This process is currently used in production of such parts as synchronizer hubs and cam lobes. The use of a plasma to deliver the nitrogen and carbon ions to the surface of the part allows for a more uniform control of surface concentrations and diffusion of the nitriding elements. It minimizes the nitridation of internal pore surfaces, thereby reducing the volume expansion that normally occurs during gaseous nitrocarburization.

This process can be applied to most iron blends and prealloys with uniform formation of the iron nitride hard phase at the surface of parts with sinter densities exceeding 6.9 g/cm³. Below this density, porosity variations in the part can lead to nonuniform dimensional changes occurring on sintered iron transverse rupture bars that have been nitrocarburized by various methods (Fig. 11). Figure 12 shows the microstructure of a nitrocarburized P/M part. Figure 13 shows the microstructure of a P/M part that was cold forged to 95% pore-free density, nitrocarburized, and then underwent an oxidation treatment.

Fig. 11 Dimensional change in sintered iron after various nitriding treatments

Fig. 12 Microstructure of ferritic nitrocarburized FC-0208 (7.0 g/cm³) hardened to file hard condition. 100×

Fig. 13 F-0000 P/M iron precision cold forged to 7.5 g/cm³ and ferritic nitrocarburized to file hard condition. (a) Tooth corner. (b) Tooth, 400×

The FNC process is best used in applications where sliding wear and fretting are involved. Because the hard nitrided layer is relatively thin, the process should not be applied where high indentation or impact loading is involved.

The ϵ -nitride layer that is formed can attain a file hardness in excess of 60 HRC, depending on the alloy content of the steel. Indentation hardness testing is not recommended when evaluating this process.

Because no transformation occurs, the P/M parts can be air cooled without loss of surface hardness. Also, no oil absorption occurs, which leaves the porosity open and free of contamination. Nitrocarburizing also provides improved strength and reduced notch sensitivity in P/M parts. Figure 14 shows the fatigue improvement of two low-carbon P/M steels after nitrocarburizing.

Sinter Hardening

Powder metallurgy alloys that can transform to the hard martensite phase upon cooling from the sinter temperature have been commercialized. This technique, termed sinter hardening, is rapidly gaining popularity in applications requiring high strength and hardness immediately after sintering. This manufacturing route has proven to be cost effective for a number of parts because it eliminates the need for a postsinter heat treatment.

Prealloyed powders have been proven useful for this purpose. The ability of the alloy to promote the formation of martensite and/or bainite during cooling from the sinter temperature is the most important factor to optimize the microstructure and therefore the properties of the sintered parts.

Manganese is added to all commercial steels in the range of 0.25 to 1.0% to increase strength and hardenability of plain carbon steels. Chromium is also a popular hardening element, but it is seldom used in prealloyed powders because of the difficulty in reducing the chrome oxide that can form at the surface of the particle and act as a barrier to interparticle diffusion. Molybdenum and nickel are most commonly used in low-alloy P/M steels because of their easily reducible oxides. These elements are very efficient in promoting increased strength and toughness. Sinter hardening requires controlled cooling after sintering in the austenite range (1120-1290 °C, or 2050-2350 °F). The factors that determine the ability of an alloy to sinter harden are cooling rate between 600 and 150 °C (1110 and 300 °F), which encompasses the martensite start (M_s) temperature of most P/M alloy steels, the alloy content, and the blend composition. The most commonly used alloy is type 4600 with additions of copper and carbon.

An optimal microstructure for a sinter-hardened material would show more than 90% martensite at the surface of the part with no less than 70% martensite in the core. This structure would provide the surface hardness and toughness of a quenched microstructure without the high stress concentration resulting from oil quenching.

Therefore, it is important to know the cooling rate and alloy content that provide the required hardenability for a part of a given mass and density. In a standard belt-type sinter furnace, an addition of 2% Cu and 0.9% C to the 4600 alloy may be necessary to provide sufficient hardenability for a given part density. With the new furnaces that are available with enhanced cooling capability, a lower alloy content or mix composition can be used to achieve the same level of hardenability.

A simple laboratory method has been developed to determine the effect of cooling rate, density, and alloy content on the hardness and microstructure of a sintered material. Cylindrical slugs of varying mass and density are sintered with thermocouples embedded at the surface and center of the slug. Another thermocouple is fixed on the belt to measure the ambient cooling rate of the furnace set at a known temperature and belt speed. Sectioning the slugs to characterize the microstructure and hardness profile at the location of the thermocouple provides the necessary information to construct a diagram as shown in Fig. 15, which shows the results for a type 4600 alloy. These microstructure-hardness-cooling rate diagrams can be constructed for various alloy blend compositions and density levels to find the most cost-effective material for a given application.

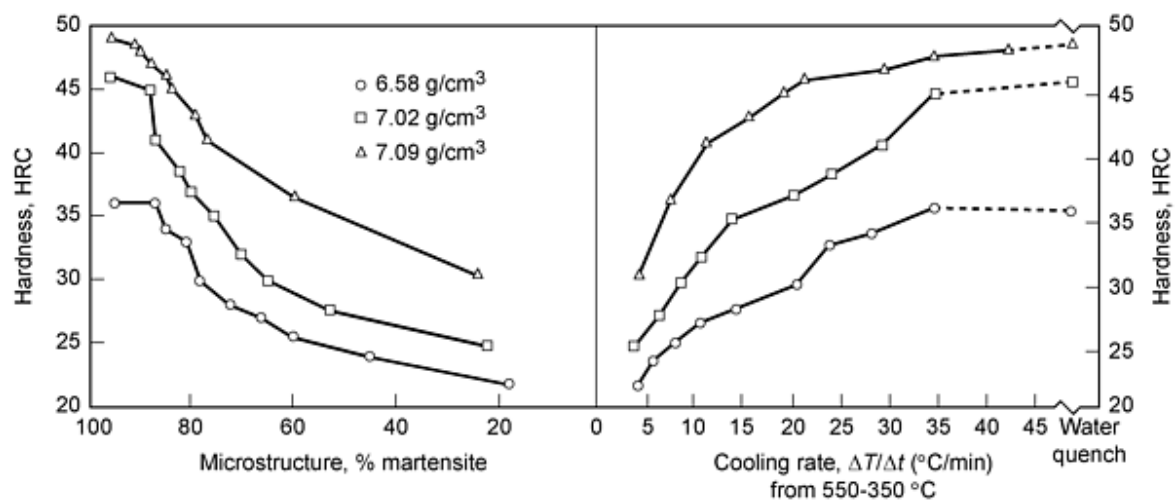

Fig. 15 Cooling rate-hardness-microstructure diagram to determine hardenability requirements. Source: Ref 17

There are several advantages to sinter hardening besides cost effectiveness:

- Microstructures can be better tailored to provide optimal strength and hardness.
- The porosity remains free of oil, which is advantageous to parts operating in controlled environments.
- Distortion in complex-shaped parts is reduced compared to oil quenching.

This reduced distortion translates into improved dimensional stability and consequently higher yield and quality of production lots.

The major drawback of sinter hardening is that the alloys used require a high carbon content to achieve the necessary hardenability. As has been shown previously, high carbon levels reduce the mechanical properties of P/M steels after hardening. Table 2 shows a comparison of properties of a type 4600 alloy with 0.5% C that was quench and tempered with a 4600 alloy (with a 0.8% C level) that was sinter hardened. As with quenched alloys, sinter-hardened alloys require post tempering treatment to attain the optimal combination of hardness and toughness.

Table 2 Comparison of properties of quenched-and-tempered type 4600 alloy (0.5% C alloy) with a sintered hardened 4600 alloy (0.8% C)

Material code	Density, g/cm ³	Ultimate tensile strength		Apparent hardness, HRC
		MPa	ksi

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Steam Treating

Many P/M parts have traditionally been steam treated for improved wear resistance, corrosion resistance, and sealing capacity. In this process, P/M parts are heated in a specific manner under a steam atmosphere at temperatures between 510 and 570 °C (950 and 1060 °F) to form a layer of black iron oxide identified as magnetite, in the surface porosity, according to the chemical reaction:

Steam treating cannot truly be described as a heat treatment because no structural changes occur in the matrix. In the process, magnetite (Fe_3O_4) is formed at the interconnecting surface porosity, filling the porosity with a second phase. Magnetite has a hardness equivalent to 50 HRC.

The process itself is straightforward; the primary variables are temperature, time, and steam pressure. Caution must be exercised to prevent the formation of hydroxides and lower oxide such as ferrous oxide (FeO) and ferric oxide (Fe_2O_3), which is red rust (see Fig. 16). Also, adhesion of the surface oxide layer is an important variable to control. Adhesion is strongly influenced by process time at temperature.

Fig. 16 Temperature-composition diagram for the iron-oxygen system. Source: Ref 11

Spalling or flaking of the surface oxide layer can occur if the process temperature exceeds 570 °C (1060 °F) and process times exceed 4 h. The maximum thickness of the surface oxide layer should not exceed 7 μm (0.003 in.). Beyond this thickness, flaking can occur due to an increase in surface tensile stress.

The recommended procedure for steam treating is:

1. Preclean parts to remove any oil or lubricants that may have been absorbed into the porosity from prior machining, sizing, or finishing operations.
2. Load clean sintered parts in loosely packed baskets and place fixture into a furnace preheated to 315 °C (600 °F).
3. Heat parts in air until the center of the load has stabilized at the set temperature.
4. Introduce superheated steam at a line pressure of 35 to 105 kPa (5 to 15 psi) and allow furnace to purge for at least 15 min.
5. Increase furnace temperature to desired steam treatment temperature and hold for no longer than 4 h at heat.
6. On completion of the treatment, reduce furnace temperature to 315 °C (600 °F). When parts reach this temperature, the steam can be shut off and the parts unloaded.

Caution should be used when opening the furnace door after the steam cycle. As indicated above, hydrogen is produced during this process and can ignite. It is recommended that a nitrogen purge be applied prior to unloading. This process, when correctly applied, can impart improved surface properties and, depending on steel composition, increase compressive yield strength.

The above process parameters refer to the standard pit-type furnace. Currently, belt-type continuous furnaces have been developed, but have had limited success in developing consistent oxide content. Needless to say, the equipment must be properly sealed to prevent air contamination, or erratic oxide formation, and discoloration can occur.

In steam-treated P/M steels, the ductility is significantly reduced due to the internal stresses created by the formation of the iron oxide. Care must be taken when steam treating high-carbon P/M steels because these internal stresses can initiate microcracking and cause severe loss of ductility. Cases have been reported in which steam-treated parts accidentally dropped on the floor shattered in a brittle fashion. The best recommendation for preventing such an incident is to specify a maximum carbon content of 0.5% for P/M parts that are to be steam treated.

Sintered density is an important consideration when applying steam treating for improved strength and hardness. Its ability to increase the wear resistance of the substrate material depends on the available porosity for oxidation. As density is increased, the amount of oxide formed is decreased, which minimizes the improvement in apparent hardness attributed to steam treating. This is shown in Fig. 17 for sintered iron.

Fig. 17 Effect of steam treating on transverse rupture strength of sintered P/M carbon steels. From Ref 1

The increase in density and apparent hardness produced by steam treating is illustrated in the micrograph of a sintered iron (Fig. 18). By filling the porosity with a hard second phase, the P/M steel offers a better support to the indentation hardness tester. Figure 19 illustrates that the transverse rupture strength is increased significantly by steam treatment for low-carbon P/M steels, but only modestly for high-carbon (0.8% C) P/M steels.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Guidelines for Heat Treating P/M Parts

Whether heat treating P/M parts is done in-house or by an outside commercial heat treater, some guidelines need to be followed to ensure that parts are properly treated. In the past, heat treatment of P/M parts was primarily specified to improve wear resistance. With the advent of high-compressibility powders and high-temperature sintering, heat treatments are now added to provide improved dynamic properties as well. Recommendations for heat treating porous P/M parts are:

- Always degrease parts prior to heat treating. In many manufacturing plants, P/M parts are dipped in a rust preventative after sintering. Also, many P/M parts are machined prior to heat treatment and can retain some of the lubricant. These oils can contaminate the heat treating atmosphere and cause discoloration.
- Do not use dense loads. Overlapping parts can cause soft spots and distortion. For best results, parts should be single spaced in layers.
- Use highly agitated quench oil with a quench-severity rating (H) of 0.7 to 1.0.
- When tempering, hold at 205 °C (400 °F) for 2 h before proceeding to higher temperatures. This minimizes the evolution of smoke and prevents ignition.

If it is planned to send parts to an outside commercial heat treater, a technical review of the part requirements and prior processing history is recommended. Many commercial shops have had bad experiences with powder metals because they did not fully understand the implications of porosity and tried to treat the parts as they would wrought steel. It is important that a good communication network is established with the heat treater so that they can be alerted to any structural changes in the P/M part caused by changes in powder lot, tooling, or sintering cycle.

A good procedure is to send sample lots to the heat treater for them to establish process capability. After the print requirements are met, the heat treater should run the parts in the same furnace under the exact same conditions as were established. Parts fabricators should give as much consideration to the heat treating process as would be given to primary processes. Reworking because of improper heat treatment not only adds more cost, but can also significantly affect the physical properties of the P/M part.

Heat Treatment of Ferrous Powder Metallurgy Parts

Howard Ferguson, Metal Powder Products Company

Mechanical Properties

The 1997 edition of MPIF standard 35 contains updated information on the heat treated properties of P/M materials. These properties are difficult to measure due to the extreme brittleness of the porous test specimens required for P/M materials. The MPIF standard only covers alloys containing 0.50% combined carbon, which is the maximum carbon level needed to produce the optimal heat treat properties.

Figure 20 charts the ultimate tensile values of various hardened and tempered P/M compositions (with a 7.0 g/cm³ density, which represents the maximum strength that can be obtained with a single room temperature compaction process). As expected, strength increases as alloy content increases, with the prealloy irons providing the most consistent improvement in properties. Maximum strength, however, results from nickel additions to prealloyed iron, which produce a heterogeneous microstructure containing soft, nickel-rich areas. These soft areas dispersed throughout a hard martensite matrix provide both high tensile and fatigue strength (see Fig. 7).

Fig. 20 Strength comparison of heat treated P/M steels at 7.0 g/cm₃ density

Heat treatment, in many cases, is specified for wear resistance. For this, the highest achievable surface hardness is required. A different material selection may be advisable when maximum toughness is required for improved fatigue endurance. Figure 21 charts the apparent hardness of various alloys at 7.0 g/cm³ sinter density that have been quenched and tempered. The FC0205 alloy provides the highest surface hardness (also at the lowest cost). This alloy is created by liquid phase sintering to form a copper-rich martensite upon quenching. This has been found to provide excellent wear and indentation resistance, although it does tend to reduce the ductility of the material.

Fig. 21 Hardness comparison of heat treated P/M steels at 7.0 g/cm³

When designing a P/M part of large mass and cross-sectional thickness that requires heat treatment, a knowledge of the hardenability of P/M alloys would be desirable. Jominy hardenability values have now been generated and published in the 1997 edition of MPIF standard 35 (Ref 6). As with wrought alloys, hardenability increases with both alloy and carbon content up to 0.80% C. However, these high-carbon alloys become very brittle upon hardening and, as stated before, a 0.50% C content is usually specified for optimal properties. Figure 22 charts the increase in hardenability with alloy content for materials containing 0.50% combined carbon and sintered to a 7.0 g/cm³ density. As shown, the FLN4-4405 alloy, which contains 0.90% Mo in alloy and 4% Ni admixed can be hardened to a depth of 0.75 in. (19 mm). This is sufficient hardenability for the majority of the P/M parts being made currently.

Welding and Joining Processes

Jack A. Hamill, Hoeganaes Corporation

Introduction

JOINING P/M components increases the possibilities of manufacturing more complex configurations than conventional die-pressed geometries. Most P/M materials can be welded or joined successfully. However, not every potential P/M welding application is cost effective in terms of labor intensity, equipment, and overall manufacturing costs.

Several references detail the related joining processes and weldability of wrought materials (Ref 1, 2). However, very little comprehensive information is available regarding the application of these practices to P/M components. This article attempts to characterize the physical differences between P/M and wrought or cast materials as they apply to joining. In addition, acceptable procedures and techniques are discussed along with the weldability of various P/M materials.

Effects of Porosity on Properties. Perhaps the most important physical characteristic of a P/M component, which makes it uniquely different in regard to joining, is porosity (Ref 3). The pore volume or relative density has a pronounced influence on several important properties that affect the welding characteristics. These include:

- *Thermal conductivity* is dependent on the amount of porosity, and greater amounts of porosity change the heat transfer mechanism and ultimately influence the welding parameters.
- *Hardenability* is dependent on the rate of heat dissipation or thermal conductivity. Pores act as thermal insulators that slow the transfer of heat, making P/M components less hardenable than wrought parts of similar composition. However, because of potential densification associated with particle melting in the heat-affected zone (HAZ), the higher stress levels associated with greater hardenability can occur in P/M components and may increase the material's susceptibility to cracking.
- *Thermal expansion* is not directly associated with porosity, but this characteristic also plays an important role in determining susceptibility to cracking. Likely differences in composition between P/M, wrought, or cast materials result in dissimilar volume changes when metals are heated and subsequently cooled. Extreme differences in expansion or contraction rates increase the potential for cracking at the weld interface.

Porosity can also cause erratic fluctuations in welding performance because of entrapped oxides or impurities. Precautionary measures must be taken to eliminate any of the following residual elements that may remain in the pores as a consequence of related process conditions:

- Lubricants
- Quench oils
- Machining coolants
- Plating solutions
- Impregnating materials
- Cleaning or tumbling agents
- Free graphite or residual ash

Joining Methods

Joining is a comprehensive term used to denote all processes that affix one part to another. Most welding processes require the application of heat with some controlled melting of the base materials and/or filler metal (fusion), while others rely on surface diffusion and/or mechanical interlocking (solid state). Both solid-state and fusion welding processes have been used successfully in joining P/M components.

Lower-density ($<6.5 \text{ g/cm}^3$) parts are most often joined using processes that do not involve molten weld metal and the associated solidification stresses. Because of fewer particle-to-particle bonds at these density levels, the relatively poor bond strength does not provide the ability to absorb high stresses generated by contracting weld metal. For example, Fig. 1 shows the result of a poor weldment design using P/M alloy F-0000 and wrought AISI 1010 stamping. The F-0000 P/M section has a density less than 6.2 g/cm^3 , and an unusually large weld bead deposit results in a classic toe crack because of high weld metal solidification stresses. Arrow indicates crack initiation site.

Fig. 1 Example of poor weldment design involving GMA welding of F-0000 P/M material ($<6.2 \text{ g/cm}^3$) to AISI 1010 stamping. The unusually large weld bead deposit resulted in a classic toe crack because of high weld metal solidification stresses. Arrow indicates crack initiation site.

The joining processes most often successful on lower-density parts are diffusion welding, sinter bonding, adhesive joining, and brazing. Parts at intermediate density levels (6.6 to 6.9 g/cm^3) can be joined using a wide assortment of processes. However, those that minimize the volume of fused metal, such as resistance projection, high-speed pulse welding (HSPW), or friction welding, enjoy the highest success rates. Parts exhibiting higher densities ($>7.0 \text{ g/cm}^3$) typically have the same weldability as wrought materials and can be joined using fusion processes that include gas tungsten arc welding (GTAW), gas metal arc welding (GMAW), electron beam welding (EBW), and laser beam welding (LBW).

Resistance Projection Welding (RPW) is perhaps one of the most often used procedures for joining P/M parts. The joining surfaces are heated from the resistance of electrical currents, and the heated materials form a weld. Electrodes that carry the current also clamp the components under pressure to provide good electrical contact. The joint must be clean and the pores free of contaminants to obtain uniform weld soundness. Projection welding generally affords good dimensional control in the weld area because of the force applied by the contacts and the related fixturing of the components. An example of an RPW component is shown in Fig. 2.

Fig. 2 Resistance projection welding application joining an intermediate density P/M spur gear to a low-carbon wrought steel stamping

In general, good weldment design requires particular attention be placed on the height and density of the projections. Other parameters including the current ($\text{kV} \cdot \text{A}$) and pressure (psi) can be preset to achieve the best results and most often are very similar to those used for wrought materials. Approximate settings for current, weld time, and electrode force can be found in the *Resistance Welding Manual* (Ref 4).

An investigation involving projection welding of wrought materials to P/M parts at densities between 5.8 and 7.4 g/cm^3 found that lower density ($<7.0 \text{ g/cm}^3$) components require greater projection heights (Ref 5). It was also found that steam-treated parts could not be satisfactorily welded at any density, and wrought chrome plated parts could not be welded to P/M components below 7.0 g/cm^3 density. All other materials tested, including plain iron, iron-carbon, Fe-Cu-C, and stainless steels, were welded successfully. In a similar investigation, RPW techniques were used to join high-carbon (0.4 to 0.8%) P/M parts, with density levels between 6.5 to 7.5 g/cm^3 , to mild steel (Ref 6). The weldments were found to be of satisfactory quality and exhibited higher torsional strengths than standard keyed components. However, the highest torsional strengths were achieved after the components had been normalized.

High-speed pulse welding (HSPW/CD) is similar to RPW in many respects, but also exhibits several unique attributes. The major differences involve the capacitor stored energy supply with the resultant short-weld-pulse duration. Energy is concentrated toward the specific weld area using a quick pulse of 3 to 15 ms in the range of 150 J/mm^3 energy and subsequent pressure of 200 N/mm^2 . However, specific weld parameters are dependent on system resistance, part shape, conductor connections, and material compositions.

The low-energy diffusion weld minimizes distortion, providing the ability to maintain reasonably tight tolerance control. Several studies (Ref 7, 8) indicate HSPW can successfully weld high-carbon materials and dissimilar material combinations to accommodate various performance characteristics. The ability to temper the weld joint using a second pulse, immediately after establishing the joint, helps reduce residual stresses while increasing strength and fatigue resistance.

Figure 3 shows a high-speed pulse weld of automotive engine bearing brace and windage baffle assembly. Brace rails are FN-0208 jointed to AISI 1010 steel stamping. Part design reduced vibrations induced from the bearing cap and improved engine performance.

Fig. 3 High-speed pulse weld of automotive engine bearing brace and windage baffle assembly. Brace rails are FN-0208 joined to AISI 1010 steel stamping. High-speed pulse weld assembly replaced an aluminum forging and reduced overall cost by 40%. Courtesy of Process Equipment Company

Gas tungsten arc welding (GTA/TIG) uses a nonconsumable tungsten electrode to establish a direct current arc (for ferrous materials) that melts the material to be welded. An inert gas shield of argon, helium, or various commercial mixtures is used to protect the electrode and weld pool from oxygen, nitrogen, and hydrogen contamination and to stabilize the arc characteristics for improved welding performance. In some P/M applications, the process includes the use of a filler metal to counteract the shrinkage that results from particle melting and subsequent densification in the weld zone. The filler must be compatible with both materials to be joined in regard to thermal expansion characteristics, strength, and corrosion properties.

The GTA process provides suitable results in many situations because it allows a greater amount of control over the welding process. The travel speed, heat input, type of filler metal, and feed rate can be controlled to achieve the best results for each application. For this reason, GTA exhibits better weldability with higher-carbon materials because of the ability to control the heat input and subsequent weld hardness. Figure 4, for example, shows a FN-0205 cap nut welded to an alloy steel, hole-saw body. In this instance, GTAW was selected because of its ability to minimize distortion associated with high heat input.

Fig. 4 P/M FN-0205 cap nut welded to an alloy steel, hole-saw body without a filler metal by automated GTAW. This single-step joining process also forms the seam of the cylindrical body.

One unique GTA application is the replacement of a casting by welding two P/M components together for use in a commercial truck differential (Ref 9). It was found that the welded P/M component exhibited higher and more consistent strength values than a bolted gray iron casting along with a 35% cost savings compared with the previous method of manufacture.

Gas metal arc welding (GMAW/MIG), unlike GTA, uses a continuous wire electrode that establishes the arc and furnishes filler metal into the weld pool. A shielding gas mixture, the composition of the mixture dependent on the mode of metal transfer and type of filler metal, is used to protect the molten weld pool from atmosphere contamination and to provide the correct arc characteristics. The short circuiting or dip metal transfer modes are particularly suited for welding P/M components because of the low energy input requirements that reduce the HAZ and minimize distortion. Typically, CO₂-based shielding gases are used with small diameter (0.89 to 1.14 mm) mild steel filler wire to weld sintered steel components. However, austenitic stainless steel fillers with inert gas shields can be used for higher carbon materials to reduce the potential for HAZ cracking. As in the GTA process, GMA affords the operator greater control over the entire welding process.

A study involving the GMA (MIG-CO₂) process concluded that various materials with admixed compositions of 0.3 to 0.9% C, 0 to 6.0% Ni, and 0 to 1.0% Mo could be welded successfully (Ref 10). The results indicate that sintered components appear to be less susceptible to hydrogen-induced cracking than wrought materials with similar hardenability. The same study also found copper-bearing materials (2.0 to 4.0%) could not be welded using the dip transfer-CO₂ process because of liquation cracking in the HAZ.

Friction welding (FRW), sometimes referred to as inertia welding, is a solid-state process that uses frictional heat generated when parts are rotated against one another. When the interface temperature of the part is heated into the forging range, an axial or upsetting force is applied to both sections. *Welding Handbook* (Ref 11) identifies the process variables as rotational speed, axial force, welding time, and upset force. Equipment power requirements range from 25 kV · A for smaller machines to 175 kV · A for larger units capable of joining 125 mm (5.0 in.) diam steel bars. Friction welding variables can be controlled by a computer program that makes the process less technique sensitive and highly automated. The time required to load and unload parts is often longer than the weld time, which can range from 0.5 to 15 s. The limiting factor in this process is the part configuration. Typically, components must accommodate the application of the rotational force at the joint interface. Materials with good dry bearing characteristics, for example, grades with free graphite in the pores, are not well suited to friction welding. The equipment, tooling, and automated material handling costs generally limit the use of this process to applications with long production runs.

Friction welding of iron-carbon and Fe-Cu-C sintered parts has been accomplished. An independent study (Ref 12) indicates this technique is capable of producing extremely favorable results when joining a full range of admixed compositions at various density levels to similar grades, dissimilar compositions, or wrought materials. Test results found that FRW exhibits lower hardness in the weld zone, in comparison with other processes, because of a slower cooling rate associated with this technique. The investigation determined that actual welding parameters are relatively flexible except for friction (axial) pressures and forging (upset) pressures. Higher friction pressures are likely to cold work a greater surface area when the forging pressure is applied. Excessive forging pressures can produce radial cracks that originate in the extruded flash and extend back into the base material. This situation can lower fatigue performance or ultimately result in joint failure. It has also been determined that welds often exhibit higher torsional load capacity in comparison with other joining techniques over a wide range of densities and material compositions.

Electron beam welding (EBW) is a sophisticated welding process that incorporates a beam of concentrated high-velocity electrons into a narrow, very intense source of heat. The weld generally is accomplished in a vacuum chamber at pressures ranging from medium to high vacuum, although sintered parts have been welded using a nonvacuum process. Electron beam welding has proved successful particularly on higher-density stainless steel P/M components. Iron-carbon sintered parts, on the other hand, have limited applications because of porosity and blowholes caused by escaping CO gas. An investigation found that as the welding speed slows, the width of the weld zone widens and the volume of escaping gases increases, causing more blowholes (Ref 13). It was also discovered that faster weld speeds produce a narrow HAZ with exceptionally high hardness values that would not be acceptable in most service environments. Considering the cost and disadvantages, it would be hard to justify this process for joining high-volume P/M structural components.

Laser beam welding (LBW) is somewhat similar to EBW, but it uses a focused laser to vaporize metal at the joint interface. Typically, CO₂ lasers are used with inert shielding gases such as helium. It is possible to add filler metal, but

additions are not always necessary, particularly on higher-density components. The joint design has a major influence on the filler metal requirements. Welding parameters generally attempt to optimize the relation between the power setting and travel speed to improve the economics and provide a narrow weld seam that results in less internal stress. An investigation into the practical use of laser welding P/M components found it can be used successfully, particularly when joining higher-density parts with materials containing lower carbon levels (Ref 14).

This process can involve significant HAZ area shrinkage because of melting and resolidification in the narrow weld zone. In addition, the findings indicate the laser process is sensitive to the type of sintering atmosphere. The formation of blowholes in the weld zone has a relationship with the number of unreduced oxides in the component(s) to be joined. Specimens sintered in endothermic gas exhibited an unacceptable condition, whereas those sintered in hydrogen, dissociated ammonia, and vacuum all proved to be acceptable. The LBW process also requires that the medium hardenability material be preheated to 250 to 300 °C (480 to 570 °F) before welding to reduce martensite formation. The narrow HAZ with the larger adjoining material mass extracts heat away from the joint, which accelerates the cooling rate. Another observation is that oil-quenched materials do not prove successful because the oil residue in the pores vaporizes and forms blowholes. Good results, however, were obtained with 316L stainless steel P/M components. These weldments exhibited very low amounts of δ ferrite (<1.0%) in the weld zone, which probably relates to the narrow autogenous (without use of filler metal) fusion zone associated with the process (Ref 15).

Brazing is another very common process used to join P/M parts. This method allows P/M fabricators to use existing sintering furnaces and atmospheres to join P/M parts or P/M wrought or cast materials. Temperature requirements range from 1065 to 1150 °C (1950 and 2100 °F), depending on the brazing alloy composition, with atmospheres that include endothermic, dissociated ammonia, nitrogen-base, or vacuum. The capillary force of the pores requires special consideration when choosing a brazing alloy. When using a standard copper brazing material the porosity near the joint wicks the filler metal into the pores, leaving an insufficient amount to establish a satisfactory bond strength. For this reason, these parts must be copper infiltrated before brazing or pressed to a density greater than 7.2 g/cm³ to limit interconnected porosity at the joint interface. An alternate method involves the use of a Ni-Cu-Mn alloy that increases liquidus temperature as iron from the mating components dissolves into the filler (Ref 16, 17). This fills the pores immediately adjacent to the brazement, leaving a sufficient amount of filler metal to establish suitable bond strength.

The preferred brazement design involves a lap rather than a butt-joint configuration. The optimal gap distance is between 0.05 and 0.13 mm. Consideration must be given to the thermal expansion characteristics of the material to be joined when attempting to maintain the proper gap distance at temperature. Ring preforms placed adjacent to the joint at the spot location of a brazing paste is preferred over sandwiching the filler between components. Fixturing may be necessary with complex configurations or when tighter dimensional control is required. Brazed parts can subsequently be quenched and tempered or steam treated without negatively impacting joint strength. The American Welding Society has established related guidelines under AWS C3.6-90, "Specification for Furnace Brazing" (Ref 18).

Diffusion/sinter bonding technique typically involves the use of materials that exhibit different sintering expansion characteristics due to composition or density level (Ref 19); for example, an outer ring having a propensity to show less growth during sintering than a press fit inner ring that has somewhat more growth in comparison to the mating part. The solid-state bond results from mechanical interlocking and alloy diffusion occurring at the interface of the mating parts. Similar results can also be achieved if two parts, placed in close contact, are copper infiltrated using a single-step process (Ref 20).

These methods have proved to be viable, cost-effective joining techniques that are currently used on production parts. However, diffusion/sinter bonding is limited to certain geometries and alloy compositions. The bond strengths are also somewhat lower than those achieved with other joining processes.

Adhesive Joining of P/M components is possible by gluing them together with epoxy resins, anaerobic or acrylic adhesives. The first two materials set up at room temperature, whereas the acrylic adhesive must cure at approximately 120 to 130 °C (250 to 265 °F). An important aspect of this procedure is that the surfaces be clean and the pores be free of any contaminants. This has effectively been accomplished using abrasives and ultrasonic cleaning with a final heating to drive off moisture. The use of alkali or acid-based cleaning agents is not recommended.

Two extensive studies identified several advantages of adhesive joining (Ref 21, 22):

- Stresses are distributed uniformly.
- Galvanic corrosion is minimized because the adhesive acts as a dielectric.
- Parts with smaller cross-sectional areas can be joined to larger sections.

Conversely, disadvantages include:

- Environmental temperatures cannot exceed 170 °C (340 °F) because substantial reductions in strength occur at elevated temperatures.
- Hostile environments, for example, high humidity and/or contact with chemically active materials, should be avoided.
- High peeling and/or shear stresses at the joint interface can result in failure.

The referenced investigations found that the best results were obtained by heat treating the adhesives using low applied coupling pressures with a minimum of 5 min at temperature. Steam treatment before adhesive joining along with increasing sintered density were found to enhance shear resistance.

P/M Welds

Successful P/M welding requires proper design and the proper choice of material(s) and joining process. This requires a thorough understanding of the performance characteristics for the application. These include, but are not limited to, the following:

- *Strength requirements*: applied load in tension, shear, torsion, and so forth
- *Dimensional restrictions*: potential problems with distortion and/or shrinkage
- *Environmental factors*: for example, galvanic corrosion from dissimilar metal combinations or effects of elevated temperature on the joint strength
- *Appearance*: surface condition
- *Economics*: cost effectiveness compared with other manufacturing methods

Once the application requirements have been established, consideration can be given to the major factors involved in the joining process.

Type(s) of Material. If strength requirements necessitate greater hardenability, control of hardness and related stresses in the weldment become more critical in welding. Also, the potential for any metallurgically incompatible elements must be eliminated. Compositions containing sulfur or high phosphorus levels are particularly suspect.

Joint design should ensure that the joint interface is not subjected to excessive loads or stress concentrations. In addition, the component geometry must lend itself to the type of joining process to be used, for example, the ability to press and control density in projections for RPW applications.

Process selection must be considered when evaluating the minimum strength requirement of the application. Typically, the fusion processes GTA, GMA, EBW, and LBW provide the highest joint strengths, while FRW and RPW are often near parity with these techniques. Brazing, diffusion, and adhesive bonding provide somewhat lower levels with respect to potential joint strength.

Fusion Weld Cracking. The most common problem with fusion welding involves cracking in or near the weld interface (Ref 23). Successful welding can be accomplished if proper consideration is given to why P/M weldments crack.

The formation of cracks in welded P/M components is most often associated with the stresses generated during solidification and cooling of weld metal (Ref 24, 25). The mass of material surrounding the weld puddle and HAZ resists the contraction forces as the metal cools, resulting in tensile stresses that initiate cracks. These stresses can be minimized by the use of several techniques:

- Preheating can drive off moisture (hydrogen) and lessen the thermal gradient across the weld zone.
- Postheating immediately after completing the weldment reduces stresses, particularly for high hardenability materials that form appreciable amounts of martensite in the weld metal and HAZ.
- Austenitic filler metals on steel or low-alloy components can be beneficial because of their superior toughness, strength, and lack of martensitic transformation.
- Processes that allow the operator to manipulate the amount of heat input can also assist in minimizing stresses (GTA, GMA).

Joint configuration plays a major role in stress formation. Mismatched joints, poor gap spacing, or narrow (low width-to-depth ratio) joints along with insufficient amount of filler metal to counteract densification can all have deleterious affects on the weldment. For example, Section A in Fig. 5 shows a throat crack resulting from increased volume of affected metal and related stress concentrations by using a large-diameter filler wire. In contrast, section B incorporates a smaller-diameter filler wire and lower energy input, which provides a successful weldment.

Fig. 5 P/M Alloy FL-4405 (6.95 g/cm^3) joined to low-carbon steel rod without different filler wire diameter. See text for details.

In addition, fusion welding is not recommended for steam-treated or quenched-and-tempered P/M components. The oxides resulting from steam treatment act as contaminants in the weld zone, resulting in erratic performance and potential for cracking. Quenched-and-tempered parts, even with a sufficient temper to drive off entrapped quenching, are not good candidates for welding (Ref 26). However, this is not to suggest that it cannot be accomplished. The most substantial drawback centers on the relatively high heat input associated with fusion processes that can change the structural constituents. This results in lower strength in the weld zone compared with the adjoining base material resulting in a stress gradient and potential fracture initiation site. It should also be noted that when welding infiltrated parts, free copper in the pores is likely to melt and subsequently migrate to the former austenitic grain boundaries.

Brazing Techniques

Joint Design. Lap joints are always preferred over butt designs. When using a lap joint, the amount of overlap is determined by a handy reference called the "rule of three," which suggests a lap distance of three times the thickness of the thinnest component. The fit between components should be between 0.05 and 0.13 mm to achieve the highest joint strength, which is typically 380 MPa (55 ksi) ultimate tensile strength. For some applications, the parts can be placed on top of or adjacent to one another without exercising any additional precautions. The exception involves brazing dissimilar metal parts having significant differences in density and/or composition. The density affects the thermal expansion coefficient whereas the composition influences dimensional change, both of which can influence the gap distance. The best procedure utilizes a method of gap width control, such as a fixed diameter wire or nipple projections placed between the mating surfaces. The brazing alloy should be placed immediately adjacent to the joint interface to assist in capillary action and flow into the joint. For large surface areas, shallow channels or gutters may be pressed into the joint face to assist in uniform flow (Ref 27).

Filler Metal. The most often used P/M brazing alloy is a patented (U.S. patent 4,029,476) Cu-Mn-Ni alloy powder (Ancorbraze 72) that can be admixed with flux and a lubricant for preforming into slugs/rings or dispensed as a paste. This material is suitable for use with iron, steel, low-alloy, or stainless P/M components. Typically, 3 to 4 g of filler metal is required for each square inch of surface area to be joined. The quantity is dependent on joint design, gap spacing, and component density. Closer gap spacing and higher component density favor lower amounts. Some applications requiring specific properties may require the use of a silver- or nickel-base brazing alloy for electrical, high-temperature, or corrosive environments.

Heating Cycle. Uniform heating of the components along with sufficient dwell time to equalize the temperature between the parts to be joined is important for proper flow and joint fill. A component having a lower mass or thinner section size will likely achieve the flow temperature before a larger mating part. This results in a greater capillary force toward the area having the highest temperature or heat energy that may cause poor joint fill. If this does occur, it is sometimes helpful to reposition the components on the furnace belt to assist in achieving uniform temperature between the parts. It may also help to increase the preheat temperature so parts can equalize before reaching the liquidus point (approximately 1065 °C, or 1950 °F, for Ancorbraze 72).

Atmospheres & Fluxes. Most of the commonly used sintering atmospheres can be used for P/M brazing. A flux is generally added to the braze alloy to assist in oxide reduction. In some circumstances, an additional borate- or fluoride-type flux may be swabbed onto the mating surfaces, particularly when brazing sintered parts, stainless steels grades, materials containing sulfur/manganese sulfide, and wetting large surface areas to be joined. It has also been determined that high CO₂ percentages in the sintering atmosphere can oxidize the fluxing agents and reduce the flowability of the brazing alloy.

By far, the most common difficulty experienced with furnace brazing P/M components is the lack of fill in the joint. This is generally associated with the following conditions:

- Improper cleaning or oxide reduction
- Excessive joint clearance
- Low sintering temperature or nonuniform part temperature

- Insufficient filler metal
- Entrapped lubricant, flux, or gases
- Movement of the mating parts before solidification

Welding and Joining Processes

Jack A. Hamill, Hoeganaes Corporation

Diffusion/Sinter Bonding

This process requires an inner component that has a tendency to expand and an outer component with somewhat lower expansion rate or in some cases a propensity to shrink. The components are fitted together as green briquettes and sintered at conventional time and temperature. Elements that enhance diffusion--copper, carbon, phosphorus--also increase joint strength. Density gradients between components also promote diffusion. When choosing a combination for diffusion bonding, consideration must be given to the desired strength level for each component along with the respective dimensional change characteristics to ensure the parts can be made within the print tolerance and strength requirements.

Welding and Joining Processes

Jack A. Hamill, Hoeganaes Corporation

P/M Materials for Joining

Most iron and steel powder compositions can be joined or welded without difficulty. However, some additions or material grades should be avoided if possible. In general, atomized iron grades have lower residual and tramp elements than sponge or other types of reduced iron powders. The cleanliness of these materials does not play a predominant role in weldment integrity, if held within acceptable limits. Nevertheless, the subtle influence of acid insolubles, oxides, and silicates over a period of time influences the service and fatigue performance. For this reason, the atomized grades are preferred for fusion, high-strength, and critical welding applications.

Carbon content has a pronounced influence on the overall weldability of a material. As a general rule, the carbon content should be held to as low a level as possible. However, carbon also greatly enhances the strength characteristics of a material. Joining processes and techniques can be developed to accommodate intermediate to high carbon levels that exhibit acceptable weld soundness and strength characteristics. For example, Fig. 6 illustrates a high-strength GMA weldment between an FN-0205 steering gear and an AISI 1035 steel shaft using an E70S-type filler wire.

Fig. 6 High-strength GMA weldment between an FN-0205 steering gear (6.9 g/cm^3) and a AISI 1035 steel shaft using an E70S-type filler wire

Materials containing sulfur additions should be avoided for welding and brazing applications. The sulfur can migrate to the grain boundaries and may cause hot cracking when fusion welded. When brazing sulfur-bearing components, the manganese in the brazing alloy can form manganese sulfide in the presence of free sulfur, reducing the ability of the material to flow. If a machining enhancement is necessary, a more appropriate choice would include a manganese sulfide (MnS) addition.

Premixes with copper additions of 2.0% can be readily joined to other materials using most processes. The exception, however, involves compositions that include both sulfur and copper additions. Too high a copper content (4.0%) was found to lower the weldment strength to levels below the strength of the parent metal (Ref 28).

Phosphorus additions (Fe_3P), somewhat like sulfur, are not particularly attractive for fusion welding applications. The low melting Fe_3P addition may promote hot cracking in the weld zone. However, GTA and HPW processes have been used for a limited number of Ancorsteel 45P applications. Admixed additions of nickel to iron or steel powders generally enhance the toughness of the material and do not pose any particular difficulties involving weldability.

Stainless steel P/M components have been successfully welded using various joining processes (Ref 29). Gas metal arc welds of 316L P/M parts at various density levels, using 316L filler metal with an argon shield, provided good overall properties. The 303 free-machining grade and those identified as nitrogen strengthened are not good candidates for welding applications. The 410 martensitic grade can be welded, but precautionary measures must be observed with regard to its hardenability.

A growing number of automotive exhaust system flanges and bosses involve welded P/M stainless materials. Extensive testing programs involving static and dynamic characterization (Ref 30, 31) of flanges and welded assemblies indicate P/M stainless materials successfully meet all the appropriate performance criteria. However, during the initial prototype welding development, it was determined that sintering conditions have a pronounced influence on welding performance.

Production trials (Table 1) indicated a change from dissociated ammonia to pure hydrogen atmosphere substantially reduces the level of carbon, nitrogen, and oxygen when processing 409 stainless materials. Relatively high interstitial levels promoted the formation of fine martensite during welding, along with substantial outgassing that resulted in excessive porosity in the weldment. Weld trials using the hydrogen sintered parts proved successful (Fig. 7). The resulting weldments were free of porosity with completely ferritic microstructures.

Table 1 Influence of sintering conditions on properties

Property	Sinter environment					
	NH ₃ 1230 °C (2250 °F)	at H ₂ 1260 °C (2350 °F)	at Vacuum 1150 °C (2100 °F)	at Vacuum 1205 °C (2200 °F)	at Vacuum 1260 °C (2350 °F)	at
Density, g/cm ³	6.57	6.70	6.68	6.95	7.02	
Dimensions, %	...	-0.6	-0.8	-2.0	-3.5	
Carbon, %	0.189	0.060	0.017	0.007	0.007	
Nitrogen, %	0.339	0.042	0.018	0.003	0.001	
Oxygen, %	0.376	0.144	0.225	0.209	0.176	
Weldability	Poor	Good	Good	Good	Good	

Fig. 7 P/M stainless steel weld variation. (a) Unacceptable weld quality associated with high interstitial gas levels. (b) Weld microstructure representing the same weld parameters but a hydrogen-sintered, low-interstitial P/M stainless boss.

Nickel-molybdenum admixed composition with a nominal 0.5% C, 5.0% Ni, 0.5% Mo having a sintered density of 7.0 g/cm³ was successfully welded using the GMA process and an austenitic filler metal without a preheat or postheat treatment (Ref 32). The friction/inertia process also provided a satisfactory, high-integrity weldment with this composition. The diffusion-bonded grades would respond in a similar manner if processed using the same techniques.

Joining Dissimilar Metals. Two considerations must be taken into account to achieve successful weldments. First, it is necessary to define the environmental conditions both metals must satisfy to ensure the best selection for the task. In addition, the physical compatibility of the metals must also be determined.

Compatibility involves several physical characteristics that affect the weldment. The properties to be considered are coefficients of expansion, electrochemical potential differences, melting temperatures, strength levels, and potential intermetallic compounds that can form between the two metals. When the coefficients of expansion are widely different, there will be internal stresses within the weldment that cannot be reduced by a postweld treatment. If these stresses are significant, the weld integrity will be jeopardized and the weldment prone to premature failure. Weldments involving dissimilar metals may also be subject to electrochemical corrosion. The differences in electrochemical potential indicate the susceptibility of the weldment to corrosion. If the alloys are at opposite spectra on the electrochemical scales, the nobility of one metal is far superior to the other and corrosion can be a potential problem. The solubility effects when joining certain metals can form brittle intermetallics when alloying occurs. The combinations most susceptible are steel and aluminum, magnesium or titanium; copper and aluminum; aluminum and magnesium; or similar combinations of titanium. When joining these alloys, caution should be exercised in choosing a welding procedure so as to prevent the formation of any brittle constituents.

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Introduction

DIMENSIONAL TOLERANCE or size control in powder metallurgy parts manufacturing can be affected by virtually every stage of the process. The size change occurring during the sintering step is a result of the powder itself, the compacting, and the sintering conditions. Post-sintering operations such as sizing, machining, hardening, and finishing can all be affected by the condition of the parts as sintered. As would be expected, every stage can be affected by the previous stage.

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Powder

Various methods of powder manufacture, even for the same type of material, influence the compacting, the sintered size, and the physical characteristics as well. Different manufacturing methods affect the particle size distribution, the particle shape, the particle hardness, and particle purity. All of these affect the apparent density (loose powder), the flow, the compressibility, the springback (incremental increase from die size) (Fig. 1), and the green (unsintered) strength of the compact. Variations in any of these parameters can have an effect on the size or tolerance control of the compact. The method of powder manufacture can affect size change in sintering, especially when the powders are blended with carbon, copper, nickel, or other alloys and combinations. The condition of the alloying powders such as particle size and oxide content also affect the size and physical characteristics of the sintered part.

Fig. 1 Springback versus density. Source: Höganäs Metal Powder Data Sheets, Sweden

The choice of the powders to be used may be based on many factors. These include price, availability, ease of compacting, green and sintered physical characteristics, and familiarity with the powder and its use. When good control of tolerances and physical properties is essential, the ability of the powder producer to make a material that is very consistent in all characteristics is a key factor.

The sintered size of a compact varies with the amount and type of the alloy, the density, and the sintering conditions. The size change plotted against the change in alloy or the change in density or the change in sintering conditions can be almost linear or a curve (Fig. 2, 3, 4). For optimal dimensional control, it is desirable to operate on the flattest part of a curve, if possible, as slight variations will have the least effect.

Fig. 2 Dimensional change for several alloys versus density. Source: Hoeganaes Corporation, Riverton, NJ

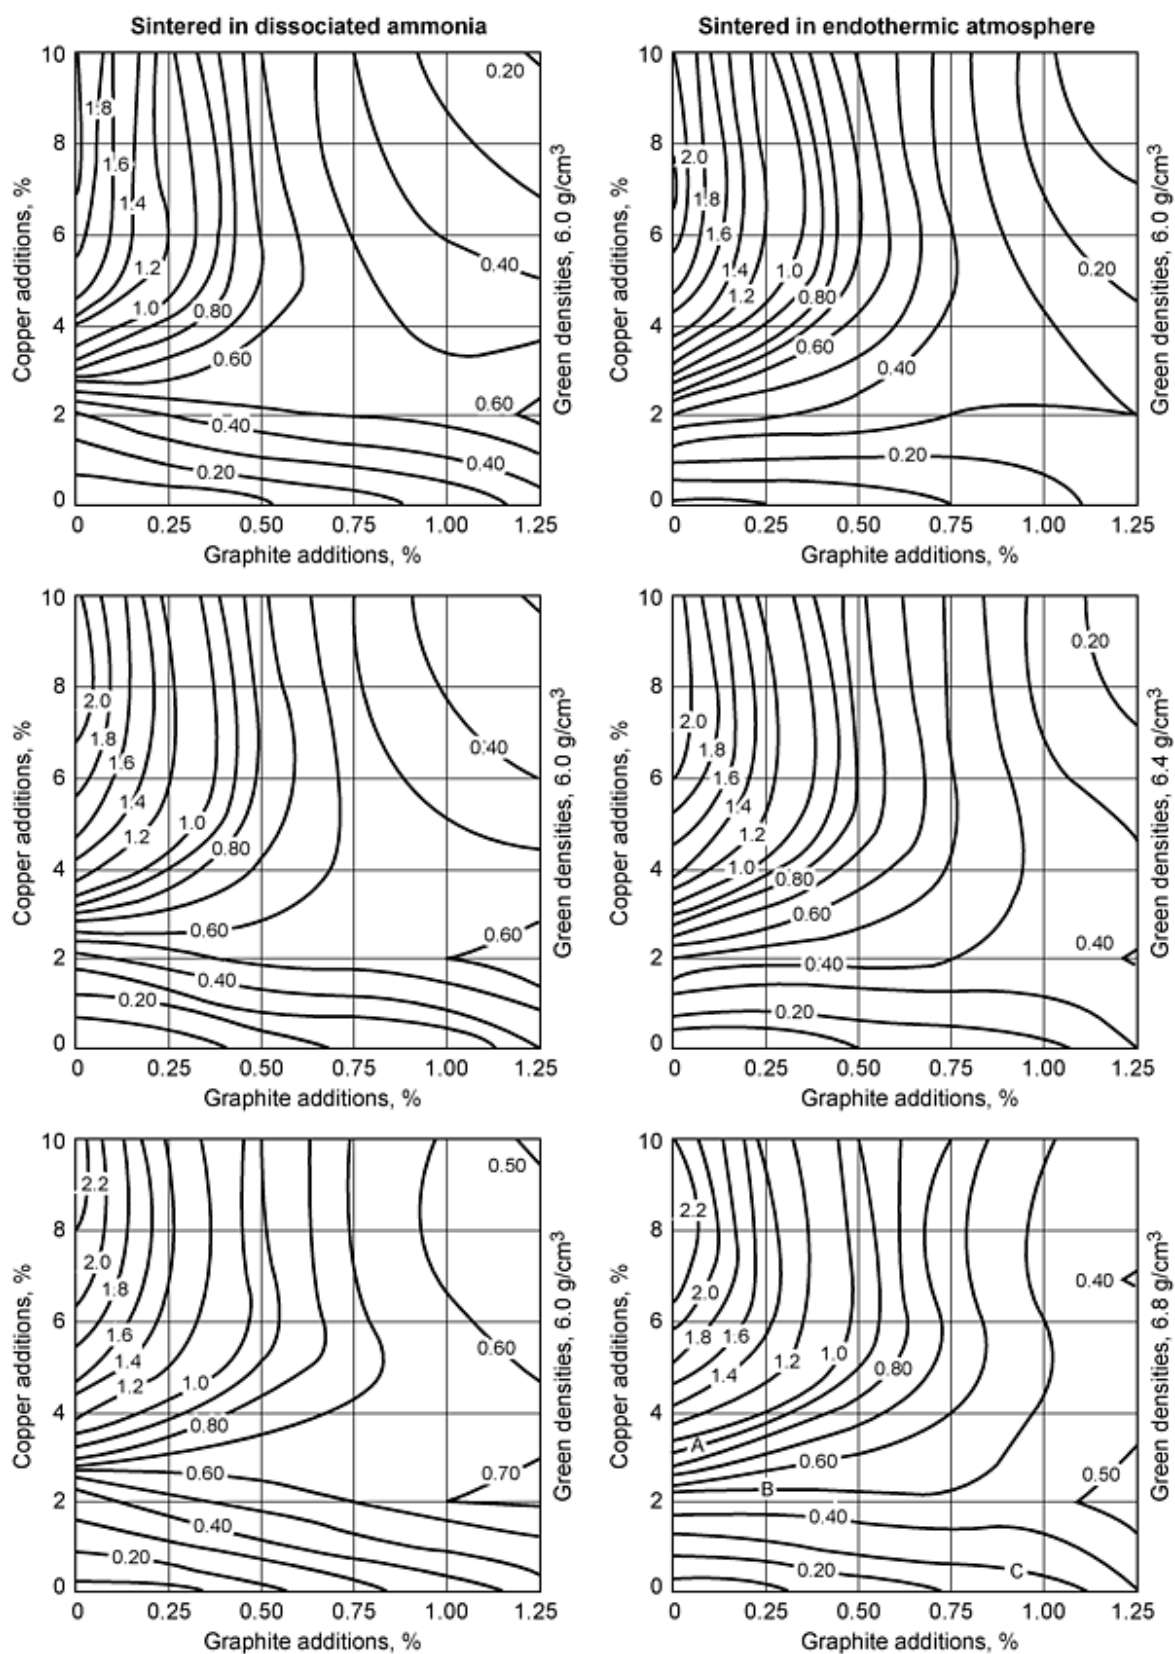

Fig. 3 Dimensional change versus density, copper, and graphite. Source: Hoeganaes Corporation, Riverton, NJ

Fig. 4 Dimensional change versus sinter temperature for various bronze powders. The "PMB" designations indicate variation in particle size distribution. Source: AMG Americas

To obtain optimal part size control based on the powder, there must be very tight control on all stages of powder manufacture. It has been shown that even the water used for atomizing affects the sintered size change (Ref 1). High sodium water (softened) shows less growth when parts are sintered in dissociated ammonia (DA) compared with low sodium water and shows the opposite effect when sintered in a nitrogen atmosphere.

Most powder suppliers now use some form of statistical process control and may operate under an appropriate ISO standard to supply the user with the most consistent powder possible. Even when powder is shipped with extremely narrow control limits on all of the parameters that can affect the tolerance control of the part, there are variables beyond the manufacturing steps that can affect the part as pressed and sintered. Powder may be altered by shipping and transport conditions. Vibration and impact such as trucking long distances over poor roads can have an effect on the flow and apparent density. Powder in containers that have not been properly sealed or that have been left open for long periods may be changed by the atmosphere resulting in oxidation and/or moisture pickup.

If the part manufacturer blends or reblends the powder, variations can occur. Changes in blending time, the amount of load placed in the blender (percent of blender capacity), the type of blender, and the various lubricants can affect the resulting apparent density, flow rate, and green strength (Ref 2). Blend uniformity can be affected by the method of loading the materials into the blender, the accuracy of the weight of the blended material, and the blender time and action itself. Any of these variables can affect the compacted and/or the sintered part. The advantage of a single large blend by the powder producer is that all of such a large blend, 10,000 lb or more for example, should be quite consistent, whereas twenty 500 lb blends may show variation from blend to blend.

Compacting

At the press, the usual control measurements are at least for thickness, weight, and visual imperfections. With some of the more advanced presses, compacting forces and/or part weight and/or tool positions may be monitored and be part of a closed-loop system to cause corrective action to be taken automatically.

In a multilevel part, several sections may be measured independently as well as the overall part. Independent thickness measurements are relatively simple, but individual sectional weight would require cutting or breaking the part accurately, which may be difficult. If a part such as a flange with a hub or a gear with a pinion (cluster gear) is controlled by two thicknesses (or by one-step thickness and an overall thickness) and the overall weight, it is likely that sectional weights and therefore their densities could vary although the overall weight is correct. For example, consider the stepped part in Fig. 5, given the following:

- Overall weight (WT 3) is 146.61 ± 1.47 g
- Overall density is 6.6 to 6.9 g/cm³
- Nominal volume of flange is 19.769 cm³
- Nominal overall volume is 21.560 cm³

If the given weight of the flange (WT 1) is measured at 134.43 ± 1.34 g (determined by breaking off hub and smoothing the break flush to flange), then the hub density could theoretically range from 5.14 to 8.52 g/cm³ (from much too soft to breaking tools), even if the part is made to flange weight, thickness tolerance, and overall weight requirements. This could lead to poor tolerance controls, variation in physical properties, and possible damage to the tools.

Fig. 5 Density control in a stepped part. The overall weight (WT 3) and dimensions are given, and the flange weight (WT 1) is measured by breaking off the hub and smoothing the break on the flange. With this method, however, the calculated values for hub weight (WT 2) are too inaccurate (see text for discussion).

Sectional densities of the compact can be controlled or compared by apparent hardness, although a very low or special load must be used to prevent the cracking of the part. Devices such as electronic probes can also be used to get relative readings or actual densities if properly calibrated for the conditions. Visual comparison of densities is possible with experience, but the surface finish of the tooling can have a large effect on the appearance of the compact. A rough visual indication of density

can be obtained by quickly "swiping" a line across the part with a broad felt-tipped permanent marker. The ink penetrates faster in the lower-density sections than in the higher-density sections. Actual density measurements of the sections is the most straightforward procedure, but may be slower.

The uniformity of fill in even a simple flat part can be affected by a number of factors:

- The consistency of the powder itself is critical. Variations in flow rate or apparent density obviously lead to poor control of weight and/or thickness and require frequent adjustments.
- The speed of the press (which affects the time allowed for the powder to fill the die) and the dynamics of the powder flow can be critical. When the fill is narrow and deep as in a long, thin-walled cylinder, speed can have a great effect.
- Presses may have a system to cause the feeder to shake when it is over the die for fill. The amount and consistency of this shaking can affect the accuracy of the fill. If this shake is accomplished by a mechanical means such as a notched cam, loose linkage may allow for excess variation.
- If the press goes to fill before the feed shoe is over the die, the air in the die must be replaced by the powder in a smooth, consistent way, or air may be trapped, which adds another variable to filling and can affect the weight and therefore the density and resulting properties (Fig. 6).
- If the punches tend to stick or "hang up" the speed with which the press completes the fill, the fill time may vary, resulting in nonuniformity. The act of sticking may not be consistent on a part-to-part basis, resulting in substantial fluctuation in the weight and/or thickness or an occasional bad part.

Fig. 6 Entrapped air during fill

In some press systems, the amount of powder in the hopper can have an effect on the weight of the powder fill. Some form of flow-control orifice between the feeder and the hopper can reduce this effect (Fig. 7). In most feeder systems, that side of the die that is nearest to the feeder is overfilled as the feeder is over it for a longer period. If the fill is not uniform on a consistent basis, such as being too heavy on one side, the feeder can have some sort of mask placed in it to control the powder flow into the die. Such masks would usually be unique to a job and belong to the specific "tooling" for that job. There are now proprietary systems that are designed to ensure a very uniform fill (Ref 3).

Fig. 7 Control orifice for more uniform fill

Another item that can affect fill uniformity for ferrous parts or even nonferrous parts with some iron in them, would be any magnetization of the tools. This is particularly true for smaller parts with thin walls. As tools are often held in magnetic fixtures during toolmaking or checking operations, the possibility of retained magnetism is present unless good demagnetization techniques are used. Even pressing tools that have been carefully and effectively demagnetized can become magnetic if the mechanic tools and wrenches, such as "hex" wrenches, have become magnetic themselves. Plates and adapters in tool sets and even hardened press parts that have not been well demagnetized can have a dire effect on the operation. Magnetism of the tools can be easily checked with a "magnetometer" made for that purpose. Otherwise, a clean sheet of stiff white paper can be placed over the individual tool or over the top of the die if the tools are in the press; then iron powder is gently sprinkled on it. If the powder takes on the appearance of magnetic lines, there could be problems. A very gentle rap to the paper may help show these lines better.

Fill weight and compacting thickness can be affected by mechanical items in a press. For example, in a press that uses cams to determine fill levels or compacting height, an out-of-round or mechanically damaged cam follower can cause some type of cyclical variation. Powder buildup under punch supports or adapters can cause a change, usually a progressive change, not of a cyclical nature.

Part size change can be caused by the heat-up of the die and tools due to thermal expansion. A 100 mm die dimension could increase by almost 0.05 mm if a steel die is heated up by 24 °C. A carbide-lined die would expand somewhat less. Long or deep parts with a lot of die wall area such as a gear or sprocket tend to heat more than a plain round die because of its increased surface area with greater total friction. A well-polished carbide die minimizes friction and heat-up.

A cracked punch or punch holder or adapter can cause excessive variation and may get progressively worse until a complete failure occurs. If a press is run near its tonnage capacity, noticeable deflection or stretching can occur under load and this affects the thickness greatly if the weight varies. For example, in a 500 ton mechanical press, a plain cylindrical part 101.6 mm (4 in.) diam by 25.4 mm (1 in.) thick of atomized iron would weigh 1400 g when pressed to 6.8 g/cm³. If the weight increased 1% to 1414 g the thickness could increase by about 0.076 mm (0.003 in.) in a typical mechanical press due to the stretching of the press. A part of half the diameter in the same press would increase only about 0.018 mm (0.0007 in.) for a 1% increase in weight. If a hydraulic press is used and is set to press to a fixed tonnage, the thickness will vary in proportion to the weight. Note that some hydraulic presses can press to an encoded dimension with high accuracy.

Presses are now available, in varying degrees of sophistication, that can monitor force and/or weight and react to these changes. This reaction can be based on a statistical trend and serve as a warning to the operator, or it can stop the press or cause the press to make an adjustment itself. Such systems can compensate for variations in powder characteristics and press effects. However, as with any system, better control of the powder or press actions gives better results. Some presses (usually hydraulic) can work on a computer numerical control (CNC) basis using precision encoders resolving to ± 0.001 mm so that all levels or movements involved are at the correct location at the correct time and arrive there at the desired rate (Ref 4). For multilevel parts, this gives virtually absolute control. Computer numeral control presses are also able to compensate for press elongation. It should be noted that this type of equipment carries a high initial cost, but this may well be justified for many jobs.

There are press systems that can "learn" a force-distance curve for a particular job, and the press can react to changes from that curve in some appropriate way. Field tests using tonnage compensation and/or weight compensation have indicated reductions in standard deviations of up to 16%. Average long-term reduction of weight variation was 40% (Ref 5, 6, 7).

Most of the previous discussion refers to control of the thickness and/or weight of the pressed part, which is seen to depend on almost all of the features of the powder itself as well as on the uniformity of press conditions. The control of horizontal (die) dimensions brings in other factors. For a plain cylindrical part, the diameter in the as-pressed (green) condition is usually quite stable, but is affected somewhat by density as a more dense part tends to springback or pop out more as it is ejected from the die (Fig. 1). Various methods of powder production affect springback also. The harder, less pure powders spring back more.

As springback is generally a function of the size itself, a larger part changes more than a smaller part, both in horizontal and vertical dimensions. Other factors that affect the horizontal size, as compacted, are wear in the die or in cores. Wear is a long-term effect and depends on the abrasiveness of the powder material, the density, the relative movement in the die at compaction, the die material hardness and finish, and wear resistance. Under some conditions a die or other tool member that creates horizontal dimensions may crack, which will give a more sudden change than wear. If a die or punch that also acts like a die, or in some other way creates a horizontal dimension and is sensitive to cracks, this should be realized in the inspection procedures for the part and this dimension monitored as a "variable." In the example shown (Fig. 8), the lower punch acts not only as a punch for the gear but also as a die for the pinion. If the punch cracks (through the small hole or not), it will cause the width of the cracked pinion tooth to increase and may destroy the pinion accuracy. This type of crack would not affect the gear teeth directly, but could affect the centrality of the hole. It should be noted that the typical wear in a core rod is not easily measured by a micrometer, as the wear may occur as grooves and the effective decrease in the hole size could be more than the measured decrease in the rod size (Fig. 9).

Fig. 8 Cracked punch affects size

Fig. 9 Error in worn core measurement

Another horizontal variable could be the location of holes (Fig. 10) or the distance between holes. Although the diameter (horizontal dimension) of a hole is usually determined by the core rod--which is subject to wear--the location of the hole is affected by the clearance between the punch and the die and the clearance between the core rod and the punch. If several punches are nested together, the location of a central core rod can be a stack-up of clearances. Theoretically, the locational accuracy of the core can be between "0" and the grand total of all clearances (in the worst case). In practice, it will be somewhere in between. For this reason, the tolerance of hole locations or center distances can be more than the die-shape or the hole-shape tolerance. The size change that can occur in sintering must also be considered.

Fig. 10 Trapped powder affects hole location

Bending or flexing of a core can affect the accuracy of its location and apparent size. A thin, relatively long core hole can be flexed by uneven powder density on different sides. For example, a hole central to a part of uniform thickness should have uniform pressure all around it and not flex, whereas a hole close to the edge may see higher density toward the inside and lower density to the outside due to differences in fill (see Fig. 11) and become "banana" shaped. A banana-shaped hole could seem undersize when measured with a "go" gage pin, although the true diameter of the hole could be correct at any one point in the hole (Fig. 12). This may often be corrected by fill compensation.

Fig. 11 Bending of a thin core near an edge

Fig. 12 Bent hole shows no-go. The pin entering the hole from the top will try to go in at a slight angle. Due to the "banana" shape, it could not go through. It would get stuck.

Therefore the part, as it comes off the press, is seen to be influenced by:

- *Consistency of the powder itself:* flow, apparent density, screen sizes; purity, alloy, or trace elements;

manufacturing processes; and springback

- *The feeding of the powder into the die:* powder "head"; speed, shake, timing, dwell; condition of the feeder, wiping action, powder left over the die level; and mechanical motions of the press tooling.
- *Changes in the tools themselves:* wear, cracking or other physical damage, cracking of punch bases and/or adapters, sticking, and variation in clearances due to powder entrapment (Fig. 10)
- *Changes in the press:* heat-up of the frame and tools and normal "common-cause" variations

To help diagnose problems of nonuniformity of a compact or sintered part, some reference to the position of the part in the tools is desirable. If the part is of an odd shape or not symmetrical, the position in the press may be obvious. If, however, the part is symmetrical--such as a disk, a cylinder, or a gear--there may be no way of verifying which side was up and the orientation of the part in the die. Forming the tools to put a small depression or other mark on the part indicates the position of the part as pressed. If care is taken in placing the mark, it may not have any harmful effects on the part. This helps to diagnose problems such as out-of-round parts, out-of-concentricity tools, nonuniform fill, chipping, cracking, and powder entrapping.

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Handling

Once the part has been compacted, it must be removed from the die table. In some cases the part slides onto or is picked up and placed onto a belt or some conveyance that delivers it directly to the sintering furnace. This may not involve direct operator intervention, but inspection should be done on a periodic basis. If bad parts are being produced, they can be isolated from those parts going into the furnace to avoid contaminating the good with the bad. It is possible that the parts could have some form of automatic inspection for weight or size or both. Parts could be monitored by the press system itself, and bad parts could be rejected off to a side.

If the parts are left to slide into a container or onto a staging table or system, care must be taken to see that physical damage such as chips or cracks does not occur. If the part is of a "C" shape, care must be taken to ensure that there is no way that the opening in the "C" can be reduced or squeezed in. That can produce a variation in "die" shape. Large and heavy parts, particularly those with small projections that could be struck, are more susceptible to handling impact than small, lightweight parts. Care must be taken if the operator has to pick up a C-shaped part, as squeezing it can cause dimensional changes or cracking (Fig. 13).

Fig. 13 Distortion of C-shaped part

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Sintering

Even if parts come off the press with extremely close dimensional and weight tolerances, the trip through the furnace can have a great effect on dimensional stability. The sintering operation is what develops the physical properties and size of the part, and many things happen in the furnace.

The final size and properties of the as-sintered part are influenced by the following:

- The material, its method of manufacture, and all basic attributes
- The alloys or additives and their uniformity
- The pressed density and the density distribution
- The pressed sizes
- The furnace conditions
- The time in delube or preheat, the time in high heat, and the cooling time and rate
- The temperatures reached at each stage
- The atmosphere, its composition, amount and flow rate, and flow pattern over the work
- The work load and its distribution in the furnace

For consistent work, the time-temperature profile that each part "sees" must be very uniform within the furnace and on an hour-to-hour and day-to-day basis. The part that comes off the press can be measured, weighed, evaluated, and examined as it is made. Parts being sintered can generally be measured and examined only after they leave the furnace, which means several hours of production before adjustments can be made based on the part itself.

Normal events that can occur to alter the sintering and therefore the tolerances could be:

- Variation in time due to change in belt speed. Most belt furnaces have a driving drum that has some form of rubber facing to grip the belt and usually a pinch roll to hold the belt tight to the drum. However, if the facing is worn or the gripping roller loses spring tension or the load varies too much, the effective speed can vary regardless of the speed of the drum.
- Speed control of the drive may have variables, and the setting of the speed may not be accurate. If the speed is measured by a ruler and a watch, errors of 5% or more are possible unless great care is taken.
- Inconsistent spacing of parts on furnace belts can alter the net effect of the heat-up and cooling rate.
- Variations in the temperature profile. In furnaces with a small number of control zones, variation in gas burners or change or deterioration of heating elements can cause a change in the temperature profile that may not be picked up by the temperature controller. More zones of control will minimize this, but not eliminate it. The newer electronic controls can be programmed to or actually learn how to obtain the most stable temperatures.

Parts that are relatively thin and flat, such as valve plates used in compressors, are often sintered placed on graphite or ceramic plates that are maintained very flat. Although this may reduce the yield of the furnace, it produces flatter parts than can be achieved by placing the part directly on the belt or on metal screens or trays that tend to go out of flat.

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Re-Pressing (Sizing)

A part can be put back into a press and re-pressed for several end purposes:

- *To increase density.* There are practical limits to the density that can be obtained in the first pressing. The dry lubricant blended with the powder is low density, about 1 g/cm^3 , and therefore occupies a lot of space. An iron compact with 1% zinc stearate as a lubricant has a theoretical solid density of 7.35 g/cm^3 . Also, the iron particles receive some cold work during pressing. Sintering eliminates the lube and anneals the part to allow for substantial density increase upon re-pressing.
- *To calibrate size.* Ferrous and nonferrous parts can be sized or calibrated by re-pressing either in a compacting press or a press made specifically for sizing. Note, however, that if all of the controls on the powder, the compacting, and the sintering were sufficiently tight then there may be no need to size. Sizing, basically, compensates for the errors in these basic steps. The exception to this is the variation in sinter size caused by unavoidable density variations such as in bronze bearings. The part can be forced into a die that is somewhat smaller than the part and over a core that is somewhat larger than the hole. The part surfaces are therefore actually burnished to size. There may be little increase in density. A part can also be sized by making it to have some clearance when placed in a die that is close to or at the final size. The part reaches the desired size by filling out sideways as it is squeezed down.
- *To coin the surface(s).* This is similar to the conventional striking of a blank to make a coin or medallion. There is usually some change in configuration with coining such as the surface of a coin or creating text or a logo. Mechanical shapes such as small counterbores or depressions as well as small, raised shapes can also be created.

The actions described previously may well be combined. A part could be re-pressed to increase density and to improve size tolerance (calibrate) and also to change some shape feature. Bronze bearings can be sized by forcing the outside diameter (OD) and inside diameter (ID) into the tools, which burnish the surfaces so there is not much increase in density as that would

reduce its ability to hold oil. If iron-base parts are sized with very little movement--such as being put into a die that is just about the size of the part--it may be difficult to hold tight tolerances. If the part density is increased sufficiently, it will be deformed beyond the elastic limit and tend to hold the size to a closer tolerance. For softer, lower-carbon parts or brass or copper parts, a reduction in thickness on the order of 10% has been used. For parts that are made of higher-carbon or alloy steels, the reduction in thickness may have to be less to avoid excess stress on the tools. Cams have been made with a "throw" (difference between the large and small radii) tolerance of no more than 0.0025 mm (0.0001 in.). These cams were made from plain iron and re-pressed. However, any attempt to add carbon or any other alloy to the iron would not allow that tolerance to be met on a consistent basis.

Holes in parts can be sized by re-pressing the entire part or by just burnishing the hole(s) with a core rod and with little or no decrease in the thickness. Roller burnishing is often used to bring a round hole into tolerance and generally works well as the inner surface of the hole can be densified locally by reducing the pore sizes without "smearing" or closing them off. This is of benefit if the hole is to function as a self-lubricated bearing.

When re-pressing a part, the lubrication is important as it is needed on the surfaces that contact the die or core rods. If a liquid or semiliquid lubricant is allowed to penetrate the pores, it is possible that hydrostatic pressure in the part, which can be a variable that can affect the ability to hold close tolerances, will be developed. Oils are usually applied by a quick dip or spray without allowing a soak time. Tumbling or coating the part with a dry lubricant such as molybdenum disulfide, zinc stearate, or other soap products eliminates the hydrostatic problem but may not do a good job of lubricating small holes and may affect the surface appearance of the part.

Re-pressing a part improves the tolerance on the die shape and the shape of holes. If the holes are not in the correct location or not concentric with the outside, sizing may not correct this, particularly if the material is relatively strong. Small diameter cores are subject to flexing. Sizing of a gear may improve the tooth shape and tooth-to-tooth errors, but may not improve runout or excessive total composite error based on runout. For parts that have a tight concentricity tolerance, such as a gear to produce AGMA class 8 or 9 or better, it may be necessary to bore or grind the ID. The concentricity of the pitch line to the OD of a P/M gear should be very good if the tools are made properly, so that the gear can usually be held on the OD to bore the ID with good results.

Techniques for Improving Dimensional Tolerance of Powder Metallurgy Parts

M.I. "Mike" Jaffe, Consultant

Machining

A P/M part can be machined to provide shapes that could not be created by P/M compacting or re-pressing, such as some undercuts, side holes, threading or tapping, and so forth. Machining, cutting, or grinding is also done to improve dimensional tolerances. As mentioned previously, a gear can have the hole bored or ground, which removes material to reestablish the centerline to improve concentricity tolerances as well as improving the size tolerance. Parts that require tight thickness tolerances and/or flatness can be surface or double-disk ground in a conventional manner. Likewise, parts that are of a suitable shape can be centerless ground to improve diameter or roundness. Although machining or grinding of P/M parts is similar to that of wrought or solid parts, there are some differences that should be noted:

- Due to porosity, P/M parts may absorb coolant or cutting or grinding fluids. These fluids should contain rust inhibitors.
- Brass or nickel-silver parts traditionally contained small percentages of lead, which improved machinability greatly. However, due to the restraints on the use of lead, other methods are being developed to improve machinability.
- Iron-base parts may have materials like manganese sulfide added to improve machinability.
- Resin impregnation of P/M parts can have a dramatic effect on increasing machinability.

Inspection Measurement

Proper and logical inspection procedures assist in maintaining optimal tolerance control. In powder manufacturing, the raw materials should be of a select grade. For atomized powders, the molten metal can be checked for proper chemistry before pouring and changes made to the melt as needed. Production lots of powders are usually tested and may be certified for screen analysis, apparent density, flow rate, compactability (density achieved by pressing at a specified tonnage), sinter size change under a specified condition, and chemical analysis for basic constituents. If the powder meets the agreed-on specifications the user should be assured of a reasonable consistency. It is obvious that tighter control of the powder results in better press-and-sinter tolerances, and this is an ongoing project with powder manufacturers. An audit by the parts producer of incoming powder certifications from time to time would help to ensure the required quality. Tests of flow rate, apparent density, and screen analysis are easy enough so that this should be done on a routine basis. Accurately controlled pressing of a tensile bar, a transverse bar, or a suitable ring that is then sintered in a laboratory furnace under standard time, temperature, and atmosphere conditions and then tested for strength, hardness, size change, and so forth is a very good way of ensuring powder control as well as a reference for sintering conditions.

Inspection procedures at the press should take into account the following variables.

Normal Variables. Weight and thickness are normal variables, and their running tolerances may be set by part requirements or by a process capability study that would yield statistical process control (SPC) limits for these parameters based on the material consistency and the equipment capability. This procedure indicates whether the equipment can, in fact, produce the required tolerances and yield a set of control limits that could indicate a process going out of control even if the attributes are well within the print specification range.

Weight can be measured manually by the operator or automatically by the pressing system. Electronic scales are the most practical, and some can be coupled to SPC monitoring systems. Automatic measuring by the press system can give a warning to the operator or go as far as making adjustments to the press fill. If the weight of a part is allowed to vary $\pm 1\%$ and the thickness is allowed to vary $\pm 0.5\%$, the density could vary $\pm 1.5\%$ or a spread of 3%, which could create problems. See the section "Compacting" in this article for a discussion of causes of weight variation.

Thickness can be measured by any of the standard measuring devices such as verniers or micrometers or dial gages (analog or digital), or laser devices. Although standard micrometers are very common, electronic digital types provide the best readability and minimize reading errors. If measurements are done manually, care must be taken to make the procedure as easy as possible and virtually "foolproof" for the operator. If there are several thicknesses to be measured that are more than a turn or two of the micrometer spindle, several micrometers or a dial indicator should be used. If a dimension, such as a step, that would be the difference of two normal micrometer or dial readings or require a depth micrometer is to be measured, a dial indicator referenced to one surface would give more accurate results with less chance of operator error (Fig. 14). For long runs of more complex parts, multipoint gaging setups can be created that measure many features at once and statistically process the data (Ref 8).

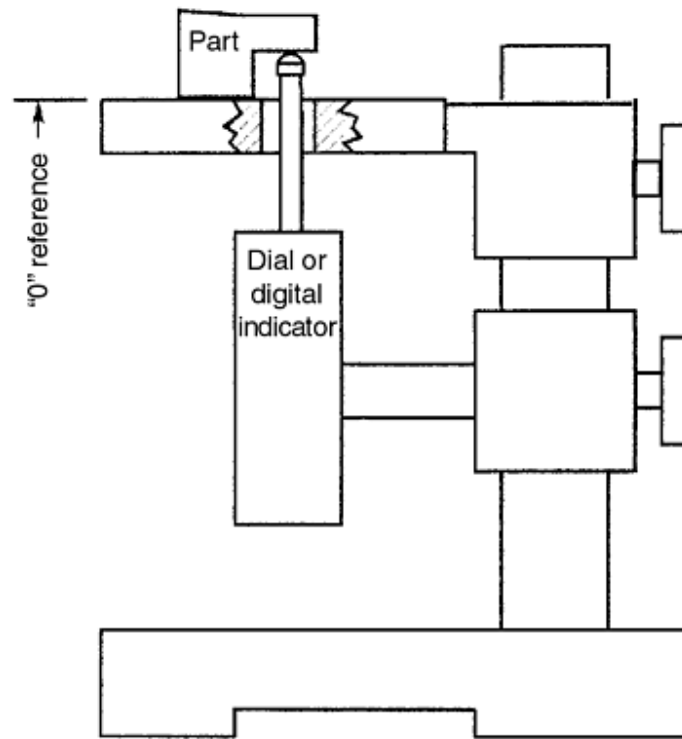

Fig. 14 Simple measurement of a step

Slow-Change Variables. Slow changes in dimensions occur with wear on the tooling components. Where tolerances are nominal, a carbide die and carbide cores can produce millions of parts before wear is a problem. Tool steels containing large percentages of finely dispersed carbides (usually made by powder metallurgy) can do exceptionally well and be less prone to cracking. Most standard tool steels have a much shorter effective life. Therefore, the frequency of inspection for dimensions affected by tool wear depends on the tools themselves as well as on the powder used and its density. Although thickness and weight should be checked frequently, die and hole sizes need much less frequent inspection at the press. Steps in a part produced by either several different punches, or a step in the die, are subject to thickness variation and need frequent control. A step produced by a step in a punch face varies with punch wear and needs less frequent checking.

Sudden changes in dimension can be caused by the breaking or cracking of the punches or dies or of other tool support items. Experience on any particular job indicates those dimensions sensitive to this so that logical inspection can be set up. Often, when a part of a tool breaks or cracks, it can be heard or the press may indicate the problem by sound or by some change in those features normally checked.

By understanding the processes and how the variations or failures can occur, good tolerance control can be achieved efficiently, resulting in better P/M parts at lower cost.

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

Introduction

POWDER METALLURGY is considered a near-net shape manufacturing process, where designers seek to eliminate or significantly reduce secondary machining operations through die design, tool movements, and core rods. This ability to improve material utilization by reducing the need for machining operations has been a key to the success of P/M. However, improved machinability is becoming more important in extending the applications of P/M (Ref 1).

Machining is conducted for several reasons. Powder metallurgy methods have excellent shape-making abilities, but conventional high-volume techniques cannot make holes, or other re-entrants, normal to the pressing/compaction direction. Thus, cross holes required for lubrication must often be drilled after sintering. Accurate surfaces required for location or assembly also must sometimes be turned or milled. In addition, end users are increasing their use of subassemblies. Hence, P/M fabricators can supply a complete system, such as an oil pump rather than a gear, which can require machining operations previously undertaken by the end user.

When a parts fabricator supplies machined components, machining operations such as drilling, tapping, or boring can be the rate-limiting factor in the operation of an assembly line. Thus improved machinability of P/M materials to remove bottlenecks can then offer substantial increases in efficiency to both parts fabricator and end user. In cases where P/M steels compete with cast irons, machinability may be the leading factor in material selection. Thus, there is considerable interest and activity in measurement and improvement of machinability of P/M steels (Ref 2).

The relatively poor machinability of P/M steels compared to competing wrought products is usually considered to originate from a combination of factors, which include porosity, microcleanliness, microstructure, and knowledge. Some understanding of these factors is necessary to distinguish how the machinability of P/M steels is inherently different from wrought steels. These topics are discussed in this article, with a focus on the conditions of the base metal and additives to improve machinability. Coverage of the machining process is addressed in the article "Machining of Powder Metallurgy Materials" in this Volume.

The differences in machinability between wrought and P/M steels can be partially explained by the presence of porosity and the differences in microstructure required to obtain similar performance levels. The machinability of P/M steels can be improved significantly by systematic use of free-machining agents, cutting tools, and investigation optimizing machining conditions. In some applications, infiltration or polymer impregnation to close porosity will improve machinability significantly. In applications where machinability is key to the success of a P/M part, evaluation of machinability and possible improvements should begin at an early stage in part development and include part producer, tool suppliers, and powder producers.

This article shows that the machinability of sintered P/M steels can be improved by the use of free-machining agents that enhance machinability and the use of improved cutting tools. It appears that the use of green machining processes offers a means to improve machinability significantly. With correct choice of machining agent, cutting conditions, and cutting tools, it is possible to produce P/M steels with machinability equivalent to that of wrought steels; however, the optimization required can be time consuming. Where machinability is critical to the application and use of a P/M part, it should be considered at an early stage in the design process in cooperation with powder producers and cutting tool suppliers.

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

The Machining Process

The machining or metal cutting process is extremely complex. It has been widely studied for wrought (Ref 3, 4, 5) and P/M steels (Ref 6, 7, 8, 9). The cutting process is generally illustrated by considering metal flow towards and over a simple cutting tool in an operation, such as turning or broaching (Fig. 1).

Fig. 1 Schematic of cutting process

During cutting, tool movement into the workpiece generates a complex stress field around the tool tip. These stresses initiate cracks in the workpiece ahead of the tool tip. The cracks grow and join to separate the metal to be removed from the bulk of the workpiece. The layer of metal deforms, flows across the tool face, and is then removed from the cutting area. Ideally, the separated metal fractures so that it is removed easily from the cutting area as "chips." From this simplified description, it is apparent that the workpiece, cutting tool, and chips undergo high stresses and strain rates during the cutting process. These conditions, plus friction between the tool and chip, cause considerable local heating. In extreme cases, the heat can cause welding of chips to the tool face, local plastic deformation, or even melting of the tool or workpiece surface. Thus, both toolmakers and developers of engineering materials have attempted to improve the performance of materials during the cutting process without sacrificing other properties.

Effect of Porosity. The presence of porosity in P/M components significantly changes the cutting process (Ref 7, 8). The first and probably most significant effect is that cutting becomes discontinuous as the tool edge breaks out of the workpiece into pores. This action of successive small impacts on the cutting edge causes more rapid tool failure than continuous cutting operations (Fig. 2).

Fig. 2 Schematic of the effect of porosity on metal cutting

Porosity reduces the thermal conductivity of P/M steels, thus temperatures of the cutting zone and cutting edge can increase rapidly, which can accelerate tool wear and harden the workpiece. Local hardening of the workpiece can make subsequent finishing cuts more difficult. Interconnected porosity provides a path for cutting fluids to escape from the cutting area, which reduces their ability to cool and lubricate the cutting edge and can reduce their ability to wash chips from the cutting area. Such behavior can be critical to "spade" or "gun" drilling operations that depend upon controlled coolant flow. The porosity and remnants of prior particle boundaries inherent in P/M parts possess much greater surface area than wrought steels, which potentially increases physical and chemical reactions between the tool and workpiece that can accelerate wear.

Effect of Microcleanliness. The presence of undesirable nonmetallic inclusions is a cause of poor machinability (Ref 9, 10). Porosity also can contribute to poor microcleanliness and machining problems by allowing subsurface oxidation or carburization of pores during and particularly on cooling from sintering or heat treatment operations. In extreme cases, networks of oxide or carbide layers can significantly reduce machinability.

Influence of Microstructure and Properties on Machinability. Powder metallurgy steels employed in structural P/M parts possess somewhat different microstructure property relationships than wrought steels. The most critical effect that porosity has upon properties is to significantly reduce bulk properties, such as strength and macrohardness, from those intrinsic to the powder particles.

The strong effect of density or porosity upon bulk properties is illustrated in Fig. 3 and 4, which show ultimate tensile strength and hardness for three widely used P/M steels: F-0008, FN-0205, and FC-0208 (Ref 12). Neither the tensile strength nor apparent hardness of these steels is exceptional. They should not cause the severe machining problems associated with very soft annealed steels or high-strength steels.

Fig. 3 Ultimate tensile strength of sintered P/M steels

Fig. 4 Macrohardness of sintered P/M steels

The machinability of P/M steels is also influenced strongly by alloying and microstructures. The high carbon contents of sintered P/M steels result in microstructures with high volume fractions of pearlite in ferrite. In some cases, the microstructure can be pearlitic with grain boundary cementite. Cementite (Fe_3C) possesses a microhardness of approximately 1150 HK, and the cementite lamellae in the pearlite can conceivably cause significant abrasive wear of cutting surfaces. The ferrite regions, which can cause adhesive wear, possess much lower hardness of 100 to 150 HV.

Frequently, P/M steels are produced by mixing elemental additives, such as copper and nickel. Under practical sintering conditions, some of these elements may not dissolve completely. For example, nickel-rich martensite will possess different properties to the pearlitic areas if the nickel is not completely dissolved in a nickel steel such as FN-0405.

Metal Powder Industries Federation (MPIF) standard 35 also permits relatively wide ranges of carbon and alloy content in P/M steels, such as FN-0205 or FC-0208 (Ref 12). A change in chemistry from minimum to maximum can change their microstructure and properties. For FN-0205, increasing carbon from 0.4 to 0.6 wt% appears to increase the pearlite and martensite content. For FC-0208, increasing carbon from 0.6 to 0.9 wt% produces an almost completely pearlitic microstructure. Higher carbon additions produce a much finer, almost irresolvable pearlite. The changes observed in both alloy systems would be expected to reduce machinability.

One recent trend is to use prealloyed powders rather than pure iron (Ref 13). These P/M steels possess significantly higher mechanical properties due to their much higher hardenability. Consequently, they possess bainitic or partially martensitic microstructures in the sintered condition with tensile strengths of 415 to 690 MPa (60 to 100 ksi). Alloys of this type can also be sinter-hardened, which allows the development of high martensite contents during cooling from sintering. The properties of sinter-hardened steel approach or exceed those of heat treated FN-0205 P/M steel (Ref 14). It is to be anticipated that these high-strength steels will be difficult to machine with techniques developed for materials with a pearlitic microstructure.

Knowledge of Differences. The microstructure and properties of P/M steels differ significantly from those of competitive materials, such as cast irons or wrought steels. Therefore, the machinability of P/M steels will differ from that of iron and steel. However, the impact of the microstructural differences upon machinability is not well known or understood. Consequently, many P/M materials are machined with cutting conditions and tools that are optimized for the competing materials. When these do not produce good results, the conclusion is that P/M steel machinability is inferior to that of its competitors. The more correct conclusion is that P/M steels are different and frequently can be optimized by improvements to machining conditions and cutting tools. Thus, the knowledge required to machine P/M steels efficiently needs to be acquired and disseminated widely.

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

Machinability Measurement

Machinability is the ability or ease with which a material can be removed from the workpiece. It represents the interaction of the cutting tool, cutting conditions, and the workpiece. Measurement of machinability requires analysis of several interacting factors and is by nature complex and time consuming. Several different indices can be used to define machinability including tool forces, tool wear, tool life, and surface finish of the workpiece. For determination of optimal conditions, tests of specific machining operations, turning, milling, or drilling are required over a range of cutting conditions, speed, feed, and depth of cut (Ref 15). Thus, it is difficult to define a single index of machinability, although in some cases, such as drilling, materials such as brass, cast irons, and steels can be ranked by a single index (Ref 16).

The most thorough technique is to define the index (e.g., tool wear) that is considered critical, then measure the effect of systematic changes on machining variables, depth of cut, speed, and feedrate upon both the critical response and other factors as a function of machining (Ref 17). The results can be used to define tool life in minutes or number of pieces cut. The method is widely used for turning and milling operations, particularly during the development and optimization of cutting tools. The technique requires a large number of tests and is prone to considerable scatter. It is often difficult to decide which index is most critical (Ref 18). Several authors have used statistical techniques (Ref 19, 20) to reduce the number of experiments and clarify the interaction of machining variables and system responses.

Example: Machinability Test for Drilling FC-0205 Steel.

Some of these points illustrated are for a machinability test using Ancorsteel 1000 with 1.75 wt% copper that evaluates the effects of drill speed and addition of free-machining agents (e.g., none, 0.35% MnS, 0.25% MoS₂) upon the machinability of FC-0205.

The test pieces were discs 4 in. in diameter by 1.25 in. thick, compacted to a green density of 6.8 g/cm³, then sintered at 1121 °C (2050 °F) in 90% N₂/10%H₂ for 30 min. The drill test conditions are as follows:

- Drill: 0.250 in HSS, 118° point
- Lubricant: none
- Hole depth: 1 in.
- Speed: 1380, 2220, 3480 rpm
- Feedrate: 0.005 in./revolution

The 1 in. holes do not penetrate the workpiece completely; thus, there are no problems of breakout contributing to failure. The test is conducted using a computer numerically controlled (CNC) machining center that has been programmed to drill approximately 50 holes per disc. The drill torque and drilling forces are measured using a Kistler dynamometer (Kistler Instrument Group, Amherst, NY) mounted below the workpiece. The data logging system samples drill forces several times during the drilling of each hole. The drill is removed to measure drill wear at intervals of five holes. The test begins with an initial screening portion in which 50 holes are drilled at speeds of 1980, 2220, and 3480 rpm to identify major differences in the materials. The screening test shows differences among the test materials and does not indicate a single best material but rather several options depending upon conditions and criteria, such as torque, thrust, or drill wear employed.

Drill Torque. The data show that drill torque is somewhat characteristic of the material and increases steadily with the number of holes drilled (Table 1). The results show that 2220 rpm was an optimum drilling speed for the materials requiring lower torque. Both free-machining agents reduce drill torque compared to the base FC-0205 composition. The addition of 0.35% manganese sulfide produces lower drill torque than molybdenum disulfide.

Table 1 Mean drill torque for 50 holes

Material	Torque, in · lbf		
	1380 rpm	2220 rpm	3480 rpm
Ancorsteel 1000	15.28	17.13	18.33
Ancorsteel 1000 MnS	13.96	12.63	14.62

Drill Thrust. There is little variation in drill thrust after 50 holes under the conditions employed (Table 2). Changing drill speed does not produce consistent changes in drill thrust. The data suggest that addition of manganese sulfide produced lower drill thrust at 2220 rpm, molybdenum disulfide produced lower drill thrust at 1380 and 3480 rpm.

Table 2 Mean drill thrust for 50 holes

Material	Thrust, lbf		
	1380 rpm	2220 rpm	3480 rpm
Ancorsteel 1000	247.4	272.8	276.5
Ancorsteel 1000 MnS	242.2	220.4	225.5

Drill Wear. The measurements of drill wear (Table 3) show the greatest variation. The individual data show that drill wear increases with increasing number of holes until failure occurs. Drill wear tends to increase with increasing drill speed.

Drilling at 3480 rpm causes rapid failure, so that only the material with manganese sulfide enables 50 holes to be drilled. However, at the lower speeds of 1380 and 2220 rpm, molybdenum disulfide produces the lowest wear after 50 holes.

Table 3 Mean drill wear after 50 holes

Material	Wear, 0.001 in.			Holes drilled at 3480
	1380 rpm	2220 rpm	3480 rpm	
Ancorsteel 1000	13.78	15.33	15.00	18
Ancorsteel 1000 MnS	12.25	11.84	14.50	50

Thus, definition of the "best" machining agent depends upon which index is critical to the machining operation or quality of the finished part. If the time available to drill the hole on a transfer line dictated drilling at the highest speed of 3480 rpm, the FC-0205 plus MnS is the only viable material. However, if the mechanical system permitted drilling at lower speed, molybdenum disulfide produced somewhat lower drill wear than manganese sulfide. If drill torque is used as an index of machinability, manganese sulfide is a better option than molybdenum disulfide.

Drill Life. The screening test showed that there is no clear "best" free-machining agent. It is thought that a longer test conducted at 2200 rpm would provide a clearer view of machinability. It is also of interest to compare the machinability of the P/M FC-0205 to materials with known free-machining response. It is considered that the FC-0205 plus MnS shows optimum performance at a drill speed of 2220 rpm. A test was conducted to compare the machinability of the FC-0205 plus MnS to those of known response including wrought 1215, a leaded free-machining steel (12L14), and an FC-0205 produced with a resulfurized powder. The wrought test pieces, using the same conditions, were cut from 4 in. diameter bars purchased from a steel stockholder.

The somewhat surprising results in Table 4 show that the machinability of the resulfurized powder is significantly better than that of the other materials systems, including the wrought steels. Drilling the resulfurized steel required lower drill torque and drill thrust and produced less tool wear at 500 holes than the other materials. The test confirmed that the machinability of the FC-0205 was not as good as the other materials. Drill failure occurred after only 95 holes, and the FC-0205 produced more wear just before failure at 95 holes.

Table 4 Results of long term test

Material	Holes to failure	Mean torque, in. · lbf	Mean thrust, lbf	Wear at 500 holes, 0.001 in.
FC-0205	95	16.56	276	29.1
FC-0205 MnS	>775	13.57	244	26.5
Resulfurized	>600	7.82	142.3	14.2
Wrought 12L14	>600	14.3	186.8	26.5
Wrought 1215	>600	15.58	177.7	19.1

The machinability of the FC-0205 plus MnS is significantly better than that of the FC-0205 and appears comparable to that of the wrought 1215 and 12L14. Drilling the FC-0205 plus MnS requires similar torque but higher thrust than the wrought steels. It appears to produce similar tool wear to that of the 12L14 but somewhat higher wear than the wrought 1215. The test shows under the drilling conditions chosen that the 1215 can possess slightly better machinability than the 12L14. The test also shows that by evaluating free-machining agents and machining conditions, the machinability of a P/M steel can be improved to that of a wrought steel.

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

Machinability Improvement

Machining P/M steels does present problems. Several different approaches to improve machinability are:

- Closure of porosity
- Green machining
- Presintering
- Microcleanliness improvement
- Free-machining additives
- Microstructure modification
- Tool materials

The effects of free-machining additives, microstructure modification, and tool materials are illustrated by controlled drilling tests conducted under laboratory conditions.

Closure of Porosity. Closing or sealing porosity improves the machinability of P/M steels significantly by changing the cutting process from intermittent to continuous. The reduction in vibration and chatter improves tool life and surface finish. Copper infiltration (Ref 8) and polymer impregnation (Ref 19) are efficient means to close porosity and can require an additional process step. Thus, they are most efficient when dictated by the end use, such as fluid power applications, that require a pore-free structure. However, the improvement in machinability can justify their use in severe machining operations or when a machining operation is the rate-limiting step in a process sequence.

Microcleanliness Improvement. The increase in the production and use of atomized rather than reduced iron powders has improved the microcleanliness of iron and low-alloy steel powders. Driven largely by the requirements of powder forging, the content of coarse nonmetallic inclusions in atomized powders has been reduced significantly (Ref 21). For an atomized FL-4600, the median frequency of inclusions greater than 100 μm in size (F_4) has been reduced from approximately 2.5 to 0.25 per 100 mm^2 . The maximum frequency of inclusions greater than 100 μm was reduced from 9 to 1.3 inclusions per 100 mm^2 . These improvements suggest that the incidence of edge damage due to the presence of coarse inclusions should be reduced significantly. Because powder forging practices are now employed to produce all atomized steel powders, P/M users of these powders have benefited.

Green Machining. One way to reduce the machining problems of P/M parts is to machine them in the green (i.e., aspressed) condition prior to sintering. The lack of bonding between particles in green compacts results in low cutting forces.

Such techniques are used in the processing of ceramic and hard metal powders. However, the green strength of metal powder compacts has been too low to withstand the cutting and clamping forces employed in machining operations.

The introduction of warm compaction technology (Ref 22) can change this perspective. The green strength of warm compacted parts is two to four times higher than that of conventional ferrous P/M parts (Table 5). This is sufficient to withstand both the cutting and clamping forces of modern machine tools. Research confirms (Ref 23) that green compacts produced with warm compaction can be machined with conventional cutting tools with low cutting forces. Drill testing (Table 6) shows that the cutting forces are relatively low. Both cutting forces and surface finish can be improved by changes to drill type and profile. These changes also alter the accuracy and surface finish of the drilled hole. Thus, the choice of tool will be a compromise between low cutting forces, surface finish, and tolerances.

Table 5 Green strength of ANCORDENSE premixes

Material	Green density, g/cm ³	Green strength, psi
M-1	7.29	4221
M-2	7.33	4800
M-3	7.37	7703
M-4	7.31	9454
M-5	7.15	6286

Table 6 Mean drilling forces for warm compacted test pieces

Drill type	Mean force, lbf
118° parabolic geometry	100.4
135° split point	45.3
135° split point-wide land parabolic flute	49.3
135° split point-wide land parabolic flute, coated	55.5

Material: Ancorsteel 85HP, 2% Ni, 0.4% graphite; green density, 7.33 g/cm³. Machining: 0.375 in. HSS drill; speed, 3285 rpm; feed, 0.012in./revolution

Presintering the green compact at a lower temperature than the final sintering operation produces a compact of relatively low hardness and strength but with sufficient edge retention to be handled and machined. Thus, the machinability of a presintered compact can be substantially better than that of the sintered part. However, presintering introduces an additional step to the manufacturing process and increases cost. It can be justified where the properties of the as-sintered part make its machining difficult or impossible. For example, high-carbon sinter hardened steels can require grinding rather than machining. In this case, providing that the part application and tolerances permit, it can be desirable to machine the part in the presintered condition rather than perform a grinding operation. Similarly, if part design calls for a through hole normal to the compaction axis, drilling the presintered preform followed by final sintering can be the only way to produce the hole economically in a high performance P/M steel.

Free-machining agents are added to P/M steel to improve machinability (Ref 8, 24). These agents are thought to perform several functions during the cutting process (Ref 9), including initiation of microcracks at the chip/workpiece interface, chip formation, lubrication of the tool/chip interface, and prevention of adhesion between the tool and chips (Fig. 5).

Fig. 5 Potential benefits of a machining agent

Several materials including sulfur, molybdenum disulfide (Ref 24), manganese sulfide (Ref 11), and boron nitride (Ref 25) are used as free-machining agents for P/M steels. They are most frequently introduced as fine powder to powder premixes, but sulfur and manganese sulfide are also available as prealloyed powders (Ref 26, 27, 28).

Sulfur and molybdenum disulfide can have strong effects upon the dimensional change and strength of P/M steels (Fig. 6, 7). Their use should be considered at the part design stage rather than as a "retrofit" when machining problems become apparent. Manganese sulfide has smaller effects upon dimensional change and strength (Ref 13) and can be used to improve the machinability of existing premixes. The effects of several potential machining agents upon the machinability of P/M steels are described below.

Fig. 6 Dimensional change of F-0008 atomized plus free-machining agents

Fig. 7 Transverse rupture strength of F-0008 atomized plus free-machining steels

Sulfides

Sulfides are probably the most frequently used free-machining agents in both wrought and P/M steels. Powder metallurgy offers more flexibility than wrought metallurgy. Sulfur can be prealloyed in the powder during the primary production process or admixed as sulfur or sulfides during the preparation of a press-ready powder premix. Premixing offers more flexibility in the composition and amount of sulfide formed in the final compact. Prealloy produces a somewhat finer dispersion of sulfides within the powder particles.

Sulfur Prealloys. Several powder producers have supplied prealloyed or resulfurized powders, where sulfur is introduced during the primary powder production process. More recently, such powders have become a niche product to meet specific market needs, and admixed manganese sulfide has become a more widely used free-machining agent. It is possible that the powder manufacturing process offers a risk of cross contamination between resulfurized and nonresulfurized grades. Such contamination would introduce undesirable and easily detected sulfide inclusions into other high powder products rendering them unacceptable for high performance applications. Cross contamination can be most easily and efficiently minimized by introducing the sulfur or sulfide as late as possible in the premix stage.

Despite these problems, several powder producers (Ref 26, 27) offer prealloyed or resulfurized sulfur powders. These can offer significant improvements in machinability over nonresulfurized powders, at some loss in compressibility due to the solution-hardening effects of sulfur in iron.

By using a resulfurized powder for an F-0008 composition, Ancorsteel 1000M drill life was increased by about 50% compared to a similar composition with no free-machining additives:

- Ancorsteel 1000M: 128 holes to failure
- Ancorsteel 1000: 83 holes to failure
- Compaction: 6.8 g/cm³
- Sintered: 1121 °C (2050 °F)
- Cutting conditions: 0.125 in. HSS drill, 3000 rpm, 0.003 in./revolution

One result (Table 7) shows that controlling both manganese and sulfur content of the prealloyed powder improves the machinability of iron powder indicated by the time required to drill holes and the number of holes drilled before failure. The use of resulfurized powders can be extended to reduced or sponge iron powders with similar beneficial effects upon drill life (Table 8).

Table 7 Machinability of resulfurized iron powders

Premix	F-0008			FC-0208		
Base powder	MP 36S	MP 37	MP 35	MP 36S	MP 37	MP 35
Time for 25 holes, s	6.2	8.1	14.52	9.3	9.9	17.7
Holes to failure	203	82	25	40	32	21
Manganese, %	0.38	...	0.94	0.38	...	0.94
Sulfur, %	0.38	...	0.236	0.38	...	0.236

Test piece compacted to 6.6 g/cm³. Sintered at 1121 °C (2050 °F). Cutting conditions: 0.25 in. HSS drill, 2300 rpm, 154 pound point loading. Source: Ref 26

Table 8 Effect of 0.5% machining agents on drill life

Condition	Drill life, holes to failure			
	No agent	Sulfur	Manganese sulfide	Molybdenum disulfide
Sponge	19	158	33	285
Atomized	83	418	890	718

Compacted to 6.8 g/cm³ and sintered at 1121 °C (2050 °F)

Admixed Sulfides. Many different sulfides have been evaluated as free-machining additives for P/M steels. The additives most frequently used are manganese sulfide, sulfur, and molybdenum disulfide. Manganese sulfide made as an 0.35 to 0.6% addition to a premix is the most widely used. Additives usually take the form of fine high purity powders less than 50 μ m in particle size as measured by laser particle size analysis (Fig. 8).

Fig. 8 Cumulative particle size distribution of free-machining agents

Effect of Sulfides upon Drill Life. The effect of sulfide free-machining agents upon drill life at an 0.5% addition is compared for three widely used premixes: F-0008, FC-0208, and FN-0205 in the as-sintered condition.

Machinability of F-0008. The machining agents improve drill life, indicated by holes completed before drill failure, when added to F-0008:

- Powder MH 1024: 45 holes to failure
- Powder MH 100: 22 holes to failure
- Compaction: 6.8 g/cm³
- Sintered: 1121 °C (2050 °F)

- Cutting conditions: 0.125 in. HSS drill, 3000 rpm, 0.003 in./revolution

In the mixes made with atomized powder, all the machining additives increase drill life significantly. Manganese sulfide and molybdenum disulfide produce larger increases than sulfur. The improvements are not as large in the materials made with sponge powders where molybdenum disulfide produces the best drill life. Surprisingly, 0.5% manganese sulfide does not perform as well in the sponge test mixes in this sequence of tests.

Although drill life is the chosen indicator of performance, the machining agents produce other changes in cutting performance that could influence production use. During the drill test, it was apparent that different agents changed chip form; for example, molybdenum disulfide produces very small chips that are easily removed from the cutting area.

The machining agents appear to influence heat transfer to and plastic deformation of the workpiece during the test. As the drill accumulates heat during the test, some materials show local plastic deformation around the cutting area. In extreme cases, the cutting forces push material through the unsupported back of the workpiece, especially in mixes with sulfur and least apparent in molybdenum disulfide. Such extreme behavior is unacceptable in production. The changes in hole diameter that precede it are a significant factor in determining tool life.

Machinability of FC-0208. The free-machining additives all improve the machinability of the FC-0208 (Table 9). The 0.5% sulfur addition produces the largest improvement in both atomized and sponge compositions. The drills do not fail before all test material is consumed. Molybdenum disulfide is more effective than manganese sulfide under the chosen test conditions.

Table 9 Effect of 0.5% machining agents on drill life

Condition	Drill life, holes to failure			
	No agent	Sulfur	Manganese sulfide	Molybdenum disulfide
Sponge	2	608+	81	108
Atomized	2	608+	72	249

Compacted to 6.8 g/cm³ and sintered at 1121 °C (2050 °F)

Effect of Sulfides. The drill test results show that the 0.5% sulfide addition improves machinability significantly. However, the addition of sulfides can change sintered properties, particularly dimensional change. The sulfides are not completely inert during the sintering process and can modify the sintering reactions.

Metallography

Free-machining agents have different effects upon the microstructures of the test premixes. These effects depend upon the nature of the base iron (sponge or atomized) and the premix composition (Ref 29) and are illustrated with reference to the F-0008 composition in Fig. 6 and 9. Sulfur appears to promote sintering of the test compositions and produces very round pores. A portion of the sulfur dissolves in the iron matrix and diffuses a short distance into the iron matrix. In sponge iron compositions, a portion of sulfur reacts with iron to form iron sulfides. Sulfur also appears to promote pore rounding during sintering.

Fig. 9 Dimensional change of F-0008 sponge plus free-machining agents

Manganese sulfide (Ref 6) is considered to be stable in both iron-graphite and iron-copper-graphite premixes. Metallography indicates that the manganese sulfide occurs in pores or the fine pores remaining at prior particle boundaries. It appears to be almost inert during the sintering process with little evidence of diffusion into the iron matrix in the compositions examined.

The effects of molybdenum disulfide appear to be between those of sulfur and manganese sulfide and to depend upon the amount added to the test composition. It appears that a significant portion of the molybdenum disulfide reacts with the sintering atmosphere. At low MoS₂ additions, almost all of the addition transforms to molybdenum, which remains within pores and at particle boundaries. Some sulfur evaporates during the sintering process and some dissolves in the iron matrix and can form sulfides on cooling from sintering temperature. At higher sulfur additions, it appears that an equilibrium is reached between the sulfur present as molybdenum disulfide and that in the particles, so that more typical slight pore rounding occurs.

R.J. Causton and T. Cimino, Hoeganaes Corporation

Stability of Sulfides

Sintering. Neither sulfur nor sulfides are completely stable during sintering. Comparison of the sulfur content of the F-0008 premix ingredients to that of the sintered test pieces shows that the sulfur recovery was lower than anticipated (Table 10).

Table 10 Sulfur recovery for sintered F-0008 sponge

Addition, %	Sulfur, %		Manganese sulfide, %		Molybdenum disulfide, %	
	Added	Measured	Added	Measured	Added	Measured
0	0	0.01	0	0.01	0	0.01
0.25	0.25	0.17	0.09	0.11	0.10	0.04
0.50	0.50	0.41	0.18	0.18	0.20	0.12
0.75	0.75	0.60	0.28	0.26	0.30	0.18
1.00	1.00	0.76	0.37	0.35	0.40	0.25

The data show that manganese sulfide is stable under endothermic atmosphere sintering. The measured and predicted sulfur contents of the manganese sulfide mix agree well. As anticipated, a significant portion of the elemental sulfur is lost during sintering. The measured sulfur content in the molybdenum sulfide premix is also less than anticipated confirming the metallographic findings that a portion of the molybdenum disulfide decomposes to release sulfur to the iron matrix and sintering atmosphere. Similar trends were observed in the atomized F-0008 and FC-0208 compositions.

These results indicate that a portion of the sulfur can be released to the sintering atmosphere. It is possible that sulfur in the atmosphere could be absorbed by other compositions present in a production sintering furnace. Given the sensitivity of physical properties to sulfur content, it appears that considerable care should be exercised in furnace loading, atmosphere, and scheduling to avoid the possibility of contaminating a furnace or subsequent premix composition.

Stability during Handling. Manganese sulfide is hygroscopic. Several authors (Ref 29) have stressed that fine manganese powders should be kept in closed containers to prevent moisture absorption and oxidation of the manganese sulfide. If simple precautions are taken (e.g., closing containers and rapidly consuming all material in an open container), the sulfide is stable and provides very consistent results.

Stability during Machining. The potential for reactions between moisture and manganese sulfide can extend to the machining process. The majority of machining tests of P/M parts are conducted in the dry condition without a cutting fluid or lubricant. In contrast, many high volume machining operations employ a water-based cutting fluid for cooling and removing chips from the cutting area. In machining some lower density P/M components on high-speed transfer lines, reactions between water-based cutting fluids and manganese sulfides occur with detrimental results upon the machining operations (Ref 30).

Effects upon Sintered Properties

The experiments indicate that free-machining agents influence sintered microstructure. Thus, they will also influence sintered properties. The effects depend upon the machining agent, premix composition, and the sintering atmosphere. Generally, sulfur and molybdenum disulfide promote growth on sintering. In contrast, manganese sulfide has less effect and could slightly reduce growth. In general, free-machining agents improve the strength of F-0008 compositions but reduce that of FC-0208 significantly.

F-0008 Atomized Iron Powder. The effects of the machining agents upon the properties of F-0008 made with atomized iron powder are illustrated in Fig. 8 and 9. Increasing sulfur and molybdenum disulfide content tend to increase strength and dimensional change from die size. Increasing manganese sulfide addition from 0 to 1% tends to decrease dimensional change and strength slightly. Sulfur and manganese sulfide have almost no effect upon macrohardness at a density of 6.8 g/cm^3 whereas increasing molybdenum disulfide content increases hardness. Both sulfur and molybdenum disulfide promote growth, in contrast, increasing manganese sulfide reduces growth slightly.

The effects of the machining agents upon transverse rupture stress (TRS) are slightly more complex than upon dimensional change. Increasing sulfur contents increases TRS slightly, whereas increasing manganese sulfide contents decreases TRS slightly. Adding molybdenum disulfide initially reduces TRS, but a 1% addition of MoS_2 increases the TRS of the F-0008 test premixes. Both sulfur and manganese sulfide increase the hardness of F-0008 test mix slightly (Table 11). Increasing molybdenum disulfide additions increase the hardness of the F-0008 atomized rapidly.

Table 11 Effects of machining agents on hardness (HRB) of F-0008 atomized powder

Additions, %	Sulfur, %	Manganese sulfide, %	Molybdenum disulfide, %
0	54	53	51
0.25	52	53	52
0.50	56	53	58
0.75	53	53	65
1.00	56	55	66

Compacted to 6.8 g/cm^3 and sintered at 1121°C (2050°F), endothermic atmosphere, 30 min

F-0008 Sponge Iron Powder. When added to F-0008 made with sponge iron, the free-machining agents had similar effects to those observed in the F-0008 composition made with atomized powder. Manganese sulfide was relatively neutral, while both sulfur and molybdenum disulfide increased the growth on sintering of the sponge-based F-0008 significantly. Adding manganese sulfide reduced growth from die slightly, the effect of the first 0.25% addition being most significant (Fig. 11).

Adding 0.25% of sulfur or molybdenum disulfide increases strength significantly (Table 12). Further increases in sulfur content do not change TRS significantly. Increasing molybdenum disulfide content to 1% increases TRS further. Manganese sulfide has no effect upon strength under the conditions tested. Adding the machining agents to F-0008 sponge causes similar changes in hardness to those observed in TRS. The first 0.25% addition of sulfur increases hardness significantly, but hardness increases slowly with further additions (Table 13). Molybdenum disulfide increases hardness significantly, but an

increase beyond 0.5% causes little increase in hardness. The hardness of the F-0008 increases only slightly with manganese sulfide additions.

Table 12 TRS of F-0008 sponge powder plus free-machining agents

Agent addition, %	Transverse, rupture strength, ksi, with addition of:		
	Sulfur	MnS	MoS
0	49.3	51.0	50.5
0.25	64.0	52.9	57.6
0.50	63.6	53.6	68.9
0.75	62.4	51.4	68.2

Compacted to 6.8 g/cm³. Sintered at 1121 °C (2050 °F), endothermic atmosphere, 30 min

FC-0208 Atomized. For the FC-0208 made with atomized powder, all three agents increase growth significantly (Fig. 10). The effect of sulfur is slightly greater than manganese sulfide or molybdenum disulfide. The data indicate that additions above 0.5% cause little further increase in growth. All free-machining agents reduce the strength of the FC-0208 composition significantly (Fig. 11). The effect of manganese sulfide was less than that of sulfur and molybdenum disulfide.

Fig. 10 Dimensional change of FC-0208 atomized plus free-machining agents

Fig. 11 Transverse rupture strength of FC-0208 atomized plus free-machining agents

FC-0208 Sponge. All machining agents increase the growth of the FC-0208 premixes made with sponge powder. They have somewhat less effect on TRS than observed in the FC-0208 premixes made with atomized powder (Table 14).

Table 14 Effect of machining agents on dimensional change of FC-0208 sponge

Additive, %	Dimensional change, %		
	Sulfur	Manganese sulfide	Molybdenum disulfide
0	+0.27	+0.31	+0.31
0.25	+0.55	+0.35	+0.54
0.50	+0.50	+0.36	+0.44
0.75	+0.55	+0.38	+0.44
1.00	+0.56	+0.38	+0.41

Compaction of 1% zinc stearate to 6.1 g/cm³. Sintering at 1121 °C (2050 °F) endothermic atmosphere, 30 min

Sulfur additions cause the greatest increase in growth; molybdenum disulfide has a somewhat smaller effect, and manganese sulfide has the least effect. A 0.25% addition of sulfur or molybdenum disulfide causes a significant increase in growth that does not increase with further additions. The growth of FC-0208 sponge tends to increase slowly with increasing manganese sulfide content.

The effects of the free-machining agents upon the TRS of the FC-0208 sponge are relatively small (Table 15). Transverse rupture strength tends to increase slightly with increasing molybdenum disulfide. It decreases slightly with increasing sulfur content. Increasing manganese sulfide causes the most significant decrease in TRS at additions above 0.5%.

Table 15 Effect of machining agents on TRS of FC-0208 sponge

Transverse rupture strength, ksi

83.0	84.3	82.0
80.1	78.6	82.5
78.1	80.5	86.0

80.3	75.9	83.0
79.9	73.8	86.0

Compaction of 1% zinc stearate to 6.1 g/cm³. Sintering at 1121 °C (2050 °F) endothermic atmosphere, 30 min

Nonsulfide Machining Agents. In wrought metallurgy, several other free-machining agents, such as lead and selenium, are employed. The P/M industry has made little use of these, possibly due to potential toxicity problems. Powder producers and parts makers (Ref 31, 32, 33) are taking advantage of the premixing operation to introduce free-machining agents that are incompatible with the processing of wrought steels. These agents are nonmetallic solids that are anticipated to assist in chip formation and lubrication of the chip cutting tool interface to reduce wear mechanisms. Unlike sulfide machining agents, these products are proprietary to specific producers and patent protected.

Enstatite is a soft mineral that shears easily under stresses but is relatively stable at sintering temperatures. K. Hayashi et al. (Ref 31) describe the use of enstatite in combination with manganese sulfide to enhance the machinability of sintered P/M steels.

Boron Nitride. Hexagonal boron nitride is a recognized solid lubricant with microstructure and frictional properties similar to those of graphite. The use of boron nitride as a free-machining agent in sintered P/M steels has been patented (Ref 32). Published data show that the addition of small quantities of boron nitride to sintered steels enhances machinability significantly in F-0008 and FC-0208 compositions (Table 16).

Table 16 Drill life holes to failure

Material	ATOMET 29	ATOMET 29M

Compaction to 6.7 g/cm³. Sinter at 1120 °C (2048 °F), 90% Ni/10% H atmosphere. Machining by 6.35 mm HSS drill, 4250 rpm. Source: Ref 32

Graphite/Sulfur. Graphite is widely used as a solid lubricant in the production of porous sintered bearings. However, its use in structural P/M parts is largely confined to that of an alloying agent intended to dissolve during sintering. Prealloyed sulfur has the ability to inhibit graphite solution so that some free graphite remains in the sintered microstructure without adversely reducing mechanical properties. Table 17 illustrates how this combination of prealloyed sulfur and graphite can produce a significant improvement in the machinability of sintered P/M steels (Ref 33).

Table 17 Effect of sulfur modification upon drill life for iron-2% copper

Graphite addition, %	Standard	Sulfur modified
0.8	<30	>600
1.0	<30	>600
1.2	<30	350

Compaction to 6.85 g/cm³. Sinter at 1130 °C (2066 °F), nitrogen atmosphere. Machining in 1 mm HSS drill, speed 10,000 rpm, feed 0.012 mm/rev. Source: Ref 33

MnX is a proprietary free-machining agent. Employed alone and in combination with manganese sulfide, it improves the machinability indicated by drill life of a wide range of P/M steels sintered in both endothermic and nitrogen hydrogen atmosphere (Ref 21, 34).

Atomized FC-0208. For FC-0208 made with atomized powder, a 0.50 wt% manganese sulfide addition produced best drill life when sintered in endothermic atmosphere (Table 18). However, when sintered in 75% H_2 /25% N_2 , 0.50 wt% MnX produces best performance. Earlier research (Ref 28) shows that 0.5 wt% additions of manganese sulfide can reduce strength and increase growth from die size. If this is unacceptable, then a 0.35 or 0.5 wt% addition of MnX increases drill life significantly. For FC-0208 premixes made with sponge powder, the combination of manganese sulfide and MnX produces longest drill life under both sintering atmospheres. The effects of the machining additives upon drill life are somewhat greater in H_2/N_2 atmospheres than endothermic.

Table 18 Drill life for FC-0208

Iron	Atmosphere	Composition MnS (MnX), wt%						
		0	0 (0.35)	0 (0.50)	0.10 (0.25)	0.15 (0.35)	0.35 (0)	0.50 (0)

	H_2/N_2	4	30	270	100	584	122	48

FN-0205. Drill testing shows that the machining agents improve the machinability of FN-0205 significantly (Table 19). All free-machining agents increase the machinability of the FN-0205 test pieces under the conditions employed. The combination of manganese sulfide plus MnX produces longer drill life than either additive alone for both iron bases and both sintering atmospheres. In premixes made with atomized iron powder, it is possible that an 0.35 wt% total addition of the machining agents produces best results. For test premixes made with Ancor MH100, a 0.50 wt% total addition of MnS plus MnX produces the best tool life. These levels of machining agent have relatively minor effect upon the sintered properties of FN-0205.

Table 19 Drill life for FN-0205

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

Tool Materials

Both part and powder producers have made significant progress in developing higher strength P/M steels to compete with fully dense wrought steels and heat treated cast irons. The combinations of strength and ductility make these alloys more difficult to machine in the as-sintered condition requiring higher performance tool materials. However, tests show that these free-machining additives alone do not always improve machinability of higher strength materials, as seen in Table 20 for Ancorsteel 85HP. A series of cutting tests were conducted (Ref 21) to assess whether changes to tool material, tool geometry, or coating could improve cutting performance in this alloy. The drill test used the same conditions as previous tests; however, this test examined higher performance cobalt high-speed steels, the effects of titanium nitride coatings, and different tool geometries, such as parabolic flutes or "split points."

Table 20 Drill life for Ancorsteel 85HP: 2% Ni, 0.5% graphite

Iron	Composition MnS (MnX), wt%					
	0	0 (0.35)	0 (0.50)	0.10 (0.25)	0.15 (0.35)	0.35 (0) 0.50 (0)
Holes to Failure	1	1	2	2	3	4 2

Compaction to 7.0 g/cm³. Sintering at 1121 °C (2050 °F), 75% H/25% Ni. Machining in 0.125 in. drill, 3000 rpm, 0.0006 in./revolution

The results indicate that when combined, improvements to tool material, coating, and drill design improve drill life (Table 21). Individual improvements to high-speed steel, flute form, or coating had relatively little effect upon drill life under the test conditions employed. However, when combined, drill life increases significantly from an initial two holes for the standard drill to 85 holes for the optimum drill.

Table 21 Effect of drill type upon drill life when cutting Ancorsteel 85HP: 2% Ni, 0.5% graphite

Steel type	Coating	Flute form	Point	Drill life
Base HSS	None	Standard	135 °	2
M42	None	Standard	135°	2
Base HSS	TiN	Standard	135°	1
HSS	None	Parabolic	135°	1
Cobalt HSS	None	Parabolic	135°	3
M7HSS	TiN	Parabolic	135°	44
Cobalt HSS	TiN	. . .	Split	85

Compaction to 7.0 g/cm³. Sinter at 1121 °C (2050 °F), 75% hydrogen/25% nitrogen. Machining at 0.125 in. drill, 3000 rpm, 0.006 in./revolution feed

Attempts to improve drill life further by using solid carbide drills have been unsuccessful. The solid carbide drills appear to be too brittle for the test conditions and drilling system employed. The test results did show clearly that drilling of very high-

strength P/M steels can be improved using similar improvements in tool materials and design to those used for high-strength wrought steels.

Machinability of P/M Steels

R.J. Causton and T. Cimino, Hoeganaes Corporation

Microstructure Modification

Wrought steels are frequently heat treated by producers to obtain optimal machinability. Annealing or normalizing treatments are used to produce a relatively coarse pearlitic or spheroidal microstructure that possesses good machinability. Higher carbon steels require longer heat treatment cycles intended to produce coarse carbides dispersed in ferrite. In contrast, low-carbon steels can be partially hardened to produce a microstructure that is less ductile and adhesive than fully annealed steels. Research has shown that reducing cooling rates from sintering can improve the machinability of FC-0208; however, the coarser microstructure reduces mechanical properties (Ref 35). A significant improvement in machinability indicated by drill motor load is only obtained at lower strength levels (Table 22).

Table 22 Comparison of mechanical properties and motor load

Cooling rate	Yield strength, ksi	Ultimate tensile strength, ksi	Hardness, HRB	Motor load, hp
8.75	36.7	36.7	48.9	4.39
16.7	50.5	50.5	57.2	4.55
39.8	58.3	58.3	73.0	4.76

Sintered density, 6.8 g/cm³

A similar result is obtained in improving the machinability of a 0.85%Mo-2%Ni-0.5% graphite by tempering and annealing. The annealing treatments do not produce the anticipated improved machinability. The 0.85% molybdenum steel also proves to be very temper resistant (Table 23). It is noteworthy that the annealing treatment at 871 °C (1600 °F) changes the failure mode of the high-speed steel drill. The drill appears to adhere to the workpiece and snap rather than overheat.

Table 23 Ancorsteel 85 HP: 2 wt% Ni, 0.5 wt% graphite

Treatment	Temperature, °C (°F)	Time, h	Cool	Holes to failure	Hardness, HRB
Temper	149 (300)	1	Natural	4	78
	302 (575)	1	Natural	8	71
	454 (850)	1	Natural	14	82
	621 (1125)	1	Natural	6	74
Anneal	871 (1600)	1	Furnace	7	57
As-sintered		3	73

The experiment indicates that the heat treatments employed did not change the microstructure and machinability of P/M steels sufficiently. The results do not justify the extra process step. Further study is necessary to define the optimal microstructure and heat treatment for machinability. It is possible that increasing tempering temperatures to 648 to 732 °C (1200 to 1350 °F) for subcritical annealing or controlled transformation annealing after sintering can improve machinability further. Because such treatments add an extra process step, they are justified only where parts require extensive machining prior to heat treatment.

Machining of Powder Metallurgy Materials

Sigurd Berg, Höganäs AB; Håkan Thoors, Swedish Institute for Metals Research; Bertil Steen, Swedish Institute for Production Engineering Research

Introduction

POWDER METALLURGY is a near-net shape process capable of producing complex parts with little or no need for secondary operations, such as machining, joining, or assembly. However, the inability to produce certain geometrical figures (e.g., transverse holes, undercuts, and threads) frequently necessitates some machining, particularly drilling. Because of the growing use of P/M materials to increase productivity and reduce costs, the study of the machinability of these materials has become increasingly important, especially because powder metals are generally considered to have poor machinability in comparison with wrought or cast metals (Ref 1). In addition, there is a trend toward the design of complex P/M parts that call for machining, in contrast to the past practice to minimize machining (Ref 2).

The machinability of P/M components is dependent upon a number of factors, including workpiece and tool material properties, cutting conditions, machine and cutting tool parameters. Some P/M material and production process parameters (such as particle size, part geometry, porosity, and compaction and sintering methods) also influence machinability. In general terms, however, machining of P/M materials can be optimized or improved by:

- Taking advantage of the good machining properties of high-density parts (above 92% of theoretical density)
- Machining in the presintered condition
- Using additives that do not require sacrifices in powder processing or part properties
- Following the suggestions of published guidelines for material and machining methods
- Running machinability tests on P/M materials

These factors are briefly discussed in this article, along with more detailed discussions of the machining guidelines that improve the machinability of sintered steels. Additives and microstructural factors that enhance machining are discussed in more detail in the article "Machinability of Powder Metallurgy Steels" in this Volume.

Machining of Powder Metallurgy Materials

Sigurd Berg, Höganäs AB; Håkan Thoors, Swedish Institute for Metals Research; Bertil Steen, Swedish Institute for Production Engineering Research

General Guidelines

Representative machining methods are turning, milling, drilling, tapping, and grinding. The basic guideline is to start with cutting conditions for wrought and cast parts and tailor them for the application. The recommendation applies in particular to lower density parts. High-density parts (>92% of theoretical density) machine like wrought metals.

Smearing of self-lubricating porous parts can be a problem. Recommended practice involves the use of sharp tools and light cuts in single-point machining, such as turning or boring.

Coolants are preferred in most machining operations. Coolant pickup can be a problem. The rate of pickup is directly related to the amount of porosity. Ideally, all machining except grinding should precede deburring. Retained deburring abrasive can cause excessive tool wear. Ceramic and cubic boron nitride (CBN) inserts are usually run dry; performance is typically better than or at least equal to that obtained with coolants.

Material Selection. Powder metallurgy carbon steels are selected primarily for parts with moderate strength and hardness, combined with machinability. Iron-copper and copper steel materials are produced from admixtures of elemental iron powder and elemental copper powder with or without graphite powder (carbon). When secondary machining is required, combined carbon contents of less than 0.5% should be specified. Copper-infiltrated iron and steel materials offer improved machinability because of reductions in interrupted cuts, and machined parts have a smooth surface finish. Among stainless steels, SS-303 is preferred when parts require extensive secondary machining. Brass, bronze, and nickel silver parts usually have good machinability.

Additives. Free-machining benefits can be obtained by means of small additions to a standard powder composition. Additives for ferrous powders include lead, sulfur, copper, or graphite; for nonferrous powders, lead is used. The advantages of changing composition in this manner can be at least partially offset by side effects. Additions can cause problems, such as dimensional changes of parts during sintering and deterioration in the properties of parts.

Prealloyed manganese sulfide powders appear to avoid those shortcomings in ferrous alloys. Manganese content is intentionally high to ensure that all sulfur is present in the form of manganese sulfide inclusions. When these inclusions are extensively deformed in the shear plane and in the flow zone adjacent to the tool surface, they contribute to higher cutting speeds, longer tool life, good surface finish on parts, and lower tool forces. In addition, chips are more readily handled than those produced by conventional P/M materials. Oil or resin impregnation of porous P/M parts also improves machinability (see the article "Resin Impregnation of Powder Metallurgy Parts" in this Volume).

Design. Certain types of holes, undercuts, and threads are examples of features that cannot be accommodated by the P/M consolidation (pressing) process and therefore require machining. Holes in the direction of pressing, produced with core rods that extend up through the tools, are readily incorporated in parts, but side holes (those not parallel to the direction of pressing) cannot be made in the same way and are generally produced by secondary machining.

Undercuts on the horizontal plane (perpendicular to the die centerline) cannot be produced if they prevent the part from ejecting from the die (Fig. 1). Annular grooves around a part are produced by machining or by making the part in an assembly of two pieces. Likewise, a part with a reverse taper (larger on bottom than on top) cannot be ejected from a die. Because threads in holes and on outside diameters prevent a part from being ejected from a die, they cannot be made with conventional P/M methods; machining is required.

Fig. 1 P/M part design considerations. (a) Undercuts on horizontal plane cannot be produced in P/M process. Machining is required to obtain such features in parts. (b) Example of undercut in flange that is beyond capability of P/M process. (c) Alternative to part in (b) that can be made without secondary machining

Machining of Powder Metallurgy Materials

Sigurd Berg, Höganäs AB; Håkan Thoores, Swedish Institute for Metals Research; Bertil Steen, Swedish Institute for Production Engineering Research

Machining Guidelines

The machining process is very complex, and tool performance is affected by the properties and condition of the workpiece and the cutting condition. For P/M materials, porosity is a major factor that reduces machinability. The cutting tool configuration (in terms of chip breaker profile, stability, and geometry of tool holder, insert style, etc.) also influences the wear processes that determine tool life.

In order to select the right tool and machining parameters, knowledge of the loads on the tool and the properties of the tool material together with an analysis of the wear mechanisms is necessary. The loads associated with the wear process (Ref 3) can be divided into four main groups:

- Mechanical load
- Thermal load
- Chemical load
- Abrasive load

To define cutting parameters, the loads on the tool must be controlled based on the active wear mechanisms. Typically, the loads on the edge of a cutting tool are different at different locations. Consequently, different wear mechanisms are activated and proceed at different rates at the various locations. The processes that influence tool life can be plotted schematically on a wear mechanism map (Fig. 2), which delineates the area's wear and "safe zones" for good tool performance.

Fig. 2 Pressure/feed rate versus cutting speed in a wear mechanism map

The following sections describe machining conditions for common operations (e.g., turning, drilling, tapping, grinding, and milling). In addition, examples are given for machinability evaluations on the turning, drilling, and tapping of various sintered steels. These examples illustrate the influence of chemical composition, tool material, tool geometry, free machining additives, feed rate, cutting velocity, cutting conditions, and surface integrity while forming the basis of guidelines for the machining of sintered steels. Effects from microstructure, carbon content, density, machinability enhancing additives, etc. are examined. Guidelines for optimum machining parameters in turning, drilling, and tapping are stipulated for a wide spectrum of P/M steel conditions based on these examples.

Turning

Usually, parts with an average hardness of HRB 52 have machining properties similar to those of cast iron. At this hardness level, parts should be held rigid, and weak sections should be supported to prevent distortion. Compressed air is used to cool the tool and maintain swarf clearances. Jets are directed onto tool cutting edges and work surfaces. Liquid coolants cannot be used because parts must be kept dry and clean for subsequent sintering. Carbide tips of ISO designation K10 with a hardness of 92.6 HRA give good results and will accept some interruptions on the cutting surface.

Tools must be held rigid, and cutting edges must be sharp with rake angles of up to 3° positive on top and side and frontal clearances of 3 to 5°. Surface speeds of 105 to 120 m/min (350 to 400 sfm) and feeds of 0.050 to 0.10 mm/rev (0.002 to 0.004 in./rev) are satisfactory for form turning, but surface speeds can be increased to 180 to 210 m/min (600 to 700 sfm) in single-point turning. Feeds can be increased within the boundaries of economic tool life, the standard of accuracy, and surface finish requirements.

In machining fully sintered parts (average hardness, 90 HRB), K10 carbide tips give a satisfactory life with 0° top rake, 7° frontal clearance, and 5° side clearance. Single-point finish turning is used, with a stock removal of 0.125 to 0.20 mm (0.005 to 0.008 in.) of surface depth and 0.050 mm (0.002 in.) of feed per revolution. Surface speeds are 120 to 135 m/min (400 to 450 sfm), and tips require a radius of 0.20 to 0.25 mm (0.008 to 0.010 in.). Form turning is not advisable because of the work-hardening characteristics of the material in this state.

Abrasive flank wear is the dominating wear mechanism in turning. PVD-TiN coating of the hard metal (HM) inserts reduces the wear rate; CVD coatings (TiN, Al₂O₃) improves the performance even further. Oil impregnation improves the machinability in general, while cutting fluid is detrimental to the machinability.

The results for the following example show that the axial force is the dominating cutting force component after ~ 0.1 mm flank wear. The micro surface roughness (within the feed marks) is improved by increased density, and addition of MnS improves the macro surface integrity. Tool life is nearly independent on the feed rate in a range of 0.05 to 0.2 mm/rev. Alloy elements in general decrease the machinability. Correlation to hardness is not enough to explain the different machining performance of P/M material. Micro smearing from "soft" phases due to inhomogeneous microstructure is one explanation for P/M materials performance in relation to conventional steel. MnS addition for intermittent cutting has a strong effect on the machinability.

Example 1: Machinability Evaluation, Turning of Sintered Steel.

Turning tests for a number of P/M materials were performed in a CNC turning lathe. The workpiece geometry was a thick-walled tube with an inner diameter of 35 mm, an outer diameter of 64 mm, and a height of 62 mm. To study intermittent turning a synchronizing hub was used. All turning was performed as a facing operation. The materials were sintered at 1120 °C for 20 min. For materials where carbon is added, an endothermic atmosphere is used, while dissociated ammonia is used for the other materials. The solid wrought reference material was OVAKO 234S (DIN 16MnCr5) 0.5% C (HV \sim 220) with the same workpiece geometry.

Initially, evaluation of tool material and cutting conditions was performed. Based on these results, a PVD-coated hard metal insert (ISO code CNMG120408-MF) was selected as standard. The depth of the cut was fixed to 0.5 mm. The force measurements were carried out using a Kistler three component piezo electric table and a digital oscilloscope (Kistler Instrument Group, Amherst, NY).

For P/M materials, the main tool wear mechanism during continuous turning is abrasive flank wear. A notch at the depth of cut that can limit the tool life is sometimes formed. The feed force and axial force are also more sensitive to changes in cutting data, wear, and the material type than the main cutting force. When the feed is increased, P/M materials show a smaller increase in these forces than the reference wrought material.

Measurements of the three cutting forces at different wear levels reveal that the axial force is the dominating force after ~ 0.15 mm flank wear. The investigations indicate that the wear rate accelerates after 0.1 to 0.15 mm flank wear dependent on grade. The correlation between wear rate and axial force is significant. Key results are summarized below.

Surface Integrity. The surface roughness of the machined surfaces in Example 1 were evaluated in terms of R_a and R_z using a laser measuring station. The R_a value is the arithmetic average of all deviations of the roughness curve from the center line. The R_z value, mean roughness depth, is the mean of the maximum peak-valley distances in five successive lengths, L_c , of the roughness profile.

The density influence on R_a is shown in Fig. 3. Increased density will increase the macro R_a value while the micro R_a value is reduced. Looking at R_z it seems as if the value is constant in this density range.

Fig. 3 Density influence on surface integrity for ASC100.29 2% Cu, 0.5% C; density variation; second edge wear,

0.2 mm

Addition of carbon to atomized iron powder with diffusion bonded nickel (4%), copper (1.5%), and molybdenum (0.5%) improves R_a . In the range 0.25 to 0.8% C the micro surface roughness seems to be the same. Addition of MnS free machining additives reduces the macroscopic roughness R_a (Fig. 4). The reduction is even more pronounced when using R_z as a measure of the macroscopic surface.

Fig. 4 Influence of carbon on the surface integrity for Distaloy AE carbon and MnS addition; second edge wear, 0.2 mm

Influence of Feed Rate. For conventional steel, the feed rate has a strong influence on the tool wear, and different wear mechanisms will be critical at different feeds. For P/M material there seems to be no change in the wear mechanism, and the tool life seems to be independent of the feed rate in a certain range. The tool grade and type of coating material determine the maximum feed rate.

For Distaloy AE 0.5% C, the maximum feed rate seems to be in the range of 0.2 mm/rev when using a PVD-TiN coated tool. By switching to a CVD multicoated (TiN , Al_2O_3) tool, the feed rate can be increased to 0.3 mm/rev (Fig. 5). For ASC100.29 2% Cu, 0.5% C, the maximum feed rate seems to be 0.2 mm/rev with a PVD-TiN or CVD- Al_2O_3 coated tool. In general CVD coating improves the performance in tool life by at least 30% compared to a PVD-TiN coated tool. The geometry of the tool has a large influence on the performance. Among the most important factors is a small tool edge radius, which decreases the axial force and prolongs the tool life.

Fig. 5 Influence of feed rate and type of coating on tool life for Distaloy AE 0.5% C and ASC100.29 2% Cu, 0.5%

Influence of Carbon Content. Carbon is the most common alloying element in ferrous powder metallurgy. The strengthening effect is due to the increased amount of pearlite in the microstructure. Above 0.8% precipitation of cementite at the grain boundaries will decrease the strength, which influences the machinability strongly as seen in Fig. 6.

Fig. 6 Influence on carbon addition on tool life of Distaloy AE. Tool material: CNMG 120408, GC 1025. Cutting conditions: feed = 0.1 mm/rev; depth of cut = 0.5 mm; criteria, $V_b = 0.3$ mm; dry

For atomized iron powder with addition of 2% Cu, there is a clear difference between 0% C and 0.25% C. Smearing of workpiece material on the tool edge is believed to be the explanation for this. The surface for this grade is also considered to be rough, both in the macro and micro range, compared to 0.25% C addition. This effect decreases with cutting speed.

Influence of Cutting Fluid. The use of cutting fluid is common when machining conventional steel. The pores present in the microstructure of the P/M materials in combination with water from the cutting fluid can cause oxidation, which is detrimental to the mechanical properties. Oil impregnation is one alternative to enhance the machinability. In our turning studies, oil impregnation has a pronounced positive effect on P/M machinability, while the use of cutting fluid is detrimental.

The main reason for the observed deterioration of tool performance with cutting fluid can be traced back to the severe thermomechanical load cycle associated with the test mode. Introduction of cutting fluid can lead to the following:

- Severe fluctuation in the tool temperature due to the better heat transfer characteristics of the water-based cutting fluid leading to severe thermal cycling
- Probable reaction between rest products from the coolant and the atmosphere during the interruption period of the machining cycle

The inability of these effects to increase the tool wear when turning conventional steel with cutting fluid indicates that both the maximum tool temperature as well as the temperature difference within a machining cycle is higher when turning P/M materials. In Table 1 the flank wear (mm) after 40 and 90 passes is presented.

Table 1 Influence of liquid coolant and oil impregnation on flank wear

Material	Composition	Flank wear, mm					
		Oil impregnated		Cutting fluid		Dry	
		40 passes	90 passes	40 passes	90 passes	40 passes	90 passes
Distaloy AE	0.5% C	0.046	0.098	0.1335	0.739	0.075	0.321
ASC100.29	2% Cu, 0.5% C	0.034	0.04425	0.1215	0.39725	0.04375	0.055

Intermittent Cutting. Initial tests to select the right tool for intermittent cutting revealed that a tougher tool material was needed than for continuous turning. The tool used for continuous cutting was subjected to chipping of the tool edge. The chipping was also reduced by the use of sharper tool geometry when machining P/M parts.

Addition of free machining additives such as MnS gave a clear improvement. The effect was emphasized at increasing cutting speed (Table 2). For conventional steel, it is a common experience that the chip becomes thinner and the forces decrease as the cutting speed is raised. This drop in forces is caused by a decrease in contact area and in shear strength due to higher temperature. This seems also to be the case for P/M material. But it is still not clear if the effect arises from improvement in chip breaking or by reduction of the shear force.

Table 2 Tool life for turning synchronizing hubs

Material	Composition	Tool life, min
Distaloy AE	0.5% C	3.36
	0.5% C, 0.5% MnS	31.62
Distaloy HP-1	0.5% C	2.79
ASC100.29	. . .	5.54
ASC100.29	2% Cu, 0.5% C	26.23

Cubic Boron Nitride (CBN) Tools. In cases where the preservation of surface porosity is vital, CBN inserts are used, especially with low-porosity materials. When CBN tools are used, surface speeds can be increased from 600 to 1000 m/min (2000 to 3280 sfm) using the same rake and clearances as those for K10 tools. These tools will also accept some degree of interruption on the cutting surface. With K10, a coolant is necessary to keep the tool cool and to maintain swarf clearance. With CBN, the procedure used depends on the workpiece material.

Cutting speeds with CBN tools can vary widely from 250 to 2000 m/min (820 to 6500 sfm). Feed rates range from 0.050 to 0.075 mm/rev (0.002 to 0.003 in./rev) with depths of cut from 0.13 to 0.40 mm (0.005 to 0.015 in.) for steels with hardnesses in the range of 50 to 400 HB; usually, it is preferable to decrease the cutting speed to below 1000 m/min (3280 sfm) when the hardness is above 250 HB. These conditions are suitable for hot-pressed or cold-pressed ceramic tools. In cases in which uncoated carbide tools are used, cutting speeds should be less than 190 m/min (625 sfm) for machining most ferrous or nonferrous alloys.

Drilling

In drilling, speeds and feeds are 80 to 85% of those for wrought metals of the same composition. For long tool life, nitrided steel, high-speed steels containing cobalt, and carbide-tipped drills are recommended.

Low helix angle drills are not recommended for softer P/M materials because of their poor chip ejection characteristics. Drills with 40° helix angles had twice the tool life of those with 30° helix angles in work performed with soft P/M materials.

Large amounts of coolant are required in drilling medium- or low-density materials; coolant should operate effectively at the drilling point to reduce abrasive wear due to powder particles at the bottom of the hole. A single-nozzle coolant system does not work properly because small or powdered chips do not easily exit through the drill flutes. A ring design system, however, is effective in eliminating the chip-clogging problem. Oil hole drills are the most effective means for removing chips from the cutting zone.

Cutting speeds of up to 25 m/min (80 sfm) and feed rates up to 0.25 mm/rev (0.010 in./rev) are recommended for high-speed steel drills. Cutting speed and feed rate could be as high as 120 m/min (390 sfm) and 0.5 mm/rev (0.02 in./rev), respectively, when solid-carbide or carbide-tipped drills are used. Carbide indexable drills are efficient because margins are eliminated. Abrasive margin wear and the welding of powder chips are also eliminated.

Holes in planes beyond the capability of the P/M process are best made by drilling when parts are in the presintered (partially sintered) state. In this state, drilling properties are similar to those of cast iron. If it is necessary to qualify the position and size of holes after final sintering, a carbide reamer or carbide-tipped reamer should be used. Roller burnishing can be used to meet accuracy and surface finish requirements. Any size change in the operation is related to the preburnished surface finish and the size of the hole. A change of 0.019 to 0.025 mm (0.00075 to 0.001 in.) in diameter is representative for a hole about 25 mm (1 in.) in diameter.

A number of studies have been performed to determine ways of enhancing drill life during P/M machining (Ref 4, 5, 6, 7, 8, 9, and 10). The following example is another. As shown in the following example, drill length is considered as a primary factor for improvements. Additives have strong influence on machinability for high performance materials. Tool life is nearly independent on the feed rate, which ranges from 0.05 to 0.16 mm/rev. Cutting fluid has no significant effect on the productivity. Distribution decreases for coated drills and for short drills.

Example 2: Machinability Evaluation, Drilling of Sintered Steel.

Blind hole drilling test was performed on a wide spectrum of P/M qualities. Cylindrical blanks with a diameter of 80 mm and a height of 10 mm are used in the test. A survey test is performed in order to select the type of drill and cutting conditions. The main comparisons were made under dry condition using a HSS drill with a diameter of 4 mm and a point angle of 118°. Total breakdown of the drill is chosen as criterion, based on the fact that drilling is commonly used as a bulk removal operation. All materials are investigated in order to divide them into four groups. The classification criterion used is the time required to drill 100 holes. Influence of cutting fluid, density, alloying contents, feed rate, and drill type are evaluated for the selected group representatives.

All the tests were carried out in a numeric controlled machining center. Early in the testing procedure, the heat generated in the workpiece during the drilling cycle was recognized to have an effect on the result, and therefore, the time between inserts was increased and temperature measurements were carried out on the workpiece. Key results are noted below.

Tool Life. Evaluation for atomized iron with diffusion bonded nickel (4%), copper (1.5%), and molybdenum (0.5%), addition of 0.8% C regarding influence of length, type of drill, and coating of the drill is shown in Fig. 7. The length of the drill has a large influence on the performance. Evaluation of centered drilling shows improvements in distribution and in performance. It is believed that the first inlet is crucial for the performance. This has its origin from the inhomogeneous microstructure of P/M material.

Fig. 7 Influence of feed rate, tool material, coating, and additives on machinability

Tool material and coating have a strong influence. Geometry changes exist among the three types of drills. Regarding feed rate, the performance is comparable with the result from the turning test presented for HM PVD-TiN tool, which ranges from 0.12 to 0.16 mm/rev. For Distaloy AE 0.5% C using HSS drill, the same tool life exists up to feed rate 0.16 mm/rev. This behavior is unique for P/M material.

Effect of Carbon Contents. Addition of carbon above 0.25% C for atomized iron powder or addition of 2% Cu will decrease the machinability. Micro smearing on the tool is believed to be the reason for the large decrease in machinability (Fig. 8).

Fig. 8 Influence of carbon contents on machinability of ASC100.29 2% Cu. Drill, HSS; point angle, 118° ; feed rate, 0.06 mm/rev; $D = 4$ mm; criteria, total failure

Density, Cutting Fluid, and Additives. Influence from density is regarded as small in the range of 6.7 to 7.3 g/cm³. Result from productivity evaluation of atomized iron powder with 2% Cu and 0.5% C at 100 holes reveals 5% decrease for the range. Use of cutting fluid has no significant effect on the productivity. Water as cutting fluid decreases the productivity. For high performance materials, additives have large influence on the machinability.

Tapping

Conventional tap drill charts should be followed to maintain 65 to 75% depth of thread. Two-flute taps are recommended for diameters up to 8 mm ($\frac{5}{16}$ in.). Three-flute taps should be used for diameters of 8 to 12.5 mm ($\frac{5}{16}$ to $\frac{1}{2}$ in.). Spiral-point taps are desirable because they throw the chip out instead of driving it into the pores of the workpiece. Some experimenting in tapping P/M parts may be required to determine which tap is best for a specific metal. As shown in the following example, chip clamping can degrade the performance, but it is improved by the use of cutting fluid. Evaluation of tapping with the use of cutting fluid for the first three holes and after tapping 50 holes is presented in Fig. 9. Tapping under dry condition reveals problems with chip clamping. Cutting fluid improves the performance. Carbon addition decreases the performance and additives like MnS decrease the torque. The distribution during the measuring length still indicates problems with chip clamping. Selection of tap geometry is considered to solve the problem.

Fig. 9 Influence of carbon/MnS addition for the moment during tapping. M5 straight flute tap with 7.2 mm tap length. Bottom hole was used in the initial investigation.

Other Cutting Methods

Milling. Slot and side milling cutters are often used for machining P/M materials. Speeds of 70 to 100 m/min (230 to 330 sfm), feed rates of 0.005 to 0.1 mm (0.0002 to 0.004 in.) per tooth, and depths of cut of 0.13 to 0.4 mm (0.005 to 0.015 in.) are recommended in machining ferrous and nonferrous alloys with uncoated carbides. Higher speeds and feeds should be used in machining aluminum. Aluminum P/M alloys have better chip characteristics than their wrought counterparts. Chips are much smaller and are broken more easily, with little or no stringer buildup.

In face milling with uncoated carbides, cutting speeds of 90 to 120 m/min (295 to 395 sfm), feed rates of 0.05 to 0.15 mm (0.002 to 0.006 in.) per tooth, and depths of cut of 0.12 to 0.4 mm (0.005 to 0.015 in.) are recommended for carbon and alloy steels and stainless steels; however, nonferrous materials can be cut at speeds up to 170 m/min (560 sfm) and feed rates as high as 0.1 mm (0.004 in.) per tooth.

Speeds of 25 to 50 m/min (80 to 165 sfm) are used in machining P/M iron, steel, stainless steel, copper, and brass with high-speed end mills. On the other hand, cutting speeds in the range of 100 to 200 m/min (330 to 655 sfm) are recommended in

machining soft iron, steels, and aluminum with carbide tools. With harder steels, stainless steels, copper, and brass, speeds should be lowered to the range of 60 to 100 m/min (195 to 330 sfm).

Reaming. To control bore accuracy in P/M parts, reaming is sometimes used instead of pin sizing, ball sizing, or burnishing. Standard reamers are satisfactory; left-hand spiral reamers have also proved successful. The cutting edges should have the best possible finish to minimize edge buildup, which results in oversize holes. If the surface finish of the hole is not a factor, the drill should leave a reaming allowance, the amount depending on hole size. Guidelines can be used:

Hole diameter		Allowance	
mm	in.	mm	in.
≤ 6.5	≤ 0.25	0.050	0.002
6.5-12.5	0.25-0.50	0.050-0.10	0.002-0.004
12.5-25	0.50-1.0	0.10-0.15	0.004-0.006

If the surface finish is critical, reaming allowances should be doubled. When possible, reamers should be used in floating holders and run at 7.5 to 15 m/min (25 to 50 sfm). Recommended feeds are:

Hole diameter		Feed	
mm	in.	mm/rev	in./rev
≤ 6.5	≤ 0.25	0.15	0.006
8-12.5	0.30-0.50	0.18	0.007
14-19	0.55-0.75	0.25	0.01

Finishing

Burnishing. When the clearance between a shaft and a P/M bearing is ± 0.012 mm (± 0.0005 in.) or less, burnishing the bearing bores after they have been installed in the housing is preferred for correcting the bore size. No more than 0.002 mm/mm (0.002 in./in.) of diameter should be displaced, and the smallest amount of displacement that will produce the true diameter is desirable. The type of burnishing tool recommended for this operation is illustrated in Fig. 10.

Fig. 10 Ball broach for burnishing bores in P/M parts. Dimensions given in inches

Given a finished bore diameter of 38 mm, +0.005 mm/-0.0000 mm (1.500 in., +0.0002 in./-0.0000 in.) (B in Fig. 10), the diameter of the starting end of the burnishing tool then becomes 38.10 mm, -0.050 mm (1.5000 in., -0.0020 in.), or 38.05 mm (1.4980 in.), and bearings would be bored to 38.075 mm, +0.0125 mm/-0.0000 mm (1.4990 in., +0.0005/-0.0000 in.). Thus, there would be a minimum clearance of 0.025 mm (0.001 in.) at the entering end of the tool, and the first land would be a line-to-line fit. The tool then becomes progressively larger, and the bearing is expanded. If there were no springback, the operation would be stopped at the fourth or fifth tool land. However, the bearing would ordinarily be burnished to 0.010 mm (0.0004 in.) oversize to allow for springback.

Roller burnishing is a cold-working operation that compresses metal rather than removes it. The technique is suitable for sintered (not heat-treated) powder metal materials for which maintenance of open surface porosity is not critical. A significant improvement in surface finish can be obtained using a roller burnishing tool. In addition, the tool is adjustable to match individual product specifications as well as to compensate for wear on the rolls and mandrel. Both through holes and blind holes can be roller burnished. Hole size tolerance depends on the input tolerance of the hole; that is, a prepared tolerance of 0.050 mm (0.002 in.) can be reduced to 0.025 mm (0.001 in.), or a ± 0.0025 mm (± 0.0001 in.) tolerance can be held if the input tolerance is 0.010 mm (0.0004 in.). Surface finishes of 0.25 μm (10 $\mu\text{in.}$) are common after roller burnishing. A lightweight, low-viscosity lubricating oil is recommended for most P/M materials.

Honing and Lapping. Holes requiring extreme accuracy can be honed or lapped by normal techniques if retention of porosity is not required. However, size control of holes in P/M parts can usually be obtained more economically by reaming or burnishing.

High-density ferrous metal parts, especially when hardened, have been successfully honed and lapped using conventional procedures.

Diamond- and CBN-plated bore finishing tools are recommended for precise hole size control. These tools can be used on standard drilling or honing machines, as well as on multiple-spindle or numerically controlled machines. The use of an adjustable sleeve attached to a mating tapered mandrel increases tool life. The selection of diamond grit size determines the metal removal rate and the surface achieved. The amount of material to be removed from the hole diameter can be determined by: $\text{surface finish (start)} - \text{surface finish (after honing)} / 100,000 = \text{required stock removal}$. If the existing finish is 1.25 μm (50 $\mu\text{in.}$) and the desired finish is 0.25 μm (10 $\mu\text{in.}$), then 0.010 mm (0.0004 in.) should be removed from the hole diameter.

Honing of infiltrated parts is seldom practical, because the stones become loaded. Neither lapping nor honing is recommended for porous parts, because either of these processes will cause the pores to become filled with abrasive particles. For special applications that require the use of lapping or honing, ultrasonic or solvent cleaning should be performed following grinding.

Grinding

Grinding of P/M parts can be very complex, especially when materials are low in density because in many cases preservation of surface integrity is essential. Usually, surface porosity decreases during grinding. A large amount of the generated powder chips is forced into pores, and many chips are welded due to the high temperature at the wheel/workpiece interface. When grinding is necessary to achieve dimensional functionality of a part, and surface porosity needs to be preserved, special processes such as ultrasonic or solvent cleaning are applied immediately after grinding. For rough applications, a downfeed of 0.025 to 0.075 mm (0.0010 to 0.003 in.) is recommended, while for finish passes, a maximum of 0.013 mm (0.0005 in.) should be used.

Stock removal rates should be either the same as or less than those used in finish turning of cast iron; wheels should be similar. It is important to keep a plentiful supply of coolant (containing an inhibitor) directed onto the wheel and the work to maintain a clean grinding wheel contact.

Grinding of P/M Tool Steels. The relative grindability of several conventional and P/M high-speed tool steels is illustrated in Fig. 11. The grinding ratio (volume of metal removal to the volume of wheel worn, as explained in the article "Principles of Grinding" in *Machining*, Volume 16, *ASM Handbook*) is clearly superior for the P/M tool steels. As expected, the grinding ratios generally decrease for both the conventional and the P/M tool steels as their alloy and carbon contents increase. The grinding conditions suggested for the CPM tool steels are similar to those recommended for conventional tool steels in the article "Machining of Tool Steels" in *Machining*, Volume 16, *ASM Handbook*. Some specific conditions for grinding CPM 10V are given in Table 3.

Table 3 Grinding recommendations for CPM 10V cold-work tool steel

Toolroom grinding (sharpening)^(a) <ul style="list-style-type: none">• Abrasive: very sharp 38A or 32A• Grit sizes: 60 to 120 depending on removal and finish requirements• Grade: Grade I most effective, but grades as soft as G can work• Bond: Vitrified• Wheel example: Norton 32A60-I8VBE
Wet surface grinding^(a) <ul style="list-style-type: none">• Grit sizes: 100-150• Wheel example: CBN (Borazon) CB 120TBA
Internal grinding^(a) <ul style="list-style-type: none">• Grit sizes: 100-150• Wheel example: CBN (Borazon) CB 150WBA
Field reports concerning abrasives <ul style="list-style-type: none">• Cubic boron nitride (Borazon) grinders must be rigid, in good condition, and able to mount wheels with

very good accuracy.

- Crystolon (silicon carbide) such as 39C60-I8VK are recommended.
- Use very sharp, very friable aluminum abrasive that remains sharp during grinding, such as 38A.
- Wet grinding recommended.

Note: Grinding wheel symbols and nomenclature are defined in the article "Grinding Equipment and Processes," *Machining*, Volume 16, *ASM Handbook*.

Tool Steels

Rapid solidification of the atomized powders used in the production of wrought P/M tool steels eliminates the segregation present in conventional tool steels and produces a very fine microstructure with a very uniform distribution of small carbides and nonmetallic inclusions. As a result, wrought P/M high-speed tool steels exhibit better machinability, dimensional control, and safety in heat treatment, grindability, and edge toughness during cutting than conventional high-speed tool steels of the same composition. A variety of Anti-segregation process (ASP) and P/M tool steels are available.

As with conventional tool steels, P/M tool steels are generally machined in two stages: rough machining of the workpiece with the steel in the annealed condition, followed by finish machining (typically grinding) after heat treatment when the steel is in the hardened-and-tempered condition. Table 4 lists the typical cutting conditions for P/M and conventional AISI high-speed steels of similar composition.

Table 4 Typical machining conditions for P/M and conventional grades of AISI high-speed tool steels

Operation	Tool width or depth of cut		High-speed tooling				Carbide tooling			
			Speed		Feed		Speed		Feed	
	mm	in.	m/min	sfm	mm/rev	in./rev	m/min	sfm	mm/rev	in./rev
Single-point turning	3.8	0.150	18	60	0.38	0.015	91	300	0.38	0.015
	0.64	0.025	23	75	0.18	0.007	111	365	0.18	0.007
Drilling	6.4	$\frac{1}{4}$	12	40	0.08	0.003
	13	$\frac{1}{2}$	12	40	0.13	0.005
	25	1	12	40	0.23	0.009
	50	2	12	40	0.33	0.013
	3	10	0.05	0.002
Broaching	3	10	0.05	0.002
Face milling	3.2	0.125	20	65	0.20	0.008	78	255	0.30	0.012
	0.64	0.025	26	85	0.15	0.006	101	330	0.25	0.010
Cutoff	1.6	0.062	14	45	0.03	0.001	53	175	0.05	0.002
	3.2	0.125	14	45	0.03	0.001	53	175	0.08	0.003
	6.4	0.250	14	45	0.04	0.0015	53	175	0.11	0.0045

An important advantage of the P/M process relates to the fact that the machinability and grindability of P/M tool steels can be improved by increasing their sulfur content to much higher than conventional levels without sacrificing toughness or cutting performance (see the article "Particle Metallurgy Tool Steels" in this Volume).

Resin Impregnation of Powder Metal Parts

Charles M. Muisener, Research, Development & Engineering Group, Loctite Corporation

Introduction

RESIN IMPREGNATION is a process that eliminates or reduces internal porosity of castings and P/M parts by saturating internal voids with liquid resins. The process has been practiced for many years on castings and P/M parts, and resin impregnation has, to a large extent, eliminated macroporosity (pore diameter $>125\ \mu\text{m}$) in castings. With further process improvements and low-viscosity resins capable of good penetration, impregnation is also capable of significantly reducing microporosity (pore diameter $<125\ \mu\text{m}$) (Fig. 1).

Fig. 1 Microstructure of P/M iron with impregnated resin in microporosity. 200×

The most common purpose of resin impregnation is to produce leak-tight parts. However, impregnation also:

- Enhances corrosion resistance
- Prepares porous surfaces for subsequent surface treatments or coatings
- Improves machinability

Depending on the product and application, sealant penetration can be minimal or deep, with interconnected porosity reduced up to 90%. When the application is preparation for surface finishing or plating of the part, penetration is usually minimal. It is much deeper for parts that need pressure retention and are machinable, including rugged hydraulic components for industrial pumps. Depth of penetration is controlled by the process time and exposure during impregnation, resin type, and the structure of the internal porosity.

Resin Impregnation of Powder Metal Parts

Charles M. Muisener, Research, Development & Engineering Group, Loctite Corporation

Impregnation Technologies

The earliest method of impregnation involved lowering heated components into a bath of phenolic resin. This method has been effective in eliminating macroporosity in castings, but it has been abandoned with the development of vacuum or pressurized methods for the impregnation of micropores. Several different resin materials also have been used, including a variety of organic polymers such as phenolics and methacrylates and also inorganic materials such as aqueous sodium silicate. Four common types of impregnation resins are:

- Sodium silicate (also known as waterglass)

- Polyester resins
- Low-viscosity heat-curable resins
- Low-viscosity anaerobic resins

Of these, anaerobic resins are the most widely used for P/M parts, as described in the section "Impregnation Resins."

Impregnation Methods. The four common methods of resin impregnation are:

- Wet vacuum
- Wet-vacuum pressure
- Dry-vacuum pressure
- Pressure injection

In all methods, a cleaning pretreatment is essential for good penetration because contaminants in the porosity impede impregnation. Vapor degreasers are used, but costs and environmental considerations are factors. Aqueous-based washing systems can be used with either oven or vacuum drying. The use of vacuum drying with its short cycle times and the cooling of the components enables direct integration with impregnation systems.

Wet vacuum is the fastest impregnation method, offering simplicity and rapid processing along with lower equipment costs. More than 95% of powder metal impregnation employs the wet-vacuum method.

The wet-vacuum process involves submerging parts in a tank of resin contained in a vacuum chamber. The vacuum cycle removes air from the tank and the pores within the part (Fig. 2a). Then the chamber is first returned to ambient pressure to allow resin to force into the pores (Fig. 2b).

Fig. 2 Wet-vacuum impregnation. (a) Application of vacuum removes gas from internal pores. (b) Atmospheric air

pressure assists penetration of resin into pores.

Vacuums between 1 and 5 mbar held for 5 to 10 min can effectively extract air from the internal porosity. Often the components are held above the resin (or in a different vessel in other methods). High vacuum within the porosity improves the penetration of the resin and reduces exudation, caused by unextracted air expanding within the part during the curing phase. Exposing resins to vacuum at the same time degases and removes contaminants from the resin.

Penetration is a function of the resin properties, the structure of the porosity, and time. Using modern materials, even large dense parts can be fully impregnated during a cycle time of 10 to 15 min.

Impregnation is followed by rinsing for removal of surplus resin on the surface. Rinsing can also be followed by immersion of the part in a catalytic activator solution to cure the resin at the surface of each porosity. This creates a hardened plug at the outer portion of the pore, thereby trapping the remaining resin for anaerobic self-cure. Finally, the part is rinsed again to remove any activator from the surface. The total cycle time is approximately 20 min.

Wet-vacuum pressure is similar to the wet-vacuum method in that parts are submerged in sealant and a vacuum is applied to parts and sealant together (Fig. 3a). The difference is that resin penetration is assisted by pressurized air after release of the vacuum (Fig. 3b). Use of pressure improves penetration at the cost of adding air compressors to the system.

Fig. 3 Wet-vacuum-pressure impregnation. (a) Vacuum removes gas from pores. (b) Pressurized air increases the penetration rate of resin into internal pores.

Dry-vacuum pressure is the slowest and most complicated vacuum impregnation method. It is traditionally used with high-viscosity sealants and high-density powdered metals. The impregnation cycle typically requires two tanks (Fig. 4), one to hold the sealant the other to process parts. Occasionally, a single tank with two separate process levels is employed. This application is sometimes specified with sealants where part porosity is very small and sealing requirements unusually

stringent. This would apply to air-conditioner compressor components and some hydraulic pump parts. The process stages are:

- Draw vacuum in process tanks to remove air from pores
- Transfer sealant from storage tank to process tank and submerge parts
- Release vacuum and pressure process tank with compressed air pressure
- Remove parts, wash, and cure

Fig. 4 Dry-vacuum-pressure impregnation

In pressure injection the part is fixtured to seal passageways to internal cavities (Fig. 5a). Then it is pressurized with a sealant that flows through the porosity network until emerging on the exterior (Fig. 5b). This treatment is applied on automotive engine cylinder liners and other components in which pressure retention of fluids and gases is required.

Fig. 5 Pressure injection impregnation. (a) Part is fixtured to direct resin flow through the part. (b) Pressurized sealant flows through porosity network.

Impregnation resins are mainly combinations of high-boiling-point methacrylate monomers formulated to meet the physical and chemical property demands of the impregnation process. The materials are low-viscosity fluids, which are cured within the porosity to form a polymer solid. The solid is achieved by formulating the monomer blend so that the resulting polymer has a cross-linked structure that is inherently inert and resistant to temperature, pressure, and process fluids.

The properties of the polymer are controlled by the blend of monomers used and the inclusion of minor ingredients such as corrosion inhibitor and antioxidants. Key monomer properties are:

- Low vapor pressure for vacuum methods
- Low viscosity for penetration (7 to 10 cP)
- Low surface tension for wetting and adhesion

Important properties of the polymer after curing are:

- Temperature resistance
- Chemical resistance
- Shrinkage on polymerization

- Adhesive strength
- Tensile strength
- Hardness

Temperature and chemical resistance are key factors. Typically, the temperature ranges of modern organic impregnation sealants are -55 to 200 °C (-65 to 400 °F). Pressure retention upper limits are governed by component designs. Many wP/M components used in hydraulic applications are subject to constant conditions of more than 65 MPa (10,000 psi) with elevated operating temperatures.

Low shrinkage is required for good sealing performance in single impregnation, while good adhesive strength between sealant and metal contribute to performance under conditions such as temperature cycling and physical flexing.

As previously noted, there are four types of materials used in P/M impregnation. Sodium silicate is rarely employed, polyester resin uses toxic elements, and heat-cure resins are complex and difficult to handle. The most common resins are anaerobic sealants.

Sodium Silicate. Also known as waterglass, this inorganic material was the first widely used impregnation sealant. Although still found in some applications, particularly where extremely high temperatures are encountered, waterglass has been largely abandoned for most porosity-sealing procedures. Problems include slow processing, difficult cleanup of parts, and lengthened solidification of sealant, allowing parts to leak long after impregnation. Because of these difficulties, sodium silicate often requires multiple impregnation cycles.

Polyester Resin (Styrene). In use since the 1940s, this organic material provides reliable sealing, has good chemical resistance, and can operate well at temperatures up to 200 °C (400 °F). However, substantial disadvantages related to costs, productivity, and environmental health and safety, along with waste disposal issues, have virtually disqualified these resins from most industrial facilities.

Heat-Cure (Elevated-Temperature-Cure) Resins. This modern approach to porosity sealing uses various forms of organic methacrylate or polyester resins cured at temperatures below the boiling point of water. Sealants in this category generally are lower in viscosity than other styrene resins and often are applied with much simpler impregnation equipment. Basically, hot-water curing at 90 °C (195 °F) satisfies the requirements of manufacturers who need porosity sealing more effective than spray sealing without the maintenance requirements of an anaerobic system.

All heat cure systems require a sealant catalyst to render the sealant reactive. These additives typically are hazardous and must be measured and mixed with care in order to achieve desired curing. Many heat-cured materials also require a strong detergent solution for satisfactory washing of excess sealant from parts. Some bleedout of sealant almost always occurs as parts heat up and the impregnation material expands during cure, with a resultant reduction in sealing integrity and possible fouling of surfaces.

Also, an operator must be present to ensure that parts remain in the heated water long enough to reach proper temperature to completely cure the sealant. Failure to do so can result in parts leaving the sealing operation with inadequate curing. If this occurs the polymer will not fully cross link, and sealant performance is affected adversely.

Self-Curing Anaerobics. Anaerobic impregnation has consistently proven to be the most effective porosity sealing system. These organic materials self-cure at room temperature, eliminating the need for a hot-water treatment. This precludes sealant bleedout, fouling of surfaces, rework of parts, and the need for operators at cure stations. A highly cross-linked product, it will not liquefy and weep out of porosity. Many manufacturers rely on the superior sealing capability and consistent performance of anaerobics to ensure that all parts reaching the assembly line are leak free, with no testing before or after impregnation.

When impregnated into a part, the anaerobic no longer has a source of stabilizing air and, thus deprived of its oxygen supply, begins to solidify chemically. Prior to that, polymerization is prevented by light aeration at constant temperatures in the sealant storage vessel.

Contact with metal promotes curing, as does application of heat and chemical activators, but none of these are essential to the process. They regulate the speed of cure by controlling the rate of reaction, allowing the sealant system to be tuned for optimal results in each application. A unique activator rinse gives anaerobics much greater versatility in sealing a wide range of pore sizes, especially larger ones.

Anaerobic impregnation is generally recommended for volume manufacturing where the highest-quality control standards are required for sealing parts. The unique, self-curing capability of anaerobic sealants, along with the ability to regulate the rate of cure, has made this material the overwhelming choice for impregnating P/M parts. There are several anaerobic impregnation techniques such as wet vacuum, wet vacuum/ pressure, dry vacuum, pressure injection, and spray sealing.

Resin Impregnation of Powder Metal Parts

Charles M. Muisener, Research, Development & Engineering Group, Loctite Corporation

Performance

Plastic impregnation generally has little or no effect on tensile strength and ductility, and often resin sealants for impregnated parts have very similar physical properties. Therefore, sealants are often considered roughly equivalent in terms of component strength and machinability.

However, there are important performance differences that have arisen with further developments and evaluation. For example, developments in improved sealing performance have coincided with adhesive strength improvement from 1 to 50 N/cm² (Ref 1). Tests of the radial crushing strengths for unimpregnated and impregnated components using different impregnants also show changes in both strength and ductility (Table 1, Fig. 6). Resin 1 has a 10% improvement in yield strength, while resin 2 shows improved ductility. The resin that improves the strength has good adhesive properties, whereas the resin improving ductility forms the harder polymer. The harder polymer is more brittle, yet the components impregnated with resin 1 exhibit more pronounced brittle failure (Ref 1).

Table 1 Radial crushing strength (K) comparison

Sample	Maximum load,N	Strength (K), MPa	Extension to maximum load, mm	Minimum deformation, mm
Unimpregnated	6504	258	0.382	0.432
Resin 1	7178	285	0.376	0.414
Resin 2	6768	269	0.352	0.472

Fig. 6 Radial crushing strength of impregnated and unimpregnated P/M part. Source: Ref 1

Corrosion Resistance. Corrosion and surface blemishes are a chronic problem in P/M parts. Pits, blisters, stains, and other imperfections break out because corrosives and industrial solvents are absorbed into pores. Even after surfaces have been treated with protective coatings and platings, the effects of internal corrosion may not appear until well after other such treatments as tumbling, spraying, painting, polishing, cleaning, and anodizing have been completed (Fig. 7).

Fig. 7 Surface condition of P/M part after plating

Without a protective thermoset plastic impregnant, corrosive solvents soak into pores, eventually seeping upward and damaging the most hardened and lustrous surfaces. The fluids involved in P/M applications are numerous, including:

- Ethylene glycol
- Water
- Lubrication oil
- Jet fuels
- Carbon removal compounds
- Motor oils
- Hydrocarbon fluids
- Hydraulic fluids
- Machining fluids
- Acids
- Gasoline
- Alkaline cleaners

Machining Benefits. One of the more remarkable developments is the demonstrable improvements in machinability with impregnated metal parts versus those that remain untreated. The precise reason for this result is unclear, but the consensus points to a natural lubricity present in thermoset plastic resins used in most P/M impregnation processes. These cured polymers minimize tool chatter or vibration, heat buildup, and the interrupted cut associated with the machining of P/M parts. They also reduce chip thickness and adhesion, improve surface finishes, help achieve consistent finish dimensions, and improve dimensional control of parts.

By filling voids in the porous metal, the impregnating material promotes better chip formation and separation by the cutting tool. The plastic fill cushions the tool as it passes through metal, giving the tool edge an uninterrupted feel, thus extending its service life through a reduction in cutting force.

Many manufacturers impregnate parts solely to derive machining benefits. For example, a major equipment manufacturer verified benefits from impregnating parts with thermoset resins including higher-quality electroplating, pressure-tight sealing of hydraulic and pneumatic parts, and major improvements and cost savings in machinability. Tool life doubled in tapping and turning operations and tripled on parts with high hardness. Overall, perishable tooling costs dropped about 50% and, in some cases, the company is machining almost ten times as many pieces per tool.

Drilling is the most common machining operation used on P/M parts, and several studies (Ref 2, 3, 4, 5, and 6) confirm lower drilling forces and longer tool life with impregnated parts. Some deterioration in surface roughness occurs (Ref 6), presumably due to melting of the impregnated resin. Nonetheless, several research programs definitively support resin impregnation as a method to significantly improve machinability. In one major program, exhaustive tests performed on various P/M alloys found that resins reduced drilling forces up to 75% in some cases (Fig. 8, 9, 10, and 11).

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Introduction

QUALITY CONTROL involves several basic principles, where the planning of a quality control program requires an understanding of process variables and the reality of statistical variation in any process or measurement. Therefore, this article attempts to first summarize the basic concepts of statistical process control as a tool to measure, quantify, and analyze inherent variations. This understanding is considered essential in present-day industrial manufacturing.

In addition, the unique aspects of quality control planning in P/M parts production are also discussed in this article. Quality control for P/M parts production involves several process factors such as powder properties, press settings, tooling designs, and furnace conditions. These factors are discussed in terms of their impact on process variations and quality improvement. This article also discusses the methods that address P/M quality control in terms of:

- Defect control by prevention or detection
- Dimensional control for form and fit requirements

Defect and dimensional control are two major quality measures for P/M production, and each has a unique set of attributes for inspection and quality assessments.

Finally, it should also be noted that quality control also depends on an effective work environment that facilitates involvement and communication. This basic factor is often exemplified by the 14 Points for Management by W. Edward Deming, the eminent statistician who championed the role of statistical process control for industrial application. His 14 Points are:

- Create constancy of purpose for the improvement of product or service.
- Adopt the new philosophy of process control and variation reduction.
- Cease dependence on mass inspection for quality control.
- End the practice of awarding business on the basis of price.
- Improve constantly and forever the system of production and service in order to improve quality and productivity and thus continuously decrease costs.
- Institute thorough and better job-related trainings.
- Institutionalize leaderships.
- Drive out fears, so that everyone may work effectively for the company.
- Break down barriers between departments.
- Eliminate slogans, exhortations, and targets for the workforce that ask for zero defects and new levels of productivity.
- Eliminate work standards on the factory floor.
- Remove the barriers that rob employees at all levels in the company of their right to pride of workmanship.
- Institute a vigorous program of education and self-improvement.
- Put everybody in the organization to work to accomplish the transformation.

The 14 Points define essential institutional elements of quality and productivity improvement through statistical thinking and methods. It should also be noted that in the spirit of his 14 Points, Deming refines and improves these tenets.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Statistical Process Control Concepts

Statistical process control (SPC) is simply a method for monitoring the statistical variations of a process, where the objective is to control or reduce variations between upper and lower process limits. Control charts (Fig. 1) are used to monitor the statistical variations, but this is just one part of the overall SPC method. For the techniques of SPC (specifically Shewhart control charts such as the schematic in Fig. 1) to be successfully employed as an off-line problem identification and problem-solving tool, it is essential to keep in mind that it is a three-step process, as follows:

1. Use statistical signals to find improvement opportunities through the identification of process faults.
2. Use experience, technical expertise, and fault diagnosis methods to find the root cause of the fault that has been identified.
3. Develop an action plan to correct the fault in a manner that will enable any gains that are realized to be held.

This three-step process can be explained by using the classical feedback control system perspective, as shown in Fig. 2. There are five distinct stages in the generic control loop (Fig. 2), which facilitate the three-step process in the following way:

1. Use of statistical signals (observation and evaluation)
2. Fault diagnosis (diagnosis)
3. Action plan (decision and implementation)

Fig. 1 Impact of having process initially in a state of statistical control versus improvement resulting from a breakthrough in performance

Fig. 2 Classical feedback control system view of SPC implementation

However, bringing a process into a state of statistical control does not necessarily mean that a fundamental improvement has been achieved. Clearly, a bad situation has been rectified by bringing the process into control, and quality and productivity are enhanced. However, bringing a process into control simply means that the process is back to where it should have been to begin with. At this point, it is then possible to begin to assess the present ability of the process to realize the potential it was initially intended to have. It may be failing to realize this potential because the implementation of the process is flawed or because the design of the process itself is flawed. In either case, the root cause(s) of the chronic common cause problem must be identified and removed at the system level. This constitutes a breakthrough in performance; that is, an improvement in the process has taken place. The results of the essential steps leading to such a breakthrough are shown in Fig. 1.

This article focuses primarily on the key statistical concepts and definitions that are essential for appreciation of the SPC methods. There are several important concepts that should be understood, including the requirements of rational sampling and the definition of measurements by attributes (or defects). Once these basic definitions are established, the next step in the three-step process is an appreciation of the root cause or fault diagnosis for variations in P/M processing. The factors related to fault diagnosis for P/M quality control and planning are discussed in the section "P/M Process Planning" in this article.

Shewhart Control Chart

A succession of parts emanating from a process under statistical control will exhibit variability in their measurements because of a constant set of common causes. These variable measurements tend to collect into a predictable pattern of variation that can be easily described by a few simple statistical measures, namely, a mean (μ), a standard deviation (σ), and a frequency distribution (normal distribution, Poisson distribution, etc.). These measures stand as a model that predicts statistical behavior if the process is subject only to a constant set of common causes.

Many years ago, Dr. Walter Shewhart showed how data from a manufacturing process could be developed and interpreted through the use of very simple but useful statistical methods. Given a sufficient number of samples, the output of any process operating solely under a set of common causes can be shown to exhibit a normal distribution. Therefore, when taking a series of samples from a process that is in control, one may expect the observed values to fall within ± 3 standard deviations of the process mean in 997 out of 1000 cases. By combining this logic with a simple system of charting measurement data versus time, an operator may easily identify the occurrences of special causes. If a point appears outside the 3 standard deviation limits, it is very likely that a special cause has had some effect on the process.

The charts generated by this system are known as Shewhart control charts. Each control chart actually consists of two charts for each characteristic being tracked. Figure 3 shows an example set of control charts. Each point on the charts represents a group of parts, called a sample subgroup, or just "sample" for short. Samples typically consists of three to six parts, though all samples for a given chart are the same size. The upper chart, called the \bar{X} (X-bar) chart, shows the history of the process mean. The lower chart, called the range chart, or R chart for short, shows the history of variation within a sample. By using the \bar{X} and R charts, significant shifts in both the process mean and spread can be detected as an indication of a process out of control.

(a)

(b)

Fig. 3 Control charts for diameter measurements of a part. (a) \bar{X} -chart. (b) R -chart. Data are for $k = 20$, $n = 5$.

The lines marked UCL and LCL represent the upper and lower control limits, respectively. These control limits are based on the mean value of the variable being charted ± 3 standard deviations. In addition, the standard deviation used for calculating the control limits is based on variation *within* sample subgroups and not on variation within the entire population of parts sampled. Because each point appearing on an \bar{X} chart is really the mean of several individual measurements, it would be improper to compare it to the 3σ limits for the entire population. For this reason, it is essential that an R accompany the \bar{X} chart, so the R values for each sample subgroup can be compared. Once statistics of \bar{X} and R are assembled for a number of sample subgroups, then charts for $\bar{\bar{X}}$ and $\bar{\bar{R}}$ can also be assembled, where $\bar{\bar{X}}$ is the average of \bar{X} from several sample groups, and $\bar{\bar{R}}$ is the average range.

When calculating initial control limits, a large group of samples, consisting of at least 25 sample subgroups, is measured and the means and control limits calculated. If any points fall outside the control limits for the R chart, and they can be attributed to some special cause, then these points are eliminated from the chart and the control limits for both charts are recalculated. Next, this process is repeated with the \bar{X} chart. Once the effects of all known special causes have been eliminated, the resulting control limits are considered to be the standard for future samples. Thus, the means and control limits are not recalculated with the addition of each new sample to the control charts. However, if the process experiences some improvement that causes a sustained shift on either the \bar{X} or R chart, then the control limits should be recalculated based on the newer data.

In addition to the test for points appearing outside the control limits, there are a number of other items that can be applied to determine if a process is exhibiting normal random variation. Two common additional tests are the run test and the trend test. If there are eight or more consecutive points on one side of the mean for either chart, it is considered a run. If a run is detected, it is likely that there has been a shift in the process mean or variability (Ref 1). If six or more consecutive points exhibit a continuing upward or downward trend on either chart, it is considered a trend. If a trend is detected, it is likely that the process is drifting (Ref 2).

Calculations for Setting Up \bar{X} and R Control Charts. Once the statistical basis for Shewhart control charts has been established, the first step in setting up \bar{X} and R control charts is the selection of the samples. As previously noted, it is important that all samples be rational samples so that variation is attributable only to one constant system of common cause. Sampling from different machines, sampling over extended periods of time, and sampling from product combined from several sources are all nonrational sampling methods and must be avoided. Rational samples are discussed in more detail later in this section.

As a rule of thumb, 25 to 50 samples should be selected to provide a solid basis for the initiation of the control charts. This helps to ensure more precise estimation of the process mean and standard deviation. The sample/subgroup size should be relatively small (between $n = 3$ and $n = 6$).

With k rational samples of n each, the following steps can be used as a guide when constructing \bar{X} , R control charts with 3σ limits (the appropriate values for d_2 , A_2 , D_3 , and D_4 in these calculations are obtained from Table 1):

1. Calculate the sample mean and sample range for each sample using $\bar{X} = \sum X/n$ and $R = X_{\max} - X_{\min}$
2. Calculate the grand mean of the n sample means and the average range using $\bar{\bar{X}} = \sum \bar{X}/k$ and $\bar{\bar{R}} = \sum R/k$
3. Calculate the control limits for the R -chart. Although the true distribution of sample ranges is not normal and not symmetric, the symmetric limits are conventionally used for the R -charts. With assumed normal distribution for the individual measurements, the following formulas can be used for the calculation of the control limits: $UCL_R = D_4 \bar{\bar{R}}$ and $LCL_R = D_3 \bar{\bar{R}}$
4. Calculate the control limits for the \bar{X} -chart. Although the required standard deviation (the standard deviation of the sample mean, \bar{X}) for setting the limits is $\sigma_{\bar{X}}$, this value is conveniently estimated by $\bar{\bar{R}}/(d_2 \sqrt{n})$, where d_2 is a function of n . For $3\sigma_{\bar{X}}$ limits, one uses a factor called A_2 , which is equal to $3/(d_2 \sqrt{n})$ and can be found in Table 1. Thus, the control limits are calculated by: $UCL_{\bar{X}} = \bar{\bar{X}} + A_2 \bar{\bar{R}}$ and

$$LCL_X = \bar{\bar{X}} - A_2 \bar{R}$$

Table 1 Factors for \bar{X} and R control chart limits

Comparison of Tolerances and Control Limits. It is important to clearly differentiate between specification limits and control limits. The specification limits or tolerances of a part are:

- Characteristic of the part/item in question
- Based on functional considerations
- Related to/compared with an individual part measurement
- Used to establish the conformability of a part

The control limits on a control chart are:

- Characteristic of the process in question
- Based on process variability
- Dependent on sampling parameters, namely, sample size
- Used to identify presence/absence of special cause variation in the process

Control limits and tolerances must never be compared numerically and should not appear together on the same graph. Tolerances are limits on individual measurements and as such can be compared against the process as a whole as represented by many individual measurements collected in the form of a statistical distribution.

Process Capability Indices (C_p and C_{pk}). Once a process is in statistical control, it is common to measure process capability in units of standard deviation for the process. There are actually two measures, C_p and C_{pk} , both called the process

capability index. The first measure, C_p , is based on the relationship between the upper and lower specification limits and the standard deviation process as follows:

$$C_p = \frac{USL_X - LSL_X}{6\sigma_X}$$

The minimum acceptable value for C_p is considered to be one.

However, because it is possible to achieve a C_p of greater than 1.0 while still producing a significant proportion of parts that do not meet specification limits, a revised version of the process capability index C_{pk} , has been widely adopted. This index, sometimes called the "actual process capability index," imposes a penalty for deviation of the process mean from the nominal value of the specification. The minimum value considered acceptable for C_{pk} is usually 1.33, although some industries are now beginning to demand 2.0 or better.

The C_{pk} index is defined as the difference between the process mean and its closest specification limit, divided by 3σ . To calculate this index, first the relationship between the process mean \bar{X} and the specification limits in the units of standard deviations is determined:

$$Z_{USL} = \frac{USL - \bar{X}}{\sigma_X}$$

$$Z_{LSL} = \frac{LSL - \bar{X}}{\sigma_X}$$

Then the minimum of these two values is selected:

$$Z_{min} = \min[Z_{USL}, -Z_{LSL}]$$

The C_{pk} index is then defined by dividing this minimum value by 3:

$$C_{pk} = \frac{Z_{min}}{3}$$

Commonly, C_{pk} must be ≥ 1.33 , but higher limits are also specified.

For example, Fig. 4 shows a process capability study of the overall length of a fully processed bevel gear (as heat-treated). The C_p of 1.75 shows that the inherent process variation is less than the maximum acceptable range for the product. The C_{pk} of 1.71 demonstrates that the process is properly targeted to produce an adequately centered finished product dimensional distribution.

Fig. 4 Process capability for a heat treated bevel gear

Rational Sampling

Perhaps the most crucial issue to the successful use of the Shewhart control chart concept is the definition and collection of the samples or subgroups. This section discusses the concept of rational sampling, sample size, sampling frequency, and sample collection methods and reviews some classic misapplications of rational sampling.

Rational subgroups or samples are collections of individual measurements whose variation is attributable only to one unique constant system of common causes. In the development and continuing use of control charts, subgroups or samples should be chosen in a way that provides the maximum opportunity for the measurements within each subgroup to be alike and the maximum chance for the subgroups to differ from one another if special causes arise between subgroups.

Sample Size and Sampling Frequency Considerations. The size of the rational sample is governed by the following considerations:

- Subgroups should be subject to common cause variation. The sample size should be small to minimize the chance of mixing data within one sample from a controlled process and one that is out of control. This generally means that consecutive sample selection should be used rather than distributing the sample selection over a period of time. There are, however, certain situations where distributed sampling may be preferred.
- Subgroups should ensure the presence of a normal distribution for the sample means. In general, the larger the sample size, the better the \bar{X} distribution is represented by the normal curve. In practice, sample sizes of three or more ensure a good approximation to normality.
- Subgroups should ensure good sensitivity to the detection of assignable causes. The larger the sample size, the more likely that a shift of a given magnitude will be detected.

When the above factors are taken into consideration, a sample/subgroup size of three to six is likely to emerge. Five is the most commonly used number because of the relative ease of further computation.

Sampling Frequency. The question of how frequently samples should be collected is one that requires careful thought. In many applications of \bar{X} and R control charts, samples are selected too infrequently to be of much use in identifying and solving problems. Some considerations in sample frequency determination are the following:

- If the process under study has not been charted before and appears to exhibit somewhat erratic behavior, samples should be taken quite frequently to increase the opportunity to quickly identify improvement opportunities. As the process exhibits less and less erratic behavior, the sample interval can be lengthened.
- It is important to identify and consider the frequency with which occurrences are taking place in the process. This might include, for example, ambient condition fluctuations, raw material changes, and process adjustments such as tool changes or wheel dressings. If the opportunity for special causes to occur over a 15-min period is good, sampling twice a shift is likely to be of little value.
- Although it is dangerous to overemphasize the cost of sampling in the short term, clearly it cannot be neglected.

Common Pitfalls in Subgroup Selection. In many situations, it is inviting to combine the output of several parallel and assumed-to-be-identical machines into a single sample to be used in maintaining a single control chart for the process. Two variations of this approach can be particularly troublesome: stratification and mixing.

Stratification of the Sample. Here each machine contributes equally to the composition of the sample. For example, one measurement each from four parallel machines yields a sample/ subgroup of $n = 4$. In this case, there will be a tremendous opportunity for special causes (true differences among the machine) to occur within subgroups.

When serious problems do arise, for example, for one or more of the machines, they will be very difficult to detect because of the use of stratified samples. This problem can be detected, however, because of the unusual nature of the \bar{X} -chart pattern (recall the previous pattern analysis) and can be rectified provided the concepts of rational sampling are understood.

The R -charts developed from such data will usually show very good control. The corresponding \bar{X} control chart will show very wide limits relative to the plotted \bar{X} values, and their control will therefore appear almost too good. The wide limits result from the fact that the variability within subgroups is likely to be subject to more than merely common causes.

Mixing Production from Several Machines. Often it is inviting to combine the output of several parallel machines/lines into a single stream of well-mixed product that is then sampled for the purposes of maintaining control charts.

If every sample has exactly one data point from each machine, the result would be the same as that of stratified sampling. If the sample size is smaller than the number of machines with different means or if most samples do not include data from all machines, the within-sample variability will be too low, and the between-sample differences in the means tend to be large. Thus, the \bar{X} -chart would give an appearance that the \bar{X} values are too far away from the centerline.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

P/M Process Planning

The first step in quality planning is a dialogue between engineering teams of the P/M part producer and the customer. At this stage, finished product (generally an assembled component) can be evaluated, and preliminary part prints may be exchanged. While the product is still "on paper" relatively inexpensive design changes should be considered to accommodate the P/M process and lower overall cost. Design factors in P/M manufacturing are addressed elsewhere in this Volume.

After final part prints have been agreed to, the P/M manufacturing process can be engineered. Several of the key factors include tooling dimensions, sintering parameters, and secondary operations such as heat treating and machining.

Dimensional and Tool Size Determination

When determining tooling sizes and process control limits, one must begin with a consideration of the final product, then work backward through the process. As parts move from compaction, to sintering, to secondary operations, the sizes usually change significantly. Additionally, the variation generally increases with each step in the process (Fig. 5). Notable exceptions are sized or machined parts, as these secondary processes are intended to improve tolerances and thus reduce variation.

Fig. 5 Typical change in size distribution after sintering and heat treatment of a P/M compact. The distribution widens after additional processing steps.

The tool designer must draw upon material and processing knowledge to determine the size of the compaction tools. Commonly, the tooling designer begins with the finished part print and then "factors" the dimensions of all tooling members. For example, for a part with a 1.000 in. outside diameter and 0.800 in. inside diameter that shrinks through processing from compacting tooling size, an appropriate factor may be 1.005. The designer thus would size the die at 1.005 in. ($1.000 \text{ in.} \times 1.005$) and the core 0.804 in. (0.800×1.005) as shown schematically in Fig. 6.

Fig. 6 Example of using tooling factor for die sizing. Factor used: 1.005; tooling not shown: upper punch, lower punch, various adapters, and so forth

The determination of the appropriate factor depends on the material, the processes used, and the parameters of the processes used. Powder manufacturers offer a great deal of baseline data for tooling size determination, but the best method is to draw upon previously tooled parts of similar processing and geometric configuration. When this previously generated data are not available, a pilot run using prototype tooling is an appropriate method of determining sizes. This reduces the likelihood of having to retool production tooling and can decrease the lead time for the first production run.

Complicated geometries can require the use of different factors for different portions of the tooling. For example, raised hubs formed by the top punch tend to have lower densities than the balance of the part. Lower densities have a tendency to shrink more, which means that the factor used should be higher than for the rest of the part geometry.

Sintering Parameters

Densification for a metallurgically sound part by sintering is determined by sintering temperature, time at temperature, and atmosphere composition. To ensure that metallurgical properties are not compromised, limits on the process inputs are normally established. General part categories, based on material and finished part application, are determined, and limits put on each of these categories. For example, the degree of sinter must be significantly better for structural parts such as gears compared to lightly stressed spacers.

When engineering the process for a new part, baseline, or trial, parameters are normally established. These settings are comfortably above the established minimums for the part category. This allows for minor adjustments during the initial sample process. Adjustments are sometimes needed to ensure that the required mechanical and physical properties are achieved.

Once the production parameters are established, it is best if they are kept nearly constant. Trying to use sintering to compensate for material or compacting variations leads to a high degree of run-to-run metallurgical variation and can contribute to part failures.

Secondary Operations

Secondary operations, discussed in more detail elsewhere in this Volume, must also be considered in process planning and control. Their relation with quality process control are briefly discussed below.

Heat Treat. As with sintering, baseline heat treating parameters are generally established based on the part material and the end use. Parameters are established during the initial sampling procedure, and adjustments from these settings are kept to a minimum to ensure consistent material properties.

Restrike. Whether the part is being re-pressed (densified), coined, or sized, the primary factor to producing good parts is the tool design. As with the design of compacting tools, the sizes may have to be factored to take into account subsequent processing that may change dimensions.

Plating. With powdered metal parts, virtually any of the commonly applied platings can be utilized. The primary difference between plating noncopper-infiltrated P/M versus wrought materials is that typically the parts first must be resin impregnated to fill the porosity before the application of the plating. Copper infiltration generally fills enough of the porosity to eliminate the need for resin impregnation.

Machining. A great many powdered metal alloys are readily machinable. The primary difference between P/M versus wrought is that P/M machining is actually a series of interrupted cuts, due to its inherent porosity. Speeds, feeds, and coolant parameters are different, but overall throughput and process control philosophy is similar to the machining of non-P/M metals.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Quality Control and Inspection

Lot Traceability

The sophistication of a system for part traceability depends on customer requirements and the risk that the producer is willing to assume. Should a problem develop, discrete traceability to a specific production operation can help reduce the quantity that might be involved in a rejection or product recall.

As a minimum, most P/M suppliers maintain traceability to the material used. Each raw material (metal powder, lubricant, additive, etc.) is assigned a unique material lot number by its supplier. If the material is blended in-house, then it is common to assign a lot number based on the blended batch. This lot number is marked on all in-house processing containers and clearly designated on the finished goods containers as well. When the powder is received as a preblend, a new lot number may be designated, or the lot number created by the powder supplier may be used throughout processing.

Unlike the plastics molding and metal castings industries, easily changed lot designators cannot be inserted into the P/M compaction tools. High molding pressures make this sort of designator impractical. If as-molded designators are desired, they are high-strength portions of the tooling that require significant setup to change. Because of this expensive setup, generally as-molded designators are changed only for each run, or up to once per week.

Individual serialization of parts can be achieved with mechanical engravers. These engravers can be used after any of the operations, including on green compacts.

Powder Inspection

Consistency of powder characteristics is key to producing a quality finished part. Chemistry, cleanliness, particle shape, and size distribution are the primary drivers of powder performance.

A few, relatively simple checks are generally sufficient to ensure the consistency of incoming powder--the first check being flow rate.

Flow Rate Check. The determination of flow rate is generally measured according to MPIF Standard 03 (Ref 3). The procedure is summarized:

1. Obtain a sample of the powder. A good way to get a representative sample from a bulk pack or drum of powder is to use a Keystone Sampler (Fig. 7) according to MPIF Standard 01 (Ref 4). This manually operated device augers its way to the bottom of the container, then opens up to retrieve powder from throughout the container.
2. Load the flowmeter funnel with the powder while keeping a dry finger over the discharge orifice.
3. Start a stopwatch simultaneously with the removal of the finger from the orifice. Stop timing when the last of the powder leaves the flowmeter. The flow rate is recorded in elapsed time in seconds.

Flow rate is critical to press setup. Faster-flowing (shorter rate in seconds) powders can fill the die cavity faster and can allow for faster press speeds.

Fig. 7 Keystone sampler for measuring powder flow. Source: Ref 4, used with permission

Apparent Density Check. Another simple method to ensure that the incoming powder is consistent lot to lot is to check apparent density. The most commonly followed method is MPIF Standard 04 (Ref 5), which is summarized:

1. A test specimen of metal powder is obtained. Again, the Keystone Sampler is a good tool for getting a representative sample from a container.
2. This entire specimen is loaded into the Hall flowmeter, and the powder should flow into the density cup.
3. Level the heaped powder in the density cup with a nonmagnetic spatula with the blade held perpendicular to the top of the cup. Do not jar the cup.
4. Tape the side of the cup slightly so that the powder settles, allowing the cup to be easily moved without spilling powder.
5. Transfer the powder to a balance and check its mass.
6. Apparent density is calculated as the ratio M/V , where M is the mass of powder from the density cup in grams, and V is the volume of the cup.

Apparent density determines the amount (weight) of the powder that fills the die. It is critical that setup personnel be aware of the apparent density value for a powder. It is especially critical that they know when a new container of powder has a large change in apparent density. The relative position of the die and lower punch(es) determines the amount of fill. If the press is set for a powder of apparent density, then loading a powder with higher apparent density into the press can have catastrophic results during pressing. The higher apparent density powder can increase the green density of the part to the point where the elastic limit of the tooling is exceeded, and the tools break.

Microscopic Evaluation. A simple check of the powder under a microscope is also a good safeguard against sending defective powder to the press. Powder discrepancies that can be detected vary from rust to gross anomalies such as large agglomerates of lubricant.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Process Control

A key aspect of process control philosophy is that shop floor operators be given as much "ownership" of their process as possible. Ideally, the operator gages the process, charts it, takes corrective action when it goes out of control, and makes the appropriate adjustments to the process when necessary.

Certain process control procedures, however, cannot be practically conducted by the production operators. Some measurements cannot be accurately determined on the production floor. Examples include green density checks and measurements requiring a coordinate measuring machine. Both of these checks are best left to the laboratory specialists.

Additionally, some adjustments, most compaction press adjustments for example, are beyond the level of technical expertise of most operators. These adjustments require specially trained setup personnel.

Compacting Process Control. A variety of statistical process controls are used across the industry for the compaction. Charts successfully employed include X-bar, range, and median. This section briefly describes key variables that influence the implementation of statistical process control for powder compaction.

For conventional rigid die compaction, generally vertical-direction dimensions and weight are statistically charted. Vertical-direction dimensions are those that run in the same direction as the compacting motion (Fig. 8). These features vary significantly as a result of the various press inputs such as voltage, temperature, and mechanical movement. Radial-direction dimensions, those that run horizontally--or not in the direction of the press stroke--generally do not vary to a large degree throughout an individual production run. Therefore, monitoring of radial-direction dimensions is not adequate to show if the pressing action is in statistical control. For longer runs, typically in the 50,000-piece or longer range, a periodic spot check is a good idea to ensure that the tooling has not worn excessively. The exact frequency required for the radial dimension checks depend on the abrasiveness of the powder, part configuration, and the wear resistance of the tool steel.

Fig. 8 Radial dimensions of part relative to typical die configuration and tool motion

Many newer presses are equipped with electronics that monitor and chart the various press characteristics. These characteristics include total press tonnage, loads at various press locations, air pressures, hydraulic pressures, and hydraulic temperatures. These outputs are sometimes used for true statistical control, but the majority of manufacturers use these outputs for simple, mechanically based, processing limits.

Green density is the density of the P/M component after compaction. A check of green density is a good verification method at the start of each production run and is checked periodically throughout the run for most parts. However, for single-level parts of less than 6.35 mm ($\frac{1}{4}$ in.) length, an in-process density check is generally not required. Assuming that the control limits established will always produce correct density parts, so long as the process does not stray from these limits, the density will always be correct.

Generally, these density checks are performed once or twice per shift. The reason for the checks is that it is possible for the weight and lengths to be within control limits and the density in a portion of the part to be either over or under specification.

For example, the process may shift, causing the flange density to increase and the body density to reduce. The overall density is correct, but portions of the part are high density and portions are low density. High degrees of density variations can cause cracks, break tools, and cause part service failures.

To ensure that the density is relatively homogenous, the green compact is sectioned and the density of each section is determined. The difference between the density sections is calculated and compared against established limits. The limits established may vary depending on a number of factors including tooling fragility and end-product use. For example, a density split limit of 0.2 g/cm³ may be established on a two-level gear. If the flange is running 7.25 g/cm³ and the body is running 7.00 g/cm³ (for a 0.25 g/cm³ split), the density should be adjusted at the compaction press. Parts run since the last density split check must be carefully evaluated to ensure that they are mechanically sound and will produce finished parts that are within print tolerances.

MPIF Standard 42 (Ref 6) is the industry standard. Application of this procedure for green density is summarized:

1. A test specimen is obtained.
2. Determine the mass of the specimen using a balance of adequate precision (Mass *A*).
3. Impregnate the specimen with oil.
4. Remove excessive oil.
5. Determine the mass of the impregnated test piece (Mass *B*).
6. Suspend the oil-impregnated specimen from the balance hook into water. Completely submerge the piece and be sure that all air bubbles are removed (Mass *C*).
7. Remove the specimen from the water and measure the mass of the balance hook as it is suspended in the same manner as it was when holding the test piece (Mass *E*).

Green density is calculated as:

$$\text{Green density} = \frac{A \cdot \rho_w}{B - (C - E)}$$

where ρ_w is a correction factor for water temperature.

Sintering Process Control. Unlike compaction, which usually has a cycle time of well under 1 min, the sintering process may take hours from beginning to end (furnace exit). On shorter runs, all of the green parts may be loaded into the furnace before a part is removed from the furnace exit. Because thousands of parts can be loaded before a part measurement can be made, a sample batch is usually run to ensure that the processing parameters are having their desired effect on the parts.

Throughout the production runs, parts are usually measured and charted to statistical control limits. Because the radial (from compaction stroke) dimensions are typically highly consistent in green compacts, these are normally good indicators of sintering performance. The variation noted in these measurements is largely from the sintering process; thus, they can be reliably used for assessing the state of sintering process control.

As with some of the newer compaction presses, many newer sintering furnaces have the capability to run true process control on the processing characteristics. With sintering, the outputs are temperature, speed, atmosphere flow rate, and so forth.

In addition to dimensional checks, part macrohardness is also generally monitored throughout processing. Control limits may be established based on the material type, the density being pressed, and the desired as-sintered properties.

Restrike Process Control. The movement of the material being repressed dictates the type of process control required. Control charts may be appropriate for vertical dimensions or radial dimensions, and sometimes both are monitored.

Heat Treat Process Control. Heat treating is similar to sintering in that radial dimensions are usually checked to ensure that the process is running well. For continuous-belt furnaces, in-process statistical charting is appropriate. The process can be adjusted throughout the run to maintain control.

With batch furnaces, all part-based verification for process control is after-the-fact inspection. The best way to ensure that the process is running properly is to have good, tight controls of the inputs (temperature, carbon content, oxygen, etc.). As with sintering, part macrohardness is usually checked. Control limits may be established based on the material type, density, sintering, and heat treating parameters.

Secondary Operations. For most other secondary operations, process control is conducted on P/M parts similarly to that of other metal fabrication techniques.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Inspection Considerations

Inspection techniques for finished parts should be based on concurrence between the customer and the supplier. There are many ways to gage most part print specifications, and the specific technique used can have a large effect on the results reported. A great many P/M part attributes may be measured with the same techniques used in other industries. There are, however, significant exceptions as briefly described below.

Hardness. In powder metallurgy there are generally two types of hardness specified--apparent hardness (macrohardness) and microhardness. The microhardness is the hardness of each particle of material, and the apparent hardness is the hardness of the surface--bridging across many particles and the porosity, too.

Apparent hardness is typically measured according to MPIF Standard 43 (Ref 7). The procedure is relatively straightforward and quick. The basics are:

1. Obtain a sample part of adequate thickness and parallel configuration (or, for cylindrical parts, a correction factor may be used).
2. The sample must be large enough so that the indenter marks from the hardness tester are at least three indenter diameters from any edge or previous impression.
3. Sand each face of the sample so that no burrs are present (burrs will cause erroneous readings), or be sure to use a holding fixture that avoids the burrs.
4. Take readings with a properly calibrated hardness tester.
5. Reject obvious outliers and report the average of at least five nonoutliers.

Typically, the outliers are on the low side. The cause of these occasional low readings is a chance happening that the hardness indenter falls right into a pore.

Microhardness is usually measured according to MPIF Standard 51 (Ref 8). The determination of microhardness is significantly more difficult than measuring apparent hardness and requires specialized equipment that many P/M users do not have on-site. The procedure involves:

1. Sectioning the part and making a polished mount for the evaluation.
2. Placing the mount in a special microhardness testing machine.
3. Under magnification, orienting the mount and making a diamond indenter mark precisely over a particle of the material.
4. Measuring the length of the penetration on the particle and converting this length to a hardness reading.

Microfinish. The porosity of P/M causes debate over the proper method of measuring microfinish. When using a standard cone stylus, unmachined P/M can give relatively high microfinish values. The individual particles are very smooth, but the probe path is interrupted by pores of varying sizes (Fig. 9). Because most parts are running against a mate that is much larger than the standard probe, many feel that the chisel probe provides a better gage as to the actual serviceability of the parts. The chisel probe bridges across the porosity and usually produces significantly lower microfinish values.

Fig. 9 Surface measurement with chisel stylus (a). (b) Effect of cone and chisel styli on an as-sized P/M surface. Source: Ref 9, used with permission.

Physical Tests. Performing a physical test on finished parts is a great method of verifying that all processes ran properly, and the final parts will perform adequately. Crush, torque, impact, and tensile tests are commonly called out on P/M part

prints. These tests greatly reduce the need for expensive, time-consuming, and sometimes ambiguous, microstructure analysis.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Defect Detection

The problem of forming defects in green parts during compaction and ejection has become more prevalent as parts producers have begun to use higher compaction pressures in an effort to achieve high-density, high-performance P/M steels. Several nondestructive inspection methods are practical for detecting defects as early as possible in the production sequence. The most promising nondestructive testing methods for P/M applications include electrical resistivity testing, eddy current and magnetic bridge testing, magnetic particle inspection, ultrasonic testing, x-ray radiography, gas permeability testing, and γ -ray density determination. The capabilities and limitations of each of the techniques are briefly summarized in Table 2.

Table 2 Comparison of the applicability of various nondestructive evaluation methods of flaw detection in P/M parts

Method	Measured/detected	Applicability to P/M parts ^(a)		Advantages	Disadvantages
		Green	Sintered		
X-ray radiography	Density variations, cracks, inclusions	C	C	Can be automated	Relatively high initial cost; radiation hazard
Computed tomography	Density variations, cracks, inclusions	C	C	Can be automated; pinpoint defect location	Extremely high initial cost; highly trained operator required; radiation hazard
Gamma-ray density determination	Density variations	A	A	High resolution and accuracy; relatively fast	High initial cost; radiation hazard
Ultrasonic imaging: C-scan	Density variations, cracks	D	B	Sensitive to cracks; fast	Coupling agent required
Ultrasonic imaging: SLAM	Density variations, cracks	D	C	Fast; high resolution	High initial cost; coupling agent required
Resonance testing	Overall density, cracks	D	B	Low cost; fast	Does not give information on defect location
Acoustic emission	Cracking during pressing and ejection	C	D	Low cost	Exploratory
Thermal wave imaging	Subsurface cracks, density variations	D	C	No coupling agent required	Fat or convex surfaces only
Electrical resistivity	Subsurface cracks, density of variations, degree of sinter	A	A	Low cost, portable, high potential for use on green compacts	Sensitive to edge effects
Eddy current/magnetic	Cracks, overall density,	C	A	Low cost, fast, can be	Under development

bridge	hardness, chemistry			automated; used on P/M valve seat inserts	
Magnetic particle inspection	Surface and near-surface cracks	C	A	Simple to operate, low cost	Slow; operator sensitive
Liquid dye penetrant inspection	Surface cracks	C	D	Low cost	Very slow; cracks must intersect surface
Pore pressure rupture/gas permeability	Laminations, ejections, cracks, sintered density variations	A	A	Low cost, simple, fast	Gas-tight fixture required; cracks in green parts must intersect surface

Source: Ref 10 and 11 (reprinted with permission)

- (a) A, has been used in the production of commercial P/M parts; B, under development for use in P/M; C, could be developed for use in P/M, but no published trials yet; D, low probability of successful application to P/M.

The four most common types of defects in P/M parts are ejection cracks, density variations, microlaminations, and poor sintering. These defects are briefly described in this section, and SPC techniques related to defects are described in the next section of this article.

Ejection Cracks. When a part has been pressed, there is a large residual stress in the part due to the constraint of the die and punches, which is relieved as the part is ejected from the die. The strain associated with this stress relief depends on the compacting pressure, the green expansion of the material being compacted, and the rigidity of the die. Green expansion, also known as spring out, is the difference between the ejected-part size and the die size. A typical value of green expansion for a powder mix based on atomized iron powder pressed at relatively high pressure (600 to 700 MPa, or 45 to 50 tsi) is 0.20%. In a partially ejected compact, for example, the portion that is out of the die expands to relieve the residual stress, while the constrained portion remains die size and a shear stress is imposed on the compact. When the ability of the powder compact to accommodate the shear stress is exceeded, ejection cracks are formed.

The radial strain can be alleviated to a degree by increasing the die rigidity and designing some release into the die cavity. However, assuming that the ejection punch motions are properly coordinated, the successful ejection of multilevel parts depends to a large degree on the use of a high-quality powder that combines high green strength with low green expansion and low stripping pressure.

Density Variations. Even in the simplest tool geometry possible--a solid circular cylinder--conventional pressing of a part to an overall relative density of 80% will result in a distribution of density within the part ranging from 72 to 82% (Ref 12). The addition of simple features such as a central hole and gear teeth presents minor problems compared with the introduction of a step or second level in the part. Depending on the severity of the step, a separate, independently actuated punch can be required for each level of the part. During the very early stage of compaction, the powder redistributes itself by flowing between sections of the die cavity. However, when the pressure increases and the powder movement is restricted, shearing of the compact in planes parallel to the punch axis can only be avoided by proper coordination of punch motions. When such shear exists, a density gradient results.

The density gradient is not always severe enough for an associated crack to form upon ejection. However, a low-density area around an internal corner can be a fatal flaw because this corner is usually a point of stress concentration when the part is loaded in service.

Microlaminations. In photomicrographs of unetched part cross sections, microlaminations appear as layers of unsintered interparticle boundaries that are oriented in planes normal to the punch axis. They can be the result of fine microcracks associated with shear stresses upon ejection; such microcracks fail to heal during sintering. Because of their orientation parallel to the tensile axis of standard test bars, they have little influence on the measured tensile properties of the bars, but are presumed to be a cause of severe anisotropy of tensile properties.

Poor Sintering. When unsintered particle boundaries results from a cause other than shear stresses, they are usually present because of insufficient sintering time or sintering temperature, a nonreducing atmosphere, poor lubricant burn-off, inhibition of graphite dissolution, or a combination of these. Unlike microlaminations, defects associated with a poor degree of sintering are not oriented in planes.

Planning and Quality Control of Powder Metallurgy Parts Production

Jack R. Bonsky, Cleveland State University, Advanced Manufacturing Center

Shewhart Control Charts for Defect Data

Many quality assessment criteria for manufactured goods are not of the variable measurement type. Rather, some quality characteristics are more logically defined in a presence-of or absence-of sense. In P/M, examples include chipped gear teeth, discolored plating, scratched surfaces, and powder accumulation on parts.

Such nonconformities or defects are often observed visually or according to some sensory criteria and cause a part to be defined simply as a defective part. In these cases, quality assessment is referred to as being made by attributes.

Many quality characteristics that could be made by measurements (variables) are often not done as such in the interest of economy. A go/no-go gage can be used to determine whether or not a variable characteristic falls within the part specification. Parts that fail such a test are simply labeled defective. Attribute measurements can be used to identify the presence of problems, which can then be attacked by the use of \bar{X} and R control charts. The following definitions are required in working with attribute data:

- *Defect*: A fault that causes an article or an item to fail to meet specification requirements. Each instance of the lack of conformity of an article to specification is a defect or nonconformity.
- *Defective*: An item or article with one or more defects is a defective item.
- *Number of defects*: In a sample of n items, c is the number of defects in the sample. An item may be subject to many different types of defects, each of which may occur several times.
- *Number of defectives*: In a sample of n items, d is the number of defective items in the sample.
- *Fractional defective*: The fractional defective, p , of a sample is the ratio of the number of defectives in a sample of the total number of items in the sample. Therefore, $p = d/n$.

Operational Definitions

The most difficult aspect of quality characterization by attributes is the precise determination of what constitutes the presence of a particular defect. This is so because many attribute defects are visual in nature and therefore require a certain degree of judgment and because of the failure to discard the product control mentality. For example, a scratch that is barely observable by the naked eye may not be considered a defect, but one that is readily seen is. Furthermore, human variation is generally considerably larger in attribute characterization (for example, three different caliper readings of a workpiece dimension by three inspectors and visual inspection of a part by these same individuals yield anywhere from zero to ten defects). It is therefore important that precise and quantitative operational definitions be laid down for all to observe uniformly when attribute quality characterization is being used. The length or depth of a scratch, the diameter of a surface blemish, or the height of a burr.

The issue of the product control versus process control way of thinking about defects is a crucial one. From a product control point of view, scratches on a magnetic catch plate should be counted as defects only if they appear on visual surfaces, which would directly influence part function. From a process control point of view, however, scratches on a catch plate should be counted as defects regardless of where they appear because the mechanism creating these scratches does not differentiate between visual and concealed surfaces. By counting all scratches, the sensitivity of the statistical charting instrument used to identify the presence of defects and to lead to their diagnosis will be considerably increased.

A major problem with the product control way of thinking about part inspection is that when attribute quality characterization is being used, not all defects are observed and noted. The first occurrence of a defect that is detected immediately causes the part to be scrapped. Often, such data are recorded in scrap logs, which then present a biased view of what the problem may really be. One inspector may concentrate on scratch defects and will therefore tend to see these first. Another may think brightness is more critical, so his data tend to reflect this type of defect more frequently. The net result is that often such data may then mislead those who may be using it for process control purposes. Therefore, it is essential from a process control standpoint to carefully observe and note each occurrence of each type of defect.

p-Chart and c-Chart Analyses

Example 1: p-Chart Analysis for Fraction Defective during Tapping.

Consider a tapping operation on a P/M bracket. Suppose the measures of quality conformance of interest are the presence of threads (generally absent due to parts being inadvertently transferred into the finished parts bin without processing) and the size of the tapped threads as measured with a go/no-go plug (generally defective due to cutting tool wear).

To establish the control chart, rational samples of size $n = 50$ parts are drawn from production periodically (perhaps, each shift), and the sampled parts are inspected and classified as either defective (from either or both possible defects) or nondefective. The number of defectives, d , is recorded for each sample. The process characteristic of interest is the true process fraction defective p' . Each sample result is converted to a fraction defective:

$$p = \frac{d}{n} \quad (\text{Eq 1})$$

The data (fraction defective p) are plotted for at least 25 successive samples of size $n = 50$. The individual values for the sample fraction defective, p , vary considerably, and it is difficult to determine from the plot at this point if the variation about the average fraction defective, \bar{p} , is solely due to the forces of common causes or special causes.

Control Limits for the p-Chart. It can be shown that for random sampling, under certain assumptions, the occurrence of the number of defectives, d , in the sample of size n is explained probabilistically by the binominal distribution. Because the sample fraction defective, p , is simply the number of defectives, d , divided by the sample size, n , the occurrence of values for p also follows the binominal distribution. Given k rational samples of size n , the true fraction defective, p' , can be estimated by:

$$\bar{p} = \sum_{i=1}^k p_i / k \quad (\text{Eq 2})$$

or

$$\bar{p} = \sum_{i=1}^k d_i / \sum_{i=1}^k n_i \quad (\text{Eq 3})$$

Equation 3 is more general because it is valid whether or not the sample size is the same for all samples. Equation 2 should be used only if the sample size, n , is the same for all k samples.

Therefore, given \bar{p} , the control limits for the p -chart are then given by:

$$UCL_p = \bar{p} + 3\sqrt{\bar{p}(1-\bar{p})/n} \quad (\text{Eq 4a})$$

$$LCL_p = \bar{p} - 3\sqrt{\bar{p}(1-\bar{p})/n} \quad (\text{Eq 4b})$$

Thus, only \bar{p} has to be calculated for at least 25 samples of size n to set up a p -chart. The binomial distribution is generally not symmetric in quality control applications and has a lower bound of $p = 0$. Sometimes the calculation for the lower control limit may yield a value of less than 0. In this case, a lower control limit of 0 is used.

c-Chart: Analysis for Number of Defects. The p -chart deals with the notion of a defective part or item where defective means that the part has at least one nonconformity or disqualifying defect. It must be recognized, however, that the incidence of any one of several possible nonconformities would qualify a part for defective status. A part with ten defects, any one of which makes it defective, is on equal footing with a part with only one defect in terms of being defective.

Often it is of interest to note every occurrence of every type of defect on a part and to chart the number of defects per sample (c). A sample may only be one part, particularly if interest is focusing on final inspection of an assembled product, or inspection may focus on one type of defect or multiple defects.

The probability law that governs the incidence of defects is known as the Poisson law or Poisson probability distribution, where c is the number of defects per sample. It is important that the opportunity space for defects to occur be constant from sample to sample. The Poisson distribution defines the probability of observing c defects in a sample where c' is the average rate of occurrence of defects per sample.

Construction of c-Charts from Sample Data. The number of defects, c , arises probabilistically according to the Poisson distribution. One important property of the Poisson distribution is that the mean and variance are the same value. Then given c' , the true average number of defects per sample, the 3σ limits for the c -chart are given by:

$$CL_c = c' \pm 3\sqrt{c'}$$

Note that the standard deviation of the observed quantity c is the square root of c' . The Poisson distribution is a very simple probability model, being completely described by a single parameter c' .

When c' is unknown, it must be estimated from the data. For a collection of k samples, each with an observed number of defects c_i , the estimate of c' is:

$$\bar{c} = \sum_{i=1}^k c_i / k$$

Therefore, trial control limits for the c -chart can be established, with possible truncation of the lower control limit at zero, from:

$$UCL_c = \bar{c} + 3\sqrt{\bar{c}}$$

$$LCL_c = \bar{c} - 3\sqrt{\bar{c}}$$

Tolerance Control

The issue of part tolerancing and, in particular, the statistical assignment and assessment of tolerances are excellent examples of the need for design and manufacturing to understand what each other is doing and why. The best intentions of the design process can go unmet if the manufacturing process is not operated in a manner totally consistent with design intent. To more clearly appreciate the relationship that must exist between the design and manufacturing operations, some of the basic assumptions of the tolerancing activity and their relationship to the manufacturing process are examined. The following sections clearly point to the importance of statistical process control relative to the issue of process capability.

The key concepts in statistical tolerancing are:

- The use of a statistical distribution to represent the design characteristic and therefore the process output for the product/part in question relative to the design specifications
- The notion of random assembly, that is, random part selection from these part process distributions when more than one part is being considered in an assembly
- The additive law of variances as a means to determine the relationship between the variability in individual parts and that for the assembly

To assume that the parts can be represented by a statistical distribution of measurements (and for the assumption to hold in reality), the part processes must be in a state of statistical control. The following example illustrates the importance of statistical process control in achieving design intent in a tolerancing problem.

Example 2: Statistical Tolerance Model for Optimal Fit of a Pin Assembly into a Molded Hole of a P/M Plate.

Figure 10 shows two simple parts: a plate with a hole and a pin that will ultimately be assembled to a third part but must pass through the hole in the plate. For the assembly, it is desired for function that the clearance between the plate hole and the pin be at least 0.015 in. but no more than 0.055 in.

Fig. 10 Pin and hole components statistically analyzed in Example 2. (a) Plate with hole. (b) Pin assembly. Dimensions given in inches

To achieve the design requirement stated above, the nominal values and tolerance for the plate hole and pin were statistically derived and are shown in Fig. 10. To arrive at these tolerances, it was assumed that:

- The parts would be manufactured by processes that behave according to the normal distribution
- The process capabilities would be at least 6σ , the processes would be centered at the nominal values given in Fig. 10, and the processes would be maintained in a state of statistical control
- Random assembly would prevail

If these assumptions are met, the processes for the two parts, and therefore the clearance associated with assembled parts, would be as shown in Fig. 11, and the design intent would be met.

Fig. 11 Statistical basis for satisfying design intent for the hole/pin assembly clearance in Fig. 10. (a) Distribution of hole. (b) Distribution of pin. (c) Distribution of clearance

Suppose that despite the assumptions made and the tolerances derived, the processes manufacturing the pin and plate hole were not maintained in good statistical control. As a result, the parts actually more nearly follow a uniform/rectangular distribution within the specifications, as shown in Fig. 12. Such could have arisen as a result of sorting or rework of a more variable process(es), in which case the results are doubly distressing, that is, poorly fitting assemblies and increased cost to the system.

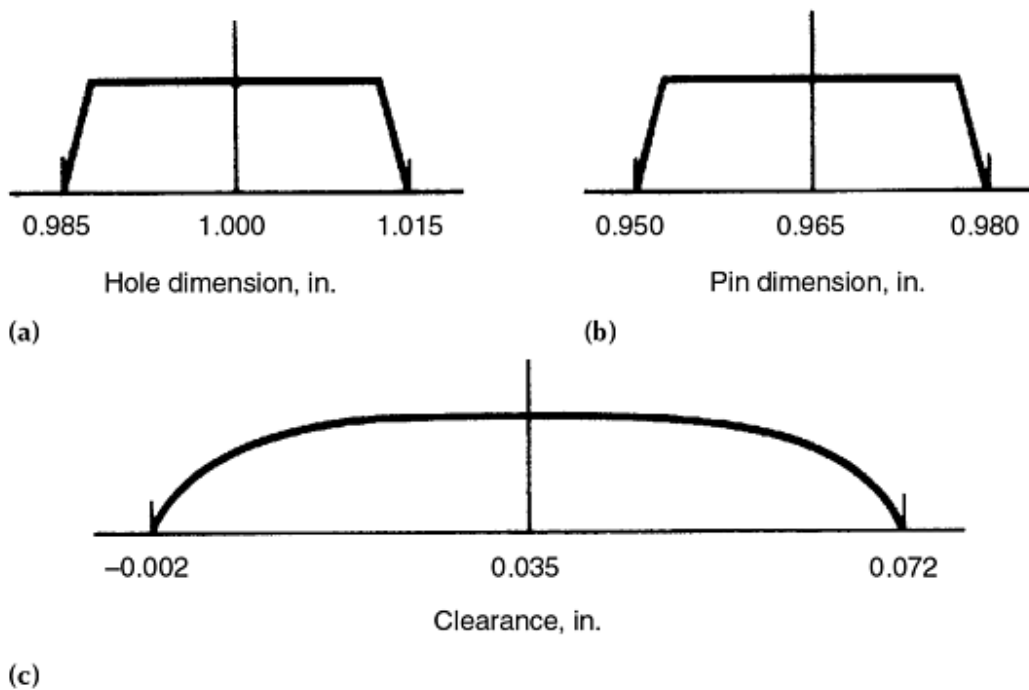

Fig. 12 Clearance implications of poor process control of plate hole and pin dimensions for components of Fig. 10. (a) Distribution of hole. (b) Distribution of pin. (c) Distribution of clearance

Figure 12 shows the distribution of the clearance if the hole and pin dimensions follow the uniform distribution within the specifications. The additive law of variances has been used to derive the variation in the clearance distributions but assuming the uniform distribution for the individual part processes. Some assemblies may not go together at all, some will fit quite tightly and may later bind if foreign matter gets into the gap, and others will fit together with a much larger clearance than desired.

The problem here is not a design problem. The plate hole and pin tolerances have been derived using sound statistical methods. However, if the processes are not in good statistical control and therefore not capable of meeting the assumptions made during design, poor-quality assemblies will follow. It should be noted that the altogether too common process appearance of a uniform distribution of measurements within the specifications can arise in several different ways:

- From processes that have good potential with regard to variation, but are not kept in good statistical control
- From unstable and/or large variation processes that require sorting/rework to meet the specifications
- From processes that are intentionally allowed to vary over the full range of the specifications to take advantage locally of wide specifications relative to the process variation

In all of the three cases mentioned above, additional costs will be incurred and product quality will be eroded. Clearly, SPC is crucial to the tolerancing issue in engineering design.

Quality Control and Inspection of Powder Metallurgy Secondary Operations

Pat Kenkel, John Engquist, and Mike Blanton, Burgess-Norton Manufacturing Company

Introduction

QUALITY PLANNING TECHNIQUES for P/M secondary operations are no different than quality planning for any other manufacturing process--the thought process should be consistent throughout. Developing quality control and inspection for any P/M part begins with the quality planning phase of the product launch process. Quality planning begins well before the purchase order is issued. A thorough review of print requirements with the customer can minimize problems later in the process development. The dimensioning techniques used when designing a part will often determine types of gaging and quality control methods to be used. Geometric dimensioning and tolerancing (GDT) is widely used in design work to ensure the part meets the form, fit, and functional requirements. If properly used, GDT will minimize misinterpretations of the print and lead to the most economical gaging solutions for the part.

It is extremely useful to have mutual (customer/supplier) agreement on gaging concepts during the quality planning process. Quality requirements must also be discussed at this time to avoid capability and processing issues later on. Classification of characteristics (C of C) and the associated capability indices should be thoroughly understood to properly process the part. Secondary operations are often added to satisfy statistical process control requirements.

Another important step in the quality planning process is to plan and develop the process(es) *before* the first parts are produced--it is much less desirable to backtrack (reactive) in the quality planning activities than to act (proactive) on a well thought out plan with failure modes defined and methods provided to prevent and/or detect those potential failure modes. Two useful tools to help in the planning process are a failure mode and effects analysis (FMEA) and a control plan.

A FMEA process is a very good engineering tool that is used to detect problem areas in the process and to mistake-proof and/or assign the correct process controls. It should be noted that the FMEA process is used to flag potential causes of failure in the process: if the potential for failure is high, efforts should first be made to minimize the potential effects of the failure. Once the risk has been minimized, the appropriate process control can be assigned. Mistake-proofing should be used to reduce risk and ensure quality.

The control plan assigns control methods to the process in an effort to help minimize process and product variation. Features to be checked, method of inspection, control method, frequency of inspection, and responsibility are assigned for each operation. The control plan takes into consideration the FMEA results as well as any classification of characteristics that the customer has defined. Depending on the characteristic, the amount of control may vary, from simple first piece layouts (for tool generated dimensions) to 100% inspection on characteristics generated using incapable machinery.

Quality Control and Inspection of Powder Metallurgy Secondary Operations

Pat Kenkel, John Engquist, and Mike Blanton, Burgess-Norton Manufacturing Company

Secondary Operations

The purpose of this article is not to discuss technology gains made in secondary operations for powder metallurgy, but to provide useful information in controlling and improving secondary processes using quality control and inspection methodologies. However, development of the following secondary operations is briefly discussed:

- Restrike--densification
- Restrike--sizing
- Heat treat
- Machining and grinding

Examples of FMEA and control plans are shown in Fig. 1 and 2, respectively, for the restrike--densification process to illustrate the use of such tools when assigning process control methods and inspection instructions to a process. Additional information on statistical process control concepts and terminology are also discussed in the article "Planning and Quality Control of Powder Metallurgy Parts Production" in this Volume.

Fig. 2 Brief example of a control plan for restrike operation

Restrike--Densification. Restrike operations are frequently used to densify parts above the density attainable at compacting. In these instances, more emphasis is placed on attaining the desired material property through densification than on achieving tight dimensional limits (although dimensional control is also important). Adequate control must be placed on the process to ensure density requirements (and dimensions) are met. Because density checks are not readily performed in a production environment, dimensional controls may be used to control density if correlation can be proved to be sufficient. When densifying thin parts, greater dimensional and weight control may be required at compacting to avoid overdensification and damage to the restrike press and/or tooling. Press and tool load monitors are effective process control tools.

Restrike--Sizing. Sizing using a restrike operation is used to enhance dimensional characteristics on P/M parts. In this instance, the density of the part has already been met in the compacting and sintering operations. Sizing is used to meet tighter dimensional limits on diameters, lengths, tapers, and so forth. The quality control methods assigned for sizing operations depend on the characteristic sized and the capability of the machine in achieving the desired limits of size; highly capable processes require very little in-process or post-process inspection while marginally capable processes require significant and frequent inspection.

Heat Treat. The properties from heat treatment (such as hardness and tensile strength) are dependent on many process variables. Carbon potential, atmosphere, heat treat temperature, quench rate and temperature, and draw temperature affect the properties of parts. A FMEA of the heat treatment should be done to list potential failures caused by incorrect settings of the above inputs. To minimize potential process failures, process control of the heat treat operation should include monitoring the inputs as well as the outputs. Minimal variation of these parameters results in significantly reduced variation of product characteristics. Again, depending on the stability of the process, more or less dimensional and metallurgical inspection is required as post-process inspection.

Machining/Grinding. Although machining and grinding are different technologies, process control issues are similar for each. Variation in the process can and should be minimized in the selection of capable machinery, the design of the fixturing, and the selection of the tooling (inserts, cutters, grinding wheels, etc.). Process control and inspection techniques vary depending on the characteristics being generated, the capability of the process, and the quality requirements specified on the blueprint (classification of characteristics). Machine controls have allowed technologies such as automatic compensation and redundant tooling to significantly reduce process variation due to tool wear and other time-related variations. The selection of the machine to be used is a big factor when analyzing the FMEA and developing control plans.

Quality Control and Inspection of Powder Metallurgy Secondary Operations

Pat Kenkel, John Engquist, and Mike Blanton, Burgess-Norton Manufacturing Company

Process Control Methods

Many methods are used to control part conformance in manufacturing processes. Control plans should be selected to minimize the financial impact to the process (either in the cost of the gage and/or the time required to gage the part), but also to allow for optimal control of the process (100% inspection controls the outgoing product, but typically is not a cost-effective-inspection method). As stated above, the control plan must include the gaging method, the control method, the frequency, and the responsibility. A discussion of each area follows.

Gaging Method. The two types of commonly used gaging in the manufacturing environment are attribute gages and variable gages. Attribute gaging is used to check conformance or nonconformance for a specific dimension/tolerance. Variable gaging is used to record actual dimensional values for comparison to the tolerance specification. Both types of gages can be used to effectively control processes.

Typically, attribute gaging is used to control relational features (GDT features such as true positions, etc.) and dimensional features that are either incidental characteristics or produced by an extremely capable and stable process (i.e., C_{pk} values over 2.00) (see the article "Planning and Quality Control Powder Metallurgy Parts Production" in this Volume for definition of C_{pk} and other statistical control indices). Attribute gages range from inexpensive go/no-go plug gages to complex, part specific

true position gages that can be very expensive. For well-centered processes, these gages can be useful in helping the operator control the process. It should also be noted that restricted tolerance attribute gaging, also called "narrow limit" gaging (50% or 75% of the tolerance band), can be used to monitor and compensate the process before nonconforming parts are produced.

One of the biggest advantages of powder metallurgy is the ability to press features that are complex. The secondary operations mentioned above refine pressed features and/or generate new features that often have a geometric relationship to pressed features. With proper GDT, functional attribute gaging is a cost-effective way to control the relationship of features generated by secondary operations to those generated at the press.

Variable gaging allows the operator to record specific dimensional data that can then be analyzed and used to make decisions on process adjustments. Variable gages are used to control processes that are incapable and/or unstable over time (tool wear, etc.). Variable gaging is frequently used on significant characteristics that require a high degree of control. Variable gages can be standard components such as digital micrometers or complex gages that are part specific. In order for the variable gage to be effective for product acceptance decisions, the gage must have a minimum resolution of 10 divisions over the tolerance band being measured (0.010 in. tolerance band needs a gage capable of measuring in 0.001 in. increments).

Variable data is generally required by customers to evaluate the capability of a process. Gage resolution used to estimate process capability may be greater than the gage resolution required for product acceptance. It should also be noted that variable gaging is often used to establish process capability, but the process can then be monitored using attribute gages (if capability is high, for example). In these instances, gaging costs may still be high, but the cost impact to the process has been minimized by using attribute gages.

Control Method. The most common control method for manufacturing processes is statistical process control (SPC). Three common statistical tools are widely used in manufacturing to control processes. For ease of understanding their use and effectiveness, they are discussed below (in order of effectiveness, least to greatest).

Sampling tables were used in industry long before the current statistical approaches were made popular. Typical sampling tables, such as MIL-STD-105E (current standard ANSI/ASQC Z1.4--1993), were developed for use with attribute gaging and mandated some acceptable quality level (AQL) limit as a decision criteria for accepting or rejecting a lot of product. Statistical methods were used to determine what the sample sizes should be for a specific lot of material. Sampling tables can still be used as a quality control tool, but are usually used to control lots of product (post-process inspection plans), not the process itself.

A histogram/frequency distribution can be used in process control to visualize the pattern of variation being generated by an operation. This picture of the data is very useful in easily determining (1) the approximate central value or central tendency (average), (2) the spread of the values (variation), and (3) the relationship of the values to the process specifications (capability index). A histogram can turn machine-recorded values (Fig. 3) into a beneficial tool to monitor a process (Fig. 4).

.502	.501	.504	.502	.500	.502	.504	.501	.503	.503

Fig. 3 Data generated at a machine

Fig. 4 Histogram of the same data as Fig. 3. A histogram gives a "picture" of the process that is easily analyzed by the operator.

Control Charts. Time-ordered data are an effective way to view process information. Control charts vary in the presentation of the data collected (individuals chart, \bar{x} -bar and R , group charts, etc.), but are useful tools to control processes over time. For example, if the same data used in the histogram in Fig. 4 are displayed as an individual chart (or average chart) (Fig. 5), the same information (average, variation, process performance) can be approximated. Because the control chart is time ordered, trends (decreasing or increasing values) can also be depicted. The range is determined as the difference in subsequent values and plotted on a range chart (Fig. 6). The range chart shows how stable the process is (the variation from one reading to the next).

Fig. 5 \bar{x} or \bar{x} -bar chart for 49 diameter measurements

Fig. 6 Range chart of variations for measurements in Fig. 5

Other control methods (nonstatistical) can be used to control manufacturing processes. If the features to be controlled are generated by the compacting or sizing tooling, an "audit" of the characteristic may be sufficient. The audit is usually done at setup (first piece) and/or at the end of the production run (last piece). This ensures that no dramatic change occurred during the process.

Another control method is 100% inspection. Inspection of all parts may be necessary if the process is incapable or out of control. If possible, 100% inspection should be avoided--it adds cost to the operation and is not an effective way to control the process (100% inspection is not 100% effective). The best control methods for capable and stable processes are statistically based. Mistake-proofing is a cost-effective approach to 100% inspection in some cases.

Frequency. The sampling frequency for a manufacturing process varies based on the classification of the characteristic, the capability of the process, and the stability of the process:

Process parameter	Inspection Frequency
Classification of characteristics	Increases as characteristics become more critical
Process capability	Decreases as capability increases
Process stability	Decreases as stability increases

A stable and capable process may only use tool control as a control method. The opposite extreme may require 100% inspection. Most process parameters can be controlled using statistical methods with either attribute or variable gaging and varying frequencies of inspection (statistical methods are discussed above).

Responsibility. Organizations assign quality and inspection responsibilities differently. The most effective inspections are done at the point of manufacture by the person(s) performing the manufacturing task. Real-time data collection and instant process feedback is the best control in any manufacturing environment. Obviously, this is not realistic in some instances (heat treating for example), so the responsibility in those situations must be assigned appropriately (to Inspection, for example). The main goal of collecting data should be to control the processes. It is useless to generate data that means nothing after the fact. Every effort should be made to utilize prevention activities, not detection activities, when developing control plans.

Continuous Improvement and Examples

The tools used in quality control and inspection can also be used to continually improve the processes mentioned above. The use of statistical analysis can be used to make small incremental improvements to processes. Design of experiments (DOEs) also utilize statistics to review data and make significant changes to improve existing processes.

Technology has dramatically improved information gathering, and consequently better, faster feedback can be made to the process to improve control. Improvements to equipment, machine tools, programmable logic controllers (PLCs) and computer numerical controllers (CNCs) have enhanced capabilities. Electronic data collection and analysis allows for communication between the machine and the data collector, thereby providing automatic compensation and reduced variation in the process. In-process gaging techniques can be used to measure the part as it is being processed (machined, ground, etc.). Below are examples where quality control and inspection techniques have been used to improve existing (or new) processes.

Case Study No. 1: Tool Life Study on CNC Lathe. A tool life study was conducted on a new CNC lathe. The lathe was purchased with an automatic tool compensation option. To implement automatic compensation, a study was done using statistical methods. A design of experiment was conducted to select the optimal tool insert and feed rate to be used (Fig. 7).

Fig. 7 Parts produced versus feed rate from lathe test

Once the best tool insert was selected, parts were 100% inspected and recorded using real-time data collection. Adjustments were made only when the measured dimension reached the high limit of conformance. The manual adjustment targeted the low conformance limit of conformance. The machine continued to produce parts until the measured dimension was again at high limit where another manual adjustment was made. This mode of operation continued over several "manual" adjustments in order to determine the tool life of the insert and the size degradation of each cutting cycle. The study showed that tool life had a predictable trend (Fig. 8). With this information, the amount of compensation and the insert life span were entered into the lathe program. The lathe now runs with no operator input and less time-ordered variation than previously observed. Variation related to tool wear and operator "hunting" was virtually eliminated. Ongoing verification of the effectiveness of automatic compensation continues with real-time control charts.

Fig. 8 Trend of dimensional change from tool wear

Case Study No. 2: Capability Study--New Equipment Purchase. A runoff of a new CNC machining center was performed and all data recorded. The runoff criteria was met, but a pronounced pattern existed in the collected data (Fig. 9). The pattern consisted of four repeating readings that drifted over time. Automatic compensation was originally set at four pieces. It was determined that the amount of compensation was set too high, and an adjustment was made. The machine tool vendor was contacted about the repeating pattern, and upon investigation adjustments were made to the tooling and machine controls (thermal adjustments, etc.). The second run of parts revealed the results shown in Fig. 10. Again, a slight drift was observed over time. After one more adjustment to the automatic compensation, the process became capable and very stable.

Fig. 9 Variation in runoff from startup test of a new CNC center

Fig. 10 Runoff variation after thermal adjustments and adjustments with tooling and machine controls

Case Study No. 3: Capability Study--Existing Outside Diameter (OD) Grinder. An existing process on an OD grinder was set to run with a 0.0005 in. tolerance band on the OD. The process was stable, but marginally capable (Fig. 11a). The product was measured and charted on every machine cycle. The process drift was analyzed to determine wheel wear and offsets (and timing) were set. Using real-time data collection, a central tendency within 0.000005 in. was achieved (Fig. 11b). Ongoing process improvements with this process have led to dramatic quality improvements over time (Fig. 12).

Quality Control and Inspection of Powder Metallurgy Secondary Operations

Pat Kenkel, John Engquist, and Mike Blanton, Burgess-Norton Manufacturing Company

Summary

The manufacture of P/M components represents focused technologies and creative innovations. When product tolerances and/or product features cannot be attained by conventional P/M processing (press-sinter), secondary operations are required. These operations may include repressing, heat treating, machining, grinding, and others. Quality requirements mandate control of operations throughout the manufacturing process. Although processes vary in technology, the quality control and inspection methodology is consistent.

A good quality planning process includes:

- Preliminary discussions between the customer and supplier (understanding of the product and the form, fit, and function of the component)
- Thorough understanding of the quality requirements (i.e., classification of characteristics, quality index requirements, etc.)
- The use of engineering tools such as FMEAs to plan manufacturing processes
- A control plan that includes gaging methods, control methods, inspection frequency, and responsibility

Consistent use of these tools and the methodology minimize the risks and failure modes in any manufacturing process. Process control methods are also used for continuous improvement.

Testing and Evaluation of Powder Metallurgy Parts

Introduction

FABRICATED P/M PARTS are evaluated and tested at several stages during the manufacturing for part acceptance and process control. This can include various types of tests, such as:

- Evaluation of dimensional changes
- Density measurements
- Hardness testing
- Mechanical testing
- Crack detection
- Metallography

This article briefly reviews the first five items, while metallography is discussed in the article "Metallography of Powder Metallurgy Materials" in this Volume.

Testing and Evaluation of Powder Metallurgy Parts

Dimensional Evaluation

Dimensional accuracy of P/M sintered parts is determined with the same measurement techniques that are used for wrought materials. Other testing methods for P/M materials are specialized, however, such as determination of surface finish. For sintered parts, a chisel-pointed stylus is used to de-emphasize the effects of porosity. A conical stylus tends to engage porosity, thus giving an exaggerated measurement of roughness. Pores do not interfere mechanically with mating parts (Ref 1).

During the manufacture of sintered parts, dimensional change must be accommodated for during each processing step. Causes of these changes include:

- Elastic springback during ejection from tooling used for cold pressing
- Growth or shrinkage during delubrication, presintering, and sintering
- Elastic springback from tooling during cold repressing or sizing
- Thermal contraction from the tools used in hot forging or hot repressing
- Tool wear in cold or hot compacting
- Machining tolerances at secondary machining and associated tool wear
- Distortion during annealing
- Growth or shrinkage during carburizing, nitriding, or neutral hardening
- Shrinkage during tempering
- Growth during steam blackening

Parts manufacturers must be familiar with the amount of dimensional change to expect for the materials and equipment in use so that tooling can be produced that accommodates these changes and produces accurate parts. Understanding and controlling these factors is essential to commercial P/M parts manufacturing, as discussed in the following paragraphs.

Springback at Molding. Metal powders have varying yield points, and green compacts have varying elastic moduli. Thus, even if a tool set is perfectly rigid, the size of the ejected compact is larger than the tool cavity. This amount also varies, depending on molding pressure and powder characteristics. Furthermore, expansion is not uniform or isotropic, except for right circular cylinders. Dies exhibit some compliance, and split dies distort slightly in use, resulting in further changes in green dimensions. Thus, green dimensions depend on die design and construction.

Sintering Dimensional Change. Compacted elemental powders generally shrink during sintering. The compacts begin as unsintered objects that are larger than die size and eventually shrink below die size. This phenomenon is illustrated in Fig. 1 for pure iron (F-0000), based on the 89.61 mm (3.528 in.) dimension of a Metal Powder Industries Federation (MPIF) standard 10 tensile bar. Prealloyed powders generally shrink during sintering (see the curve for AISI 4680 steel in Fig. 2). Graphite additions to iron do not inhibit shrinkage from green dimensions, but they do cause additional elastic springback from the mold dimension. Such materials thus begin sintering $\sim 0.5\%$ larger than die size (see Fig. 2).

Fig. 1 Dimensional change on sintering of F-0000, F-0008, and 45P irons. Sintered at 1120 °C (2050 °F) in dissociated ammonia. Green density: 6.8 g/cm³. 45P: atomized iron plus 0.45% phosphorus added as ferrophosphorus master alloy. F-0000: pure atomized iron. F-0008: atomized iron plus 0.9% graphite

Fig. 2 Dimensional change on sintering of FC-0208, 4680, and FN-0208 irons. Sintered at 1120 °C (2050 °F) in dissociated ammonia. Green density: 6.8 g/cm³. FC-0208: sponge iron plus 2% Cu plus 0.97% graphite. 4680: prealloyed AISI type 4600 steel plus 0.9% graphite. FN-0208: atomized iron plus 2% Ni plus 0.9% graphite

Elements such as carbonyl nickel accelerate the shrinkage of iron mixes (see FN-0208 in Fig. 2). In iron mixes, copper tends to cause growth. The higher the density of an iron particle (low surface area), the greater its dimensional growth with copper

additions. Carbon dissolved in iron prior to copper diffusion inhibits growth (see Fig. 3 and 4). Growth of copper-tin premixes is shown in Fig. 5.

Fig. 3 Dimensional change on sintering of MH100 iron. Values inside the graph indicate the percentage change from die size. MH100 iron sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Green density: 6.4 g/cm³. Source: Ref 2

Fig. 4 Dimensional change on sintering of ATOMET 28 iron. ATOMET 28 powder plus 0.9% graphite plus 0.75% zinc stearate plus copper as shown. Green density ranges from 6.2 to 7.0 g/cm³. Sintered 30 min in dissociated ammonia at 1120 °C (2050 °F). Source: Ref 3

Fig. 5 Dimensional change on sintering of 90-10 bronze. PMB 18 premixed bronze sintered 15 min in hydrogen at various temperatures. Green density: 6.3 g/cm³. Source: Ref 4

Growth of these bronze premixes is strongly density dependent, with densities near 7.0 g/cm³ providing greater growth and densities near 6.0 g/cm³ providing significantly less. Dimensional change data during sintering are complicated by the fact that dimensional change parallel to the pressing direction is not the same as dimensional change occurring perpendicular to the pressing direction.

Annealing Dimensional Change. Annealing dimensional change is similar to change occurring during extra sintering or stress relaxation, as compacts continue to shrink. Lower density compacts experience the most shrinkage. With pure copper that has been pressed, sintered, and repressed to high density, annealing in a hydrogen atmosphere that contains gases can cause growth or blistering. The hydrogen diffuses into the pores that are isolated from the surface. If hydrogen encounters residual oxygen, water vapor is formed, which causes expansion and growth. This phenomenon also can be caused by residual sulfur or the presence of lubricant. Consequently, the initial sintering of pure copper should remove as many impurities as possible while the pores are still open.

Dimensional Change during Heat Treating. Carbon and nitrogen absorbed during carburizing and nitriding of steel cause growth in areas in which they dissolve. During quenching, regions that form martensite experience growth. Thus, if a small part is through-hardened to all martensite, all regions (inside and outside diameter) experience outward expansion. Many sintered steels have modest hardenability, and only the outer 3.2 mm (0.125 in.) adjacent to surfaces forms martensite and expands.

On quenching a medium- or large-sized part (with a section >9.5 mm, or 0.4 in.), the interior remains as ferrite and fine pearlite, experiencing neither shrinkage nor growth. The outer surfaces expand outward, and the inner surfaces shrink inward. This phenomenon also is evident in case-hardened wrought parts. Thus, prediction of exact size change during heat treatment is difficult.

Steam Blackening. Sintered parts frequently are treated in steam at 540 to 595 °C (1000 to 1100 °F) for 1 to 4 h to fill the pores and coat the surface with a hard coating of black iron oxide. The coating causes a uniform growth of 0.0025 to 0.0050 mm (0.0001 to 0.0002 in.) similar to electroplating. The amount of blackening should be controlled, as measured by hardness and destructive break tests; excessive oxide coating thickness may lower impact properties. Thickness of the oxide layers also

can be measured metallographically with a polishing procedure described in the section of this article on density measurement.

Evaluation of Dimensional Change in Incoming Powder. New lots of blended or raw powder are checked against internal standard lots to ensure consistent sintered dimensional change. Transverse-rupture bars 31.8 by 12.7 by 6.4 mm (1.25 by 0.50 by 0.25 in.) are molded at a fixed density or pressure from both the standard and test lot of powder. The two sets of bars are sintered simultaneously in a laboratory or production furnace. Dimensional change in the 31.8 mm (1.25 in.) length are checked against the requirements of American Society for Testing and Materials (ASTM) standard B 610.

Although dimensional change from sintering a bar made from the standard powder can differ from previous tests, comparable dimensional changes in the test bar made from incoming powder demonstrate the difference in the performance of the powders. Dimensional change in test and standard lots must agree to within a specified range ($\pm 0.1\%$ of the bar length). These bars also can be used to evaluate sintered strength and hardness.

Dimensional Control. Table 1 illustrates typical dimensional tolerances of P/M materials. Separate tolerances apply to as-sintered, as-sized, and as-heat treated conditions. For concentricity between an inside diameter and an outside diameter, a total indicator reading of ≤ 0.075 mm (0.003 in.) is permitted. The distance between holes can be as great as 0.075 mm + 0.013 mm/mm (0.003 in. + 0.0005 in./in.). Gears can be molded to American Gear Manufacturers Association (AGMA) class 7, which is limited primarily by the concentricity of the bore to pitch line. If gears are held on the pitch line and bored more concentrically, AGMA class 10 or 11 is achieved.

Table 1 Typical P/M tolerances (other than length)

Material	Condition					
	As-sintered		As-sized		As-heat treated	
	mm	in.	mm	in.	mm	in.
Brass	± 0.089	± 0.0035	± 0.013	± 0.0005
Bronze	± 0.089	± 0.0035	± 0.013	± 0.0005
Aluminum	± 0.051	± 0.002	± 0.013	± 0.0005	± 0.013	± 0.0005
Iron	± 0.025	± 0.001	± 0.013	± 0.0005
Copper alloy steel	± 0.038	± 0.0015	± 0.025	± 0.001	± 0.038	± 0.0015
Nickel alloy steel	± 0.038	± 0.0015	± 0.025	± 0.001	± 0.038	± 0.0015
Stainless steel	± 0.025	± 0.001	± 0.013	± 0.0005

Note: Up to 12.7 mm (0.500 in.). Length tolerance, ± 0.102 mm (± 0.004 in.), unless machined or ground. Source: Ref 1

Other processes, such as P/M hot forging, injection molding, and high-temperature sintering, produce wider tolerances than presented in Table 1. Powder metallurgy forged dimensional tolerances are given in Table 2. High-temperature sintering tolerances are given in Table 3. Injection-molded tolerances range from 0.075 to 0.10 mm/mm (0.003 to 0.004 in./in.), even though parts have experienced 12 to 15% linear shrinkage (Ref 5).

Table 2 Tolerances on P/M forged parts

Parameter	Nominal dimension		Tolerance	
	mm	in.	mm	in.

Testing and Evaluation of Powder Metallurgy Parts

Measurement of Density

Density is the ratio of mass to volume. For a given material, degree of sintering, and heat treatment, density determines mechanical and physical properties. For example, higher density in sintered steels results in higher tensile strength, elongation, and impact resistance values. As-pressed, or green, density also influences growth or shrinkage that occurs during sintering. With nonuniform green density, parts grow or shrink nonuniformly, as in a thin-walled bronze bearing with a low-density region equidistant from the ends. This results in a significantly smaller diameter at midlength than at the ends and necessitates repressing or sizing for close dimensional control.

If cubes or right cylinders could be extracted from actual parts, linear dimensions could be measured and volume could be calculated easily. From the weight of a part, density can be easily calculated. This yields a value that, under ideal conditions, differs by 0.04 g/cm³ (0.5%) from a reference (Ref 6). Unless the sintered part is directly molded to an easily measured shape,

such as a transverse-rupture bar (31.8 by 12.7 by 6.4 mm, or 1.25 by 0.50 by 0.25 in.), this method of measuring linear dimensions is used infrequently.

Methods Based on Archimedes' Principle. Typical methods of measuring density depend on Archimedes' principle, in which hydrostatic forces in liquids exert buoyant forces proportional to the part volume. This measurement is standardized in ASTM B 328 (Ref 7), MPIF test method 42 (Ref 8), and International Standards Organization test method ISO 2738 (Ref 9). When an object is immersed in a liquid, the liquid exerts an upward buoyant force that is equal to the product of the object volume and the density of the liquid. The difference in weight between an object weighed in air and its weight when suspended in water is equal to the object volume in cubic centimeters times the density of water. Approximating the density of water as unity:

$$V = W_{\text{air}} - W_{\text{water}}$$

where V is the volume, cm^3 ; W_{air} is the weight in air, g; and W_{water} is the weight of object suspended in water less the weight of the suspending wire in water (tare), g. Density in g/cm^3 is then:

$$\text{Density} = W_{\text{air}} / (W_{\text{air}} - W_{\text{water}})$$

For unsintered materials molded with 0.75% lubricant, pores are well sealed, and water cannot penetrate. For such parts, the above calculation is suitable. It is also suitable for materials with pores that are sealed off from the surface (materials close to theoretical density). For most sintered materials that are 70 to 95% dense, water tends to infiltrate the pores during weighing in water. This minimizes the buoyancy effect of the water (that is, the liquid is acting on a smaller volume) and results in an erroneous calculation of low volume.

This low volume then causes an erroneously high density value. Infiltration of water into pores usually is accompanied by air bubbles escaping from the part. If the part is blotted to remove surface water and reweighed in air after weighing in water, any weight gain indicates that water has entered the pores. Although not a standard procedure, volume can be approximated as the weight in air after removing the part from the water, minus the weight in water.

To prevent infiltration of water, all three standard test methods require that the pores of the part be filled with oil. Oil impregnation is done after the part is weighed in air; this is carried out under vacuum or by immersion in hot oil. Oil prevents the water from entering the pores. The volume of the part is then determined as the part weight in air with oil in the pores, minus the weight of the oiled part suspended in water. Care should be taken to select an oil that is not soluble in water or not soluble in water plus wetting agent. Such oils also must exhibit superior demulsibility.

The precision of the ISO method is $\pm 0.25\%$, regardless of sample density, and assumes a water density of $0.997 \text{ g}/\text{cm}^3$. Moyer (Ref 6) has reviewed the literature on precision methods of density determination (Ref 10, 11, 12, 13, 14, 15, 16) and has devised a method that provides accuracy to two or three decimal places, depending on sample porosity. The basic measuring apparatus is shown in Fig. 6. Requirements of precision density measurement include:

- Balance capable of measuring to the nearest 0.0001 g
- Vibration- and draft-free atmosphere
- Measurement of the density of the immersing liquid (water) by checking the density of a substance of accurately known density (four decimal places)
- Conversion of all densities back to 20 °C (68 °F) by compensating for thermal expansion of the sintered part
- Maintenance of liquid level at a constant height on the suspending wire
- Careful brushing of all bubbles from the test object

Fig. 6 Density measurement apparatus

Using the above procedures, Moyer reports standard deviations of 0.0130 to 0.0005 g/cm³ on 17 g parts with densities ranging from 5.12 to 7.85 g/cm³, respectively.

To determine density variation from one point to another in a complex part, the available samples must be considerably <17 g. According to ASTM B 328, a minimum sample of 2 g is recommended, because a relatively high error rate results from measuring small samples. Table 4 shows density errors that can occur because of weighing errors, if all weighing errors are assumed to occur so as to maximize density errors. A 1 g sample on a balance accurate to 0.01 g (per ASTM B 328) could result in a density range from ± 1.05 g/cm³ to a mean of ~ 6.5 g/cm³.

Table 4 Effect of sample size and weighing errors on density measurement

Balance accuracy (weighing error), g	Density range, g/cm ³ , for a sample weight (at 6.50 g/cm ³) of:		
	0.1 g	1.0 g	10.0 g
0.01	0	± 1.0459	± 0.0922
0.001	± 1.0459	± 0.0922	± 0.0091
0.0001	± 0.0922	± 0.0091	± 0.0009

Metallographic estimates can be made of the area fraction of porosity, which is numerically equal to the volume porosity, and thus the density of sintered materials. The method is not standardized, and accuracy of results depends on the skill of the metallographer to define the correct area fraction of porosity. Frequently, the amount of porosity is exaggerated or minimized because of overpolishing or underpolishing (Ref 17). A suitable method for sintered iron-base materials is to:

- Remove oil and cutting fluids from the pores by Soxhlet extraction or heating in air or atmosphere to 315 °C (600 °F).
- Impregnate the pores with epoxy resin; generally does not fill all the pores, and polishing is required.
- Mount the sample in epoxy, bakelite, or other suitable medium.
- Wet grind through 600 mesh silicon carbide-coated paper.

- Open smeared pores by immersion etching in 2% nital for 1 min.
- For samples up to 12.7 by 12.7 mm ($\frac{1}{2}$ by $\frac{1}{2}$ in.), polish with 1 μ m alumina on Struers felt cloth or an equivalent long-napped cloth for 3 min on a 250 rpm, 20 cm (8 in.) diam wheel, using moderate to heavy hand pressure. This opens pores and exaggerates their presence.
- Restore pores to true area fraction by polishing for 3 min by hand, using a 1 μ m diamond on Struers MOL cloth or equivalent, and moderate to heavy pressure. Use a 20 mm (0.8 in.) strip of diamond paste per specimen.
- Final polish for 30 to 60 s, using 0.05 μ m alumina with Buehler Microcloth or equivalent long-napped cloth on a 20 cm (8 in.) diam polishing wheel at 125 rpm with light pressure; an automatic polisher is suitable.
- Wash, dry, and examine unetched at 200 \times .

A simple manual method to estimate the area fraction of porosity uses a 100 by 120 mm (4 by 5 in.) photograph of the sample taken at a magnification of about 200 \times . A grid of 13 by 17 thin black lines 6.4 mm (0.25 in.) apart should be constructed on clear vinyl to fit on the photograph. The grid contains 221 intersections. By placing the grid over the photograph, then counting the number of intersections that lie completely over the pores and adding one half of the number of intersections that are on the edge of the pores to obtain the effective number of intersections, the area fraction of porosity is calculated:

$$A_p = (221 - N_p)/221$$

where A_p is the area fraction of porosity; and N_p is the effective number of grid intersections overlaying pores. For common iron-base materials, theoretical density is 7.87 g/cm³; density (ρ) can be estimated as:

$$\rho = (1 - A_p) \times 7.87 \text{ g/cm}^3$$

This method can achieve a precision of about ± 0.1 g/cm³, depending on the laboratory. The advent of metallography with a television monitor and quantitative metallographic functions allows rapid measurement of area fractions of pores. This method is highly dependent on proper sample preparation.

Testing and Evaluation of Powder Metallurgy Parts

Apparent Hardness and Microhardness

Porous materials exhibit wider variation in hardness testing than wrought counterparts. The entrance of the indenter into pores or groups of pores generally causes this effect. At least five consistent readings should be taken, in addition to any obviously high or low readings, which are discarded. The remaining five readings should be averaged.

Because most published data show typical hardness values, the buyer and seller must agree on specified or minimum values. The seller and user of P/M materials also should agree on which area or areas of a part are to be hardness tested. The average of five or more consistent readings must meet the standard hardness, not any single reading. Recommended scales for taking accurate measurements are summarized in Table 5.

Table 5 Common hardness scales

Material	Sintered hardness scale	Heat treated hardness scale
Iron	HRH, HRB	HRB, HRC
Iron-carbon	HRB	HRB, HRC
Iron-nickel-carbon	HRB	HRC
Prealloyed steel	HRB	HRC
Bronze	HRH	...
Brass	HRH	...

Unlike fully dense materials, high hardness does not mean high tensile strength. As discussed previously, 15 to 30% fine pearlite in the iron-carbon sintered materials improves tensile strength: consequently, it is evident that high hardness values are not an indicator of high strength. Because P/M steels exhibit low hardenability, hardness specifications should be based on parts that have demonstrated successful service.

Although not yet widely used, the Rockwell B scale may be combined with a carbide ball for testing and controlling hardened parts. Scattering of data is minimized with the Rockwell B 1.58 mm ($\frac{1}{16}$ in.) diam ball, and it is useful up to 120 HRB (Ref 18, 19).

Microhardness of porous materials can best be measured with Knoop or diamond pyramid hardness indenters at loads of 100 g or greater. In atomized irons, particles exhibit minimal porosity; consequently, the Knoop indenter is suitable. It makes a very shallow indentation and is only infrequently disturbed by entering undisclosed pores. Care should be exercised in preparing the sample surface (see the guidelines given in the article "Metallography of Powder Metallurgy Materials" in this Volume. Use of the diamond pyramid indenter is particularly well suited to irons, which contain numerous fine internal pores.

Because of its greater depth of penetration, the diamond pyramid indenter frequently encounters hidden pores. Microhardness testing and measurement of case depth are covered by Metal Powder Industries Federation standard MPIF 37.

For examining tempered steels, a light etching in 2% nital for 6 s is recommended. Fine pearlite appears as dark areas, unresolved at 1000 \times . Martensite appears light colored, with little or no evidence of platelets or needles (Fig. 7). This degree of etching enhances clarity and contrast for measuring the diamond indentation. Subsequent darker etching clearly shows the martensite needles and any retained austenite or carbides. Picral (4%) is recommended for subsequent etching (15 s) by immersion.

Fig. 7 Hardened and tempered Fe-0.8C alloy. Light areas are martensite (60 HRC); dark areas are fine pearlite (40 HRC). 4% picral etch

For microhardness testing of sintered steels, care must be exercised in the definition of a case and the choice of microconstituent to be tested. For example, in a carburized and quenched nickel steel with 0.3% C in the core, martensite, fine pearlite, ferrite, and nickel-rich areas are visible. Nickel-rich areas should be ignored. The surface is nearly all martensite with some fine pearlite. If 50 HRC is defined as the case depth cut-off, the existence of a fine pearlite colony, which is below 50 HRC, would seem to indicate that the reading was taken beneath the case. Case may be defined as the point where there is <50% martensite by area, or where the hardness falls below the 50 HRC equivalent. By comparison, in testing a wrought material without porosity, a heavier load that makes a large indentation should be used, which averages the microstructures while pinpointing the 50 HRC equivalent. In a P/M steel, this would result in the pores being averaged in with the other phase.

The use of light loads (<100 g) causes errors when converting to the Rockwell C scale if the 500 g Rockwell conversion table is used (Ref 20). An alternative is to provide individualized calibrations by removing pieces from several Rockwell standard blocks, with hardnesses ranging from 20 to 60 HRC, and metallographically mounting the working faces. These standards are carefully polished, allowing a direct calibration to be made between the Rockwell C scale and the length of the indentation. When this calibration is graphed, an unknown sample can be taken, the length (in filar units) of the hardness indentation made at 100 g can be measured, and the filar units can be converted to Rockwell C values.

Mechanical Testing/Tensile Testing

MPIF standard 10 describes specimens for tensile testing. Specimens include flat unmachined test bars or machined rounds. Unmachined flats are more prone to slippage of grips or breakage in the gauge region.

For testing to be meaningful, it is important to verify that such bars are free of microlaminations (Ref 21), which requires careful metallographic evaluation. Highest quality bars are molded in well-bolstered die sets (890 kN, or 100 ton rating), with generous exit taper, high green strength powder, and top punch hold-down, if possible. The formation of microlaminations is accentuated by high molding pressures of 415 to 1380 MPa (30 to 100 tsi).

With all test bars, it is necessary to determine that substantial carburization or decarburization resulting from sintering or hardening does not exist. If bars are heat treated, the microstructure at the surface and in the interior should be described in the test report, because many P/M steels have low hardenability.

For heat treated materials, unmachined flat specimens tend to slip in the grips. A machined bar provides more accurate data. The machined bar shows an increase in apparent tensile strength of $\leq 50\%$ compared to molded bars. Even with machined bars, some heat treated materials exhibit such low elongation that failure occurs prior to reaching 0.2% permanent deformation.

Transverse Rupture Strength. The transverse-rupture test breaks a 31.8 by 12.7 by 6.4 mm (1.25 by 0.5 by 0.25 in.) test bar as a simple beam. The test is theoretically valid only for perfectly brittle materials and measures the stress in the outer fiber at fracture. For many sintered steels, transverse-rupture stress is considered to be equal to twice the ultimate tensile strength. This is only an approximation. MPIF standard 35 presents transverse-rupture stress values that correspond with ultimate tensile stress values for common P/M materials.

The transverse-rupture test is useful for comparing and evaluating materials for strength, even if the bar bends before fracture. These bars are preferred, because they can be molded and sintered conveniently. Testing is faster than when using a tensile bar. When heat treated, the test bar does not experience distortion. This testing procedure is used mainly as a quality control tool to ensure the maintenance of minimum mechanical properties. During P/M part production, this method is used to evaluate properties of incoming powder, such as compressibility, sintered strength, and dimensional change.

Unnotched Charpy Impact Strength. A 10 by 10 by 76 mm (0.35 by 0.35 by 3.00 in.) molded bar is used for impact testing. The unnotched bar provides a more sensitive test, suitable for use on materials with an impact strength below 14 J (10 ft · lb). The bar is conventionally struck on the surface that contacted the die at molding.

Proof Testing. The most common method of demonstrating the strength of sintered parts is through mechanical tests that stress parts to failure. Qualification samples or first production lots are used to establish desired strength values; these data are incorporated in the part design specification.

For testing gears, several teeth are removed. The remaining teeth are loaded in a predetermined arrangement on a fixture. The load to fracture is recorded. To be meaningful, the destructive test must imitate service loading on the part.

Impact or drop weight tests also are used to evaluate materials. A drop weight test does not only use an acceptance or rejection evaluation. This testing procedure investigates the impacts above the acceptance level and below the rejection value. When a part does not break, each succeeding load is increased until breakage occurs. Thus, if load P does not break a part, $1.05 P$ is used on the succeeding impact.

Testing and Evaluation of Powder Metallurgy Parts

Crack Detection

Crack detection is accomplished by various methods, such as mechanical proof testing, metallography, and filtered particle or magnetic particle inspection. Promising nondestructive testing methods for P/M applications also include electrical resistivity testing, eddy current, and magnetic bridge testing, magnetic particle inspection, ultrasonic testing, x-ray radiography, gas permeability testing, and γ -ray density determination. The capabilities and limitations of these techniques are summarized in Table 6.

Table 6 Comparison of the applicability of various nondestructive evaluation methods to flaw detection in P/M parts

Method	Measured/detected	Applicability to P/M parts ^(a)		Advantages	Disadvantages
		Green	Sintered		
X-ray radiography	Density variations, cracks, inclusions	C	C	Can be automated	Relatively high initial cost; radiation hazard
Computed tomography	Density variations, cracks, inclusions	C	C	Can be automated; pinpoint defect location	Extremely high initial cost; highly trained operator required; radiation hazard
Gamma-ray density determination	Density variations	A	A	High resolution and accuracy; relatively fast	High initial cost; radiation hazard
Ultrasonic imaging: C-scan	Density variations, cracks	D	B	Sensitive to cracks; fast	Coupling agent required
Ultrasonic imaging: SLAM	Density variations, cracks	D	C	Fast; high resolution	High initial cost; coupling agent required
Resonance testing	Overall density, cracks	D	B	Low cost; fast	Does not give information on defect location
Acoustic emission	Cracking during pressing and ejection	C	D	Low cost	Exploratory
Thermal wave imaging	Subsurface cracks, density variations	D	C	No coupling agent required	Flat or convex surfaces only
Electrical resistivity	Subsurface cracks, density variations, degree of sinter	A	A	Low cost, portable, high potential for use on green compacts	Sensitive to edge effects
Eddy current/magnetic bridge	Cracks, overall density, hardness, chemistry	C	A	Low cost, fast, can be automated; used on P/M valve seat inserts	Under development
Magnetic particle inspection	Surface and near-surface cracks	C	A	Simple to operate, low cost	Slow; operator sensitive
Liquid dye penetrant inspection	Surface cracks	C	D	Low cost	Very slow; cracks must intersect surface
Pore pressure rupture/gas permeability	Laminations, ejections, cracks, sintered density variations	A	A	Low cost, simple, fast	Gas-tight fixture required; cracks in green parts must intersect surface

(a) A, has been used in the production of commercial P/M parts; B, under development for use in P/M; C, could be developed for use in P/M, but no published trials yet; D, low probability of successful application in P/M

The problem of forming defects in green parts during compaction and ejection has become more prevalent as parts producers have begun to use higher compaction pressures in an effort to achieve high-density, high-performance powder metallurgy (P/M) steels. Proper press setup for molding P/M parts also is critical to prevent cracking. In a flanged part that experiences a change in diameter, density in the hub and flange should be nearly equal. Unequal density leads to powder displacement from one part level to the next and to the formation of shear cracks. Such cracks often occur at 45° to the pressing direction and at

surfaces at the junction (radius) between the hub and flange. At press setup, equal density should be obtained in the hub and flange. A high green strength powder and a press that maintains a small counter pressure on the top of the part during ejection from the tools (top punch hold-down) should be used.

Mechanical Proof Testing. A sampling of sintered parts can be broken to confirm the presence of a suspected cracking problem--for example, pushing flanges off hubs in such a manner that in addition to shear effect there is some stretch effect at the crack. The presence of a few unexplained low readings indicates that an initiating crack is present.

Metallography. Low-powered binocular microscopes can be used to detect cracks at changes in diameter. Metallography is a more time-consuming method. A sampling of parts are sectioned parallel to the pressing direction. When mounted and carefully polished to expose open pores and cracks, the presence of minute cracks is readily apparent (Fig. 8).

Fig. 8 Cracks and unbounded particles at the junction (radius) of a horizontal flange and vertical hub resulting from shear during compaction. Unetched

Liquid-Penetrant Crack Detection. During liquid-penetrant testing, the surface of the part is covered with a colored or fluorescent penetrating fluid that fills all cracks and some pores. Surface liquid is then washed off, leaving the penetrant in the cracks. A layer of developer powder, which acts as a blotter, is applied to the surface. The penetrant leaves the cracks and is absorbed by the developer layer near the crack. Crack indications are visible by color contrast or by fluorescence under ultraviolet light. Most sintered parts have porous surfaces that absorb and then release sufficient penetrant in all regions so that it is impossible to distinguish the crack from the porosity background.

The dye penetrant equipment found in P/M shops is generally used only for checking parts of the tooling and machinery for cracks. The dye does not preferentially reside at cracks in P/M parts, because the pore radius and the crack radius are equivalent. However, there might be an application for green parts because the surfaces of green parts are sealed against penetration by liquids through smearing of the metal powder against the die wall and through the formation of a thin coating of dry powder lubricant on the surface. Cracks intersecting the surface may form an opening in this layer that could be detected by the dye penetrant

Filtered Particle Crack Detection. One proprietary process of filtered particle crack detection (Partek) involves brief immersion of the test piece in a suspension of fluorescent particles. Particles are filtered and collect near the surface of cracks as the fluid enters. Cracks are clearly visible under black light. This one-step method is used to detect cracks in presintered porous tungsten carbide blanks (Ref 22).

To the extent that an unsintered part has open porosity, this method also can be used on green parts. Density cannot be too high, however, and excessive lubricant tends to clog the pores. Successful use of this method on presintered porous tungsten carbide blanks indicates that it may be suitable for sintered P/M parts with open pores into which fluid can enter. Small cracks fluoresce brightly, while large cracks are darker than the surrounding fluorescing surface.

Magnetic Particle Crack Detection. A magnetized part demonstrates abrupt changes in magnetic field when the field crosses a crack. When dry or wet magnetic particles are passed over the part, any magnetic leakage field at the part surface attracts and holds iron particles. These assemblies of particles over cracks are visible with the unaided eye or with black light on fluorescent particles.

This method also detects some near-surface cracks. Unsintered parts, however, are not adequately bonded to support a magnetic flux, and the method is consequently unsatisfactory. Magnetic particle detection methods have been successfully used for many years for inspecting medium-density sintered automotive parts, by both P/M parts producers and automotive manufacturers. It is possible to automate the inspection process by using digital image processing.

Direct Current Resistivity Testing. A voltage field within a conductive solid will create currents that are influenced by structural irregularities, including cracks and porosity. The arrangement shown in Fig. 9 is used to measure the voltage drop in a current field localized between two electrode probes. This method has been used to detect seeded defects in laboratory specimens. It has also been successfully applied to the production of sintered steel parts (Ref 23).

Fig. 9 Four-point probe used in the resistivity test. The outer probe pins are the current leads; the inner pins are the potential leads.

The direct current resistivity test can be used on any conductive material; it is not limited to ferromagnetic materials. Although further development is needed, resistivity measurements appear to be a promising technique for the nondestructive evaluation of both green and sintered P/M parts. In addition to detecting cracks in green parts, as well as part-to-part density variation, studies have shown that changes in resistivity due to poor carbon pickup during sintering were also detectable (Ref 23). Resistivity testing has also been used later in the processing sequence to screen heat-treated parts for incomplete transformation to martensite. Another study has yielded the relative density/conductivity relationship, suggesting that resistivity tests could be used as a rapid check for localized density variations (Ref 24). As with ultrasound, the elastic modulus and the toughness of porous steels can also be distinguished by resistivity checks (Ref 25).

Pore Pressure Rupture Testing of Green Compacts. A novel test is available for detecting ejection cracks in green compacts (Ref 26). A pressure seal is formed around a corner or area of a part where experience has shown that cracks are likely to occur. The area is then pressurized to ~ 3.5 MPa (500 psi) using a fixture such as that shown in Fig. 10. If a crack is present, the gas pressure in the crack will be sufficient to propagate the crack the rest of the way through the part. This would be classed as a proof test rather than a nondestructive test because the part is destroyed if defects are present.

Fig. 10 Pore pressure rupture test for crack detection in green parts. Source: Ref 26

The test can be used in a nondestructive manner on sintered parts. The gas permeability of the pressurized area is measured at reduced pressures, and the presence of cracks or low-density areas is indicated by high permeability, as shown in Fig. 11.

Ultrasonic

Many characteristics of solids can be determined from the behavior of sound waves propagating in them. Ultrasonic signals impinging on a sample at one surface are transmitted at speeds and attenuated at rates determined by the density, modulus of elasticity, and continuity of the material.

Green Compacts. The characterization of green compacts by ultrasonic techniques appears to be hindered by problems of extreme attenuation of the incident signal. In one case, signals of 1 to 20 MHz were transmitted through an 8 mm (0.3 in.) thick compact of atomized iron with 0.2% graphite added. Attenuation did not allow back-wall echo measurement. Density was found to influence the transmitted intensity, with specimens at 95% relative density allowing some degree of transmission over the entire range of frequencies tested, while specimens at 87% relative density damped the incident signals entirely. It has also been shown that the velocity of ultrasound in green parts is highly anisotropic and that the experimental reproducibility is very poor (Ref 27).

Sintered Parts. In sintered parts, both the velocity of sound and their resonant frequencies have been related to density, yield strength, and tensile strength. Plain carbon steel P/M specimens were used in one series of tests, and the correlation was found to be close enough for the test to be used as a quick check for the degree of sintering in production P/M parts (Ref 28). Other work has demonstrated the relationship between sound velocity and tensile strength in porous parts (Fig. 12). The same types of relationships have also been documented in powder forgings (Ref 30).

Fig. 12 Correlation of ultrasonic velocity with tensile strength of sintered steel. Source: Ref 29

Sintered parts have been found to transmit ultrasound according to the relationships shown in Fig. 13. The highest wave velocities occurred in the pressing direction. An additional distinction was found between the velocities in the longitudinal and lateral axes of an oblong specimen, and these results were shown to be reproducible between different powder lots and specimen groups. The anisotropy of velocity diminished at higher densities and disappeared above 6.85 g/cm^3 .

Fig. 13 Anisotropy of ultrasound velocity in sintered transverse rupture strength bars. Source: Ref 27

The relationship between ultrasonic velocity and ultimate tensile strength or tensile yield strength in test bars is shown in Fig. 14 which illustrates this relationship for as-sintered 0.65% carbon steel. Table 7 gives sintering times and densities that resulted in various tensile properties and velocities. With similar data for a specific part, ultrasonic velocity can be easily measured, thereby determining the state of sintering or mechanical properties. It remains to be seen if this process is capable of detecting cracks and other flaws.

Table 7 Characteristics of as-sintered FN-0208 alloy specimens prepared with Ancorsteel 1000B powder, 0.75% carbon, and 0.75% Acrawax C

Metallography of Powder Metallurgy Materials

Leander F. Pease III and Douglas L. Pease, Powder-Tech Associates, Inc.

Introduction

POWDER METALLURGY MATERIALS encompass enough differences to necessitate providing specific specimen preparation procedures in addition to those given in the Section "Metallographic Techniques" in *Metallography and Microstructures*, Volume 9 of the *ASM Handbook*. The major difference between parts made of metal powders and those made of wrought metal is the amount of porosity. Sintered materials generally exhibit 0 to 50% porosity, which affects mechanical properties and strongly interferes with metallographic preparation and interpretation of the structure. When examining micrographs, it is important to understand how the specimens were prepared. Careful metallographic preparation is significant in the analysis of sintered structures because the shape of the porosity is as important as the amount in judging sintered strength and degree of sintering.

In the metallographic preparation of most sintered specimens, the pores are smeared during sectioning, grinding, and rough polishing. This occurs to some degree even in materials whose pores have been filled with plastic resins. Proper polishing should open the smeared pores, then reveal their true shapes and area fractions. Routine metallography of the type used on a

medium-carbon, ingot-base steel will not suffice. Because test method ASTM B 328 (Ref 1) cannot be used to measure density differences over short distances such as 0.25 to 6.25 mm, (0.01 to 0.25 in.), the true amount of porosity must be determined by image analysis to facilitate local density measurement. When the specimen is properly prepared, the area fraction of porosity will equal the volume fraction of porosity, and these must equal the porosity calculated from the actual measured density and pore-free density of a uniformly dense part:

$$V_p = (P_d - M_d)/P_d$$

where V_p is the volume fraction porosity, P_d is the pore-free density, and M_d is the measured density, for example, by ASTM B 328. Detailed information on density and porosity measurements may be found in the article "Surface Area, Density and Porosity of Powders" in this Volume.

Assuming that a part is uniformly 80% dense, in a properly prepared specimen, 20% of the area should appear as porosity. The surface of cold pressed and sintered parts will always be somewhat denser than the interior because of pressure losses caused by interparticle friction. However, parts that are P/M forged in tools at approximately 370 °C (700 °F) can have a chilled surface lower in density than the hotter, softer interior.

During sintering of cold-pressed compacts, the original particle boundaries disappear and result in a plane of fine pores that then grow into larger pores. In as-pressed parts, particle boundaries appear as thin gray lines in the metallographically mounted material. The progress of sintering can be judged by the disappearance of these boundaries. The original particle boundaries are similar to elongated, disk-shaped pores and have very sharp corners. These are extreme stress raisers. There is virtually no bonding across the original particle boundaries. Proper specimen preparation is required to distinguish residual original particle boundaries from the thin, gray boundaries that often appear between the edges of a particle and pores that were smeared during grinding and polishing. Therefore, an improperly prepared specimen with smeared porosity is often erroneously judged to be undersintered. If microhardness testing is to be performed, proper presentation of the porosity will result in fewer Knoop diamond indentations falling into hidden pores and thus in fewer wasted or incorrect readings. For additional information on microhardness testing of P/M materials, see the article "Testing and Evaluation of Powder Metallurgy Parts" in this Volume.

The open porosity in a mounted sintered part may trap water (moisture). During etching, this water may bleed out, resulting in staining. Water also corrodes some sintered materials. It may evaporate and then condense on the objective lens of the microscope, resulting in a foggy image. Etchants cause similar problems. Open porosity may trap abrasives and carry them onto subsequent cloths, which should hold only fine abrasives. The result is an increased tendency toward scratching of specimen surfaces. Filling the pores with epoxy resins alleviates these difficulties, but requires considerable technique.

Many of the interesting structures seen in P/M parts are caused by porosity and by the mixtures of elemental powders that constitute many alloys. These mixtures do not always result in homogeneous, well-diffused structures. Such heterogeneity is not necessarily detrimental and, in certain nickel steels and diffusion-alloyed steels, may be advantageous because the softer nickel-rich phases increase impact resistance and reduce the tendency toward ductility-limited tensile strength. It is therefore important to recognize when the observed heterogeneity is beneficial. The pores allow carburizing and nitriding gases to penetrate the interior of a sintered steel part, resulting in less-well-defined cases on carbon steel and the nitriding of 300 series stainless steels. The P/M steels are generally low in manganese. When the low alloys are prepared as elemental mixes with nickel and carbon, hardenability is lower than for fully dense, homogeneous low-alloy steels. Hardenability is not a problem in the fully dense prealloyed steels fabricated by forging or metal injection molding.

Automatic Grinding and Polishing

An automatic grinder can produce flat specimens using wet SiC papers of 220, 500, and 1200 mesh, 30 N (6.7 lbf) force per specimen, 300 mm wheel, 125 rpm, counterrevolving the specimen. Grind no more than 30 s on a paper, for six 30 mm (1 $\frac{1}{4}$ in.) mounts done at the same time. Before polishing, ultrasonically clean for about 5 min. The ultrasonic cleaner used for washing P/M specimens consists of a power supply and a small tank, which holds a water bath containing a small amount of surfactant such as liquid soap. The surfactant provides the energy coupling needed between the water bath and a beaker of solvent, such as alcohol, is suspended in the bath. The water bath and beaker together should fill the ultrasonic tank to within 25 mm (1 in.) of the top, (to provide protection to heating elements that the ultrasonic cleaner may contain). The specimen is placed inside the beaker and rests face down on cotton wadding or a paper towel. The power source produces high-frequency waves in the room-temperature water bath. The waves strike the beaker and force the alcohol into the pores of the specimen, removing foreign substances. Because the specimen is placed in the alcohol bath, the washing takes place in what soon becomes a contaminated solution. Debris accumulates in the cotton or on the paper towel, and the solution must be changed periodically. In addition to removing polishing grit when changing to successively finer media, it has also been reported that the ultrasonic action may help to open pores that were smeared at grinding (Ref 4).

Rough polishing consists of 10 min on short-nap cloth with a 3 μm diamond paste at 30 N (6.7 lbf) force on each specimen and 125 rpm on a 300 mm (11.8 in.) wheel. Final polishing for 1 to 2 min with 0.05 μm alumina on long-nap microcloth at 125 rpm, 1 N (4.4 lbf) force results in a mount free of scratches and flat to the edge. If the pores were well filled with epoxy resin, they will be seen in their true area fraction and shape. If the interior pores are not well filled, the above procedure must be supplemented by several repetitions of light etching (15 s immersion in 2% nital) and repolishing 1 to 2 min with the 0.05 μm alumina. To learn if the pores are still smeared, examine the mount at about 1000 \times and look for thin gray boundaries of the pore edges, for example, Fig. 9.

Manual Grinding and Polishing

Grinding. Rough grinding of the mount must produce a planar surface for subsequent grinding and polishing. The preferred procedure involves using a water-cooled and lubricated wheel with 240, 400, and 600 mesh SiC papers. The paper is held to a rotating disk that makes use of the vacuum created by a thin layer of water under the sheet of abrasive paper. Alternatively, the paper can be held in place adhesively or by special flat magnets that grip a thin ferrous backing on the grinding paper. The same grinding may be carried out on wet papers placed on top of a sheet of glass. When using grinding wheels, the specimen is held in a fixed position on the wheel so that all scratches are in one direction, which requires even and moderate pressure. When changing papers, the specimen is rotated 90° to allow one to note the disappearance of the previous scratches. The use of one single sheet of SiC paper for more than two or three specimen mounts is not recommended because it leads to lack of

flatness of the specimen surface. Grinding using 240 to 600 grit abrasives and moderate pressure at 125 to 250 rpm on 200 mm (8 in.) laps requires approximately 30 s for each paper. Using Al_2O_3 for edge retention (Fig. 3) gives a hard mount surface that requires longer grinding and polishing times.

It is important to grind a 30° bevel around the mount periphery. This allows the mount to pass smoothly over the subsequent polishing cloths and prevents the plowing aside of abrasives by a sharp edge. Failure to use a bevel slows polishing on long-nap cloths.

Polishing. Following grinding, the specimen is flat to the edges, and the pores are almost completely smeared (Fig. 4). Subsequent polishing generally rounds the specimen edges, because the mounting resin is much softer than the metal specimen. This rounding can be prevented by the use of embedded ceramic materials for edge retention, or such conventional techniques as plating of the specimen surface before mounting. Polishing must open all the pores, show true area fraction of porosity, remove scratches and disturbed metal, and minimize edge rounding. The presence of epoxy resin or wax in the pores facilitates opening the smeared pores, but does not eliminate the problem.

Fig. 4 Pressed and sintered Fe-0.8C alloy (6.8 g/cm^3), as-ground on 600 grit silicon carbide. Micrograph shows the closure of pores and flatness of specimen (the surface is shown at left). Arrows indicate closed pore edges. $95\times$

During polishing, the abrasives first open the pores closest to the specimen edges (Ref 5, 6), giving the impression that surfaces are less dense than interiors (Fig. 5, 6, 7). For ferrous materials, the fastest way to reveal the pores results in slight edge rounding but is adequate for routine work. These steps should be followed:

1. Etch 2 min in 2% nital by immersion. For materials other than low-alloy steels, use the customary agents. Etching before polishing initiates pore opening but does not exaggerate pore size.
2. Rough polish 2 min using $1 \mu\text{m}$ Al_2O_3 moderate hand pressure on a long-nap felt cloth (Ref 7). Use 250 rpm on a 200 mm (8 in.) diam wheel rotating the specimen counter to the wheel to prevent comet tails. The long-nap cloth and the fairly coarse Al_2O_3 rapidly open the pores (see Ref 8 for an example of another technique that requires 300 min).
3. Repeat steps 1 and 2 once or twice. This procedure generally opens all the pores. To the unaided eye, the surface of the specimen should exhibit a uniform orange-peel appearance with no shiny specular (mirrorlike) regions. If necessary, repeat steps 1 and 2 until the surface is uniformly roughened. Even P/M forgings and metal-injection-molded parts at 98 to 99% of full density display porosity to the unaided eye.
4. This aggressive rough polishing exaggerates the pore area fraction by eroding and rounding pore edges. That is, the specimen will appear erroneously low in density. Final polishing must restore the true area fraction of porosity.
5. Polish 2 min using $1 \mu\text{m}$ diamond on a short-nap cloth at 250 rpm with moderate hand pressure. This sharpens pore edges and restores the pores to their true area fraction and eliminates most scratches, but leaves the edges of the specimen slightly rounded. A 19 mm ($\frac{3}{4}$ in.) long bead of diamond paste, weighing approximately 0.06 g (0.002 oz), is recommended for each 2 min of polishing. Use an alcohol-base solvent or thinner for the diamond paste so that it will wash off in water. Oily thinners penetrate the residual pores

and bleed out of the specimen.

6. Final polish 30 s using a long-nap microcloth and $0.05\ \mu\text{m}$ deagglomerated Al_2O_3 . Use light hand pressure or an automatic polisher with 100 g weight (1 N, or 4.5 lbf) on the specimen at 125 rpm. This removes the fine scratches on most ferrous materials. The true area fraction of porosity of the surface is now restored. Reference 6 includes information on this method, and it also demonstrates that it is possible to open pores and show the correct porosity area fraction using a method that requires approximately 12 min and does not use diamond. It consists of 10 min of hand polishing using $1\ \mu\text{m}$ Al_2O_3 on a synthetic suede, short-nap cloth at 250 rpm on a 200 mm (8 in.) lap and 2 min of light hand polishing using $0.05\ \mu\text{m}$ Al_2O_3 at 125 rpm on the same type of cloth.

Fig. 5 Effect of polishing on pore opening in a pressed and sintered Fe-0.8C alloy: deliberately under-polished specimen. This region, which is adjacent to the specimen edge, shows all the pores open. Compare with Fig. 6 (center of specimen). 180×

Fig. 6 Effect of polishing on pore opening in a pressed and sintered Fe-0.8C alloy: interior of same specimen as in Fig. 5. After 2 min of polishing, there are numerous smeared pores. Compare the amount of porosity with Fig. 5. This micrograph shows how the inner part of a specimen polishes more slowly than the edge. 180×

Fig. 7 Effect of polishing on pore opening in a pressed and sintered Fe-0.8C alloy: repolished version of Fig. 6 showing more pores in the center of the part (some remain smeared over). The density appears higher than the true density of 6.8 g/cm³. 180×

To produce a surface with no edge rounding, it is necessary to eliminate the 1 μm Al₂O₃ and long-nap cloth polishing. Instead, after the 2 min etch in 2% nital, step 5 should be repeated several times. More than five repetitions may be required to open all the pores on a large specimen, particularly if it is soft and undersintered. The wheel should be recharged with diamond at each repetition. However, the 2 min etching should not be repeated, because the 1 μm diamond paste does not rapidly remove etching effects.

Newly developed P/M materials require modified polishing procedures to show the correct area fraction of porosity. Such methods could be developed using standards of known density. Other modern methods of automatic polishing may open all pores, but should first be tested by preparing a specimen of known density, then measuring the area fraction of pores. The measured area fraction should agree with calculations made from the known density.

A vibratory machine in which the specimens circulate around a bowl with the abrasive slurry may also be used. The use of a short-nap chemotextile cloth (Texmet) and 0.3 or 1 μm Al₂O₃ will yield a specimen that is virtually free of edge rounding. However, for specimens that have been ground through 600 grit, this procedure requires approximately 3 h because of the slow material removal rate and the need to open all the pores.

The rate of material removal may be measured using a Knoop indenter mark as a reference (Fig. 8). First, a mark approximately 100 μm long is made in a known location on the specimen. A simple reference point in the interior of the specimen can be made using a Rockwell superficial indenter with the 15 kgf load. The Knoop mark is then placed approximately 0.4 mm (0.015 in.) away from the superficial indenter mark and at a known orientation to it. The Knoop mark is measured from a photograph or with the measuring stage of the microhardness tester. After polishing for a fixed time, such as 1 to 2 min, the Knoop mark is relocated and remeasured. The material removed normal to the specimen surface is the change in length of the Knoop diagonal divided by 30.51 (for a standard indenter). For a 25 by 25 mm (1 by 1 in.) specimen, polishing using a 250 rpm, 200 mm (8 in.) diam lap, 1 μm Al₂O₃ on a synthetic suede, short-nap cloth, and moderate hand pressure will remove 0.4 $\mu\text{m}/\text{min}$. A smaller specimen, such as 12 by 6 mm (0.5 by 0.25 in.) will polish at 1.45 $\mu\text{m}/\text{min}$. Additional information on material removal rates can be found in Ref 5.

Fig. 8 Knoop indenter mark (100 gf) used as a reference to note the rate of material removal from the surface by measuring the change in length and depth of the indentation. Surrounding black pores in this unetched, pressed and sintered Fe-0.8C alloy (6.8 g/cm³) are also revealed. 295×

Soft material, such as pure iron or copper, may still exhibit some fine scratches after the 0.05 μm Al₂O₃ polishing described above in step 6. One solution is to use a new long-nap cloth (microcloth) with adhesive backing attached to a flat glass plate or to a flat bench top. With the deagglomerated 0.05 μm Al₂O₃, charged onto the cloth at a ratio of 1 part (by volume) powder to 4 parts distilled water, the specimen should be polished in the abrasive slurry using approximately 50 light hand strokes straight back and forth. This will eliminate the fine scratches from the prior polishing; remaining scratches will be aligned

parallel to the direction of polishing, and their source identified. This light final polishing does not cause comet tails or pore beveling. Colloidal silica, for example, Mastermet (Buehler, Ltd., Lake Bluff, IL), is excellent for a final polish.

Titanium alloys require a 4 min rough polishing using 1 μm Al_2O_3 on felt cloth at 250 rpm on a 200 mm (8 in.) diam lap with moderate hand pressure. This opens and slightly enlarges the pores. The autopolisher with 3 μm diamond on DAC cloth for 10 min at 30 N can be used. Final polish is colloidal silica on microcloth, at 1 N (4.5 lbf), 125 rpm, and for 1 min.

Metal Powder Particles

The powders, if mounted in epoxy resin as noted above, present a planar surface suitable for fine grinding. It is usually possible to begin using wet 600 grit SiC on revolving wheels or fixed sheets of paper. Approximately 30 s of grinding exposes enough particles to be viewed. The specimen is washed and then polished by hand for 2 min using 1 μm diamond on a short-nap cloth (MOL) at 250 rpm on a 200 mm (8 in.) diam lap. The use of an alcohol-base, water-soluble lubricant allows easy specimen cleaning in water.

The powders must not be overpolished, or the epoxy resin will be polished away between them and the particle edges will become rounded. Final polishing should be performed using deagglomerated 0.05 μm Al_2O_3 on a long-nap microcloth for 30 s with light hand pressure on a 200 mm (8 in.) diam, 125 rpm lap. Prolonged polishing or heavy hand pressure during final polishing rounds the particle edges.

Because some particles have internal pores that may have been smeared, it is important to examine some of the particles, unetched at 500 or 1000 \times , for the thin, gray lines that are the edges of smeared pores (Fig. 9). If such undisclosed pores are noted, 15 s etching and 1 μm diamond polish must be repeated. Etching the mounted powders removes enough surface material to lower the particles below the surface of the epoxy resin, which then provides an opportunity to repolish them. The repolishing should always be performed using 1 μm diamond followed by 0.05 μm Al_2O_3 for 30 s on a long-nap cloth.

Aluminum powders and alloys must be polished using 1 μm diamond, rather than Al_2O_3 , which reacts with aluminum powders. Final polishing is best done with colloidal silica on microcloth for 30 to 60 s. Hard powders, such as tungsten, may be examined as-polished using 1 μm diamond. Final polishing of very soft materials, such as pure copper, may be carried out using a fixed, long-nap cloth, as described previously for full-size specimens. The colloidal silica noted previously also works well on pure copper. Pure iron powder may require two or three 30 s fine polishings and light 15 s etching in 2% nital to remove fine scratches. The procedure also opens porosity in fine-porosity sponge iron.

Fig. 9 Intermediate stage of polishing showing the edges of smeared pores, (see arrows), which have not yet been opened by the polishing. The material is pressed and sintered Fe-2%Cu-0.8%C, 6.8 g/cm³. Magnifications of 500 to 1000× are required to see these features. These smeared pore edges must be removed by polishing and etching so that the original particle boundaries characteristic of undersintering can be seen, in the unetched condition, e.g., Fig. 27, 28, and 29. Unetched. 960×

Metallography of Powder Metallurgy Materials

Leander F. Pease III and Douglas L. Pease, Powder-Tech Associates, Inc.

Macroexamination

Macroexamination of sintered materials is not commonly practiced. In wrought or ingot-base materials, forging flow lines, oxide segregation, and stringers are studied extensively. These features are not usually found in P/M materials, but there are certain other uses for macroexamination.

In sectioning a heat treated P/M steel, care must be taken not to overheat the specimen and temper or reharden it locally. The etching performed during grinding and polishing to help open the pores will indicate any macroscopic striated darkening from overheating, as shown in Fig. 10 and 11. By revealing a lighter or darker surface than the interior, this same intermediate etching using 2% nital on steels will show if a specimen ground through 600 grit SiC paper is likely to have a decarburized or carburized surface layer. This effect is apparent to the unaided eye.

Fig. 10 Ferrous P/M specimen cut with the use of a coolant. No evidence of overheating. Nital. 12×

Fig. 11 Ferrous P/M specimen cut without the use of a coolant. Evidence of overheating (dark area at right edge of specimen). Nital. 12×

During manual polishing with 1 μm Al_2O_3 , a porous appearing layer similar to orange peel develops near the outer edges of the specimen adjacent to the mounting medium. This layer spreads inward during subsequent polishing until the entire cross section appears uniformly porous to the unaided eye. If the surface is shiny or specular in certain regions, it almost surely will be found to contain pores that polishing has failed to open (Fig. 6 and 9). The penetration depth of the epoxy resin through the side surfaces of the specimen can be seen during polishing, because the regions where the epoxy is in the pores displays the orange peel appearance. The regions with unfilled pores are temporarily smeared over and shiny. After final polishing, the surface roughness from the pores is much diminished, but variations in density in a part are visible to the unaided eye.

Nital etching of elemental nickel steels reveals the nickel-rich areas as light-reflecting sparkles. Unsintered (green) or sintered, unprepared parts may be examined to 25× for cracks or the presence of added copper in iron. The fracture surface of a heat treated part shows varying degrees of discoloration in bands parallel to the outer surfaces. These dark bands are probably caused by oil impregnation during oil quenching, and the color is caused by in situ partial decomposition of the oil during quenching or tempering. The Metal Powder Industries Federation (MPIF) test method 37 for case depth (now obsolete) used the difference in the fracture appearance of the case region and the interior to measure case depth (Ref 9).

Scanning Electron Microscopy

The scanning electron microscope is a useful tool for examining metal powders, fracture surfaces, as-pressed and sintered surfaces formed by dies and punches, and, potentially, the as-polished sections used for optical microscopy. Scanning electron micrographs of iron, prealloyed steel, and stainless steel powders are shown in Fig. 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, and 24 in the series of representative micrographs in this article. In addition, Fig. 25 and 26 show the smooth outer surfaces of parts that were contacted by punches or dies during consolidation. Figure 26 illustrates the unsintered view of the side of a part that contacted the die. The powders have been pressed into close contact, and the boundaries between particles

are readily visible. Sintering, which completes the bonding of adjacent powder particles, is traced in the accompanying optical micrographs (Fig. 27, 28, 29, 30, 31) that illustrate the disappearance of the particle boundaries and the rounding of pores in a diffusion-alloyed steel.

The development of bonding between metal particles may also be followed by examining their fracture surfaces. As bonds develop, the fracture shows cup-and-cone or dimpled-fracture regions where the bonds have been torn apart. The regions between the ductile cups and cones are the smooth surfaces of the original particles, which were not bonded to the adjacent particles. The progress of sintering may be followed through the increasing number and area fraction of the ductile torn regions. This is well illustrated in the scanning electron micrographs shown in Fig. 32, 33, 34, 35, 36, 37, and 38. The energy spectra of the x-rays generated by the electron beam striking the atoms of the specimen can be analyzed to determine which elements are present at the fracture surface. The fracture surface may be scanned for the wavelength characteristic of a particular element and to record the intensity or concentration of the element as a function of location. This concentration appears on an x-ray map as a collection of dots. That display shows if the element is uniformly distributed or somewhat segregated, which is useful for monitoring the dissolution of copper or nickel in steel, or for checking for oxides of manganese or silicon.

Metallography of Powder Metallurgy Materials

Leander F. Pease III and Douglas L. Pease, Powder-Tech Associates, Inc.

Microexamination

Etchants commonly used for the metallographic examination of sintered metals are listed in Table 1. The initial use of the etchant, as noted previously, is to open the smeared porosity before and during the coarse polishing with 1 μm Al_2O_3 . However, once fine polishing is completed, it is very important to examine sintered parts in the unetched condition. This displays the number and distribution of original particle boundaries present (Fig. 27, 28, 29). Etching reveals grain boundaries, which would be easily confused with the particle boundaries that also appear as thin gray or black lines. Cracks, density variation, oxide films or particles, and pore shape or rounding are easier to view in the absence of distracting etched features.

Table 1 Etchants used for examination of P/M materials

Etchant	Procedures and applications
2% nital: methyl alcohol plus 2% concentrated HNO_3	For as-sintered irons and steels (best for ferrite and low-carbon steels); immersed for 10-15 s; heat treated steels: 6-7 s
Concentrated picral: picric acid in methyl alcohol; some undissolved crystals remain in the container bottom	For higher carbon-containing materials to develop good contrast with carbides, pearlite, other eutectoid products, martensite, and retained austenite; etch by immersion, 15-20 s
Glyceregia: 10 mL HNO_3 conc, 15 mL HCl, 35 mL glycerol^(a)	Show grain boundaries, twin boundaries, and carbides in austenitic and martensitic stainless steel; immerse for 1-2 min or swab lightly
4% FeCl_3 in H_2O	Develops red color in copper-rich regions in bronze; etch by swabbing, 10-20 s
2 g $\text{K}_2\text{Cr}_2\text{O}_7$, 4 mL NaCl, 8 mL H_2SO_4, 100 mL H_2O	Develops grain boundaries and small grain clusters in bronze; etch by swabbing, 10-20 s
Keller's reagent: 2.5 mL HNO_3, 1.5 mL HCl, 1.0 mL HF, 95 mL H_2O	For aluminum and aluminum alloys; immerse 8-15 s, wash in water; do not remove etchant products from surface
5% nital	For as-sintered tool steels; immerse 5 min
5 mL HNO_3 conc, 10 mL 48% HF, 85 mL H_2O	For titanium and titanium alloys; immerse 5 s
5 mL NH_4OH, 3 drops H_2O_2, 5 mL H_2O	For brasses; swab 20 s; make fresh solution every 20 min
450 mL H_2O, 25 mL H_2SO_4, 25 mL HNO_3, 25 g chromic oxide, 4 g NH_4Cl	For bronzes not etching clearly in the above $\text{K}_2\text{Cr}_2\text{O}_7$: Just before use, mix a few mL of this etchant with equal amount of 3% H_2O_2 and swab for 10 s

(a) Use hood for fumes and hand and eye protection when mixing this solution

For iron and low-carbon sintered materials, 2% nital is preferred because it reveals the ferrite grain boundaries. It is applied by immersion for 10 to 15 s. The specimen is washed in running water, rinsed in methyl alcohol (optional), then dried in a cool air stream or wiped dry. (If any open porosity is present, the use of warm air may cause subsequent evaporation of entrapped water or alcohol onto the lens of the microscope.) For steels with medium-to-high carbon content or for heat treated structures, concentrated picral in methanol works well. It enhances the contrast of carbide platelets in the eutectoid in as-sintered structures.

Picral develops good contrast in the martensite needles and retained austenite of heat treated materials. The 2% nital also works well for these structures and does not stain hands and clothing. Heat treated specimens etched in nital should be immersed 6 to 8 s (swabbing causes streaks), rinsed in running water then alcohol, and then blown dry. This underetches the martensite, but enhances contrast between the fine pearlite (a dark, unresolved, nodular constituent) and the light-colored martensite. This is an optimal condition for checking microhardness, because the martensite is light, clearly seen, and forms a good background for measuring the length of the Knoop diamond indentation. The use of picral for 15 to 20 s or 2% nital for slightly longer enhances the contrast of martensite and retained austenite. For magnifications of 1000 \times , a lightly etched structure affords maximum clarity.

Sintered stainless steels are best etched in glyceresia using a protective hood and ventilation. Because this is a strong acid mixture, eye and hand protection are advised. The glyceresia is applied by immersion with the specimen surface upward; a fraction of a millimeter of the liquid is poured on top of the metal to be etched. When freshly prepared, the action is fairly slow and may require 1 to 2 min. The etchant may also be applied using a very light swabbing action. Glyceresia decomposes with time; it may turn orange and emit nitrous oxide. As the etchant darkens toward orange or brown, it becomes more reactive and less predictable. Shelf life may be extended by cool storage. Nonetheless, glyceresia rarely can be used for more than 2 h before disposal. Additional etching should be preceded by repolishing using 1 μm diamond and 0.05 μm Al_2O_3 to avoid unwanted etching artifacts.

In well-sintered stainless steel, moderate grain size, annealing twins, and grain boundaries free of precipitated carbides are visible. When carbides are present, the grain boundaries are not clean and straight, but ragged, broader, and fast etching. Prolonged etching causes the formation of pits, which may be confused with pores. The stainless steels are judged by freedom from precipitated carbides and original particle boundaries. Some of the new classes of high-temperature sintered stainless steels exhibit very well-rounded pores, which may even be isolated from each other. Such high degrees of sintering are rare in low-alloy steels.

Copper and bronze materials are etched in a 4% ferric chloride (FeCl_3) solution or the potassium dichromate ($\text{K}_2\text{Cr}_2\text{O}_7$) solution in Table 1. The $\text{K}_2\text{Cr}_2\text{O}_7$ etchant is preferred for bronze. During sintering of bronzes, the elemental tin melts, forming a series of increasingly higher temperature intermetallic compounds, then completely dissolves in the copper at approximately 785 to 845 $^\circ\text{C}$ (1450 to 1550 $^\circ\text{F}$). The result of good sintering is a bronze with a moderate grain size and no free tin or blue-gray copper-tin intermetallic compounds. Intermetallic compounds are present during the early stage of sintering and in a final undersintered condition.

As sintering proceeds, the copper recrystallizes and its grains grow as the tin diffuses to form α -bronze. The presence of many reddish copper areas or large area fractions of fine-grained copper-rich or α -bronze indicates undersintering. The undersintered materials are the most difficult to etch and to show clear structures. The $\text{K}_2\text{Cr}_2\text{O}_7$ etchant should be applied (always by swabbing) for 15 s. The specimen is then placed under running water, and swabbing is continued for a few seconds. It may be necessary to polish and etch several times to obtain a clear structure free of distortion from grinding.

Some bronzes are made from mixtures of copper and copper-tin compounds. During sintering, the gray copper-tin compounds should dissolve in the copper and form α -bronze. If the sintering is not complete, the rounded gray copper-tin particle will be seen in the unetched microstructure. Interestingly, upon etching, they are preferentially attacked by the ($\text{K}_2\text{Cr}_2\text{O}_7$) reagent and are not visible in the etched structure. They are, therefore, easily overlooked. Other bronzes are not uniformly etched by the ($\text{K}_2\text{Cr}_2\text{O}_7$) reagent and the final etchant in Table 1 is recommended to reveal their grain structure.

Bronzes may contain up to 4% free graphite. The epoxy resin helps secure the graphite flakes for polishing and viewing. The use of 1 μm diamond and light final polishing with 0.05 μm Al_2O_3 on a long-nap cloth usually preserves the graphite.

Brasses and nickel silver are etched using a mixture of ammonium hydroxide (NH_4OH) diluted with 50% H_2O and a few drops of 10 to 30% hydrogen peroxide (H_2O_2) added at the time of etching. This is carried out by placing approximately 5 mL of the diluted ammonia solution in a watch glass and adding 3 to 4 drops H_2O_2 . The mixture is swabbed on the brass with a cotton-tipped stick for 20 to 40 s (Ref 11). The nickel silver requires 1 to 2 min to etch. The etchant decomposes after 30 min, and a new mixture with the H_2O_2 should be prepared as required. The $\text{K}_2\text{Cr}_2\text{O}_7$ etchant noted above for bronze also works well on the brass and nickel silver.

Aluminum parts are etched using Keller's reagent, which is applied by swabbing with cotton for 15 to 30 s.

Titanium parts are etched by immersion for 15 s using 10% concentrated hydrofluoric acid (HF), 5 mL concentrated nitric acid (HNO_3), and 85 mL H_2O .

Tool steels are etched using 5% nital (5% HNO_3 concentrated in methyl alcohol). As-sintered materials should be swabbed for 5 min. As-annealed materials may etch within 20 s.

Microstructures of P/M Materials

Powder metallurgy materials include many alloy systems. A number of these systems are discussed in the sections that follow, with the main phases and compounds noted. Related information on the production, characterization and testing, consolidation, and applications and properties of these powder systems can be found in this Volume.

Iron-Base P/M Materials

Pure iron or very-low-carbon steel is a common structural or bearing material. The microstructure is predominantly ferrite, with modest amounts of pearlite in proportion to the minor amounts of carbon in solution. Several kinds of iron powder are commonly used, including sponge, atomized, electrolytic, and carbonyl powders (Fig. 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52). They have widely differing properties because of differences in surface area, residual alloying, internal porosity, and particle size. For additional information, see the article "Production of Iron Powder" in this Volume.

Sponge irons, which are produced by the reduction of iron oxide, are very irregularly shaped powders with high surface areas. They are more difficult to compress, but develop good green strength and excellent sintered strength at low densities. The pores inside the particles vary in size according to the temperature and time of reduction from the parent oxides. Low-temperature hydrogen reduction of mill scale leads to a fine sponge, and extended carbon reduction of ore concentrate results in a coarser sponge. These powders are characterized by moderate levels of unreduced oxides inside the particles. (Fig. 39, 40, 41, 42, 43, 45, 47, 48, 49, 50).

Atomized iron powders press easily, but for densities up to 6.6 g/cm^3 , the sponge irons result in higher sintered strength. Therefore, the atomized materials are usually found in materials pressed at 6.6 to 7.2 g/cm^3 (the pore-free density of iron is 7.87 g/cm^3). (Fig. 51).

Electrolytic Iron Powder. The high green strength, high compressibility, irregular particle shape, and high purity of electrolytic iron make it suitable for a number of applications, such as soft magnetic parts and enrichment of food products. Because of its high production costs, however, current usage is limited. (\$2.00 to 4.25/lb versus \$0.40/lb for atomized iron).

Carbonyl iron powders may have a particle size of 2 to 5 μm and are often used in metal-injection-molded P/M parts (see the article "Powder Injection Molding" in this Volume). Their high surface area and fine particle size allow the material to sinter to near-full density with large associated shrinkages. The resulting structure will be ferrite, with small rounded and isolated pores.

Iron-Graphite Mixtures. Sintering results in rapid diffusion of carbon into iron, with resulting steels containing up to 0.8% C. These steels show increasing amounts of pearlite with increasing carbon content calculated using the lever rule. The combined carbon for these materials is approximately 0.8% times the area fraction of pearlite. That area fraction does not include the area associated with porosity. For materials with hypereutectoid carbon contents (typically >0.8%), iron carbide networks appear in the grain boundaries, and the impact, tensile strength, and elongation are reduced. This carbide network is not to be confused with the divorced eutectoid carbide platelets that will appear occasionally in a grain boundary in the hypoeutectoid steels with less than 0.3% C. This effect is seen in ingot-based steels as well. Sintered iron bearings are fabricated with graphite in solution as well as present as free graphite flakes. The combined carbon is judged by the lever rule, which is important in quality control of iron-graphite bearing materials. Iron-carbon P/M structures are shown in Fig. 53, 54, 55, 56, and 57.

Iron-Copper Alloys. Copper is frequently added to iron because it melts and rapidly dissolves, greatly increasing the strength of the iron. When copper melts, it is drawn by capillary action into the smallest available pores and capillaries. In an atomized iron powder, the copper flows between the particles that are pressed into close contact. It then dissolves in the iron at these points of contact. The copper activates the sintering of the particles that are in contact, resulting in rapid disappearance of particle boundaries and substantial neck growth.

The copper may separate the iron particles as it flows among them, causing growth of the part in 1 to 2 min. The subsequent dissolution of the copper and local lattice expansion at points of contact cause later growth. In an undersintered part with 2% added Cu, some of the residual copper may still be visible as a thin line between two iron particles. With sponge irons, the copper can flow into the fine pores inside the particles and thus not cause as much separation of particles. The high surface area also contributes to rapid sintering. These two effects are thought to explain why the sponge iron and copper mixtures do not expand as much on sintering as the mixes based on atomized iron.

In conventional sintering of iron-copper alloys (20 to 30 min at 1105 to 1120 °C, or 2025 to 2050 °F), at least 2% Cu disappear into solution in the iron. With 5% or more Cu, some free copper is always present as a copper-rich solid solution with the iron. Depending on the rate of cooling, copper-rich phases precipitate in the iron, and, vice versa. The copper-rich phases precipitate in the iron, darkening the ferrite; slow cooling increases darkening. This effect is limited to the outside of the iron particles, because the melted copper does not readily diffuse to the particle centers under conventional sintering conditions. Picral etching will help to stain the copper precipitate areas for easier identification. Iron-copper P/M structures are shown in Fig. 58, 59, 60, 61, 62.

Iron-Copper-Carbon Alloys. The most common of the moderate-strength, as-sintered alloys is Fe-Cu-C with 0.5 to 0.8% C and 2 to 5% Cu (Fig. 63, 64, 65, 66). It combines the features described above for iron-carbon and iron-copper alloys. The carbon goes rapidly into solution in the iron (perhaps in 5 min at 1040 °C, or 1900 °F) and tends to prevent the sintering expansion prevalent in zero- or low-carbon iron-copper alloys. The combined carbon can be estimated by the lever rule, although the eutectoid may be as low as 0.75% C in this ternary system.

Copper-Infiltrated Steels. High-density iron-carbon alloys with 10 or 20% Cu are prepared by infiltrating the copper alloy into the porous steel matrix. Upon sintering and infiltrating, the copper alloy melts and flows into the iron-carbon matrix with which it is in contact. The copper tends to fill the highest-density, smallest-capillary regions of the matrix first. The coarse-pored lowest-density regions are filled last with whatever liquid copper remains. The structure often appears as islands of ferrite and pearlite with a continuous copper-alloy phase. The alloy of copper may include such elements as manganese and cobalt, which dissolve in iron and alter the alloy content of the steel matrix. Manganese increases the hardenability of the matrix. Elemental nickel contained in the matrix goes into solution in iron and copper, greatly increasing hardenability. Such

materials may exhibit regions of martensite, even as furnace cooled. Copper-infiltrated steel structures are shown in Fig. 67, 68, 69, 70, 71, and 72.

Low-alloy steels of the 4600 series type are atomized as low-carbon materials with good compressibility. Because of their alloying elements, they display excellent hardenability and are usually used fully hardened. When viewed in the as-sintered condition, such materials exhibit ferrite and a eutectoid product that does not appear similar to the normal iron-carbon materials. The lamellae are more uniformly spread throughout the structure, and the tendency among the constituents to group into ferrite and pearlite is lessened, which complicates estimating the combined carbon content metallographically. However, this should be possible by devising metallographic photo standards of reference. The powder may contain up to 5% unalloyed iron as a contaminant. In the as-sintered structure, these free-iron particles do not tend to pick up carbon and thus stand out as ferrite (the carbon preferentially dissolves in the prealloyed steel powder particles). Upon quenching, the unalloyed particles are low in carbon and alloy content, do not harden, and are all ferrite or ferrite/pearlite mixtures. Low-alloy steel structures are shown in Fig. 73, 74, 75, 76, 77, 78, 79, and 80.

Iron-Phosphorus Alloys. The additions of iron phosphide (Fe_3P) to atomized iron results in the dissolution of phosphorus in amounts less than 1%. The phosphorus initiates a transient liquid-phase sintering reaction, then goes partly into solution in the iron, resulting in a material with excellent soft magnetic properties. Some of the phosphorus remains visible as a second phase with the ferrite. For magnetic properties, a low carbon content and freedom from pearlite are required. For optimal toughness and strength characteristics, a mixture of up to 1% P and up to 0.3% C is used. The phosphorus also causes pore rounding by virtue of the transient liquid phase, which gives the alloys their toughness and characteristic well-sintered appearance. Iron-phosphorus alloy structures are shown in Fig. 81 and 82.

Free-Machining Steels. The machinability of sintered irons and alloys is improved by adding sulfur. Historically, this has been accomplished by mixing fine sulfur powder (-325 mesh) into sponge iron. More recently, sulfur is dissolved in the liquid melt before atomizing (prealloyed sulfur) to form manganese sulfide (MnS) with carefully controlled amounts of manganese. Manganese sulfide particles have also been mixed with iron for a similar benefit. These additions result in particles of MnS in the pores as a gray phase, or a MnS phase inside the iron particles, if it was prealloyed. The use of high-hydrogen atmospheres at sintering desulfurizes a material to depths of 0.25 to 0.50 mm (0.01 to 0.02 in.), an effect whose analog in carbon is better known. Structures of P/M steels with additions of manganese and sulfur for enhanced machinability are shown in Fig. 83, 84, and 85. Boron nitride powder is also mixed into iron in small amounts to improve machinability. Finally, the most effective enhancer of machinability is impregnation of the pores of the sintered material, using a plastic resin.

Nickel Steels. The most common high-strength heat treated materials are the nickel steels. In these mixtures, 2 or 4% elemental Ni is added to iron, along with 0.4 to 0.8% C and up to 2% Cu (optional). The usual nickel is very finely divided and is often prepared by carbonyl decomposition (production of nickel powder by carbonyl vapor metallurgy processing is discussed in the article "Production of Nickel-Base Powders" in this Volume). The copper is generally added for size control during sintering, because nickel induces shrinkage and copper causes expansion. The copper activates sintering, as noted previously in the section "Iron-Copper Alloys," and promotes the dissolution of nickel in the iron. Nickel-steel structures are shown in Fig. 86, 87, 88, 89, 90, 91, 92, 93, 94, 95, 96, 97, and 98.

Nickel-rich regions comprise 20 to 50% of the area of these structures. The regions are extensive because the nickel content of their interiors has been diluted to 12% Ni by inward diffusion of iron. The nickel-rich regions tend to etch lightly. Their interiors often are unetched austenite, and their peripheries contain martensite or bainite with microhardnesses of 40 to 55 HRC, converted from 100 gf Knoop. The pearlite colonies are usually surrounded by a white band that appears similar to ferrite, but never contains eutectoid products. It is probably a higher-alloy diffusion zone. The austenitic cores of the nickel-rich regions increase toughness and strength in these alloys and tend to inhibit ductility. The undiffused nickel-rich regions figure significantly in the overall performances of the alloy. These islands with hard phases in the as-sintered condition contribute a degree of wear resistance that would not normally be expected.

It is difficult to assess the degree of sintering by studying the nickel-rich areas because copper additions greatly affect their extent and appearance. Sintering is best judged by the disappearance of original particle boundaries and by pore rounding. It is difficult to discern the combined carbon level in the nickel steels because of the presence of the nickel-rich regions, the white diffusion layer, porosity, and the probable lowering of the eutectoid carbon level by the nickel.

Diffusion-alloyed materials, such as Distaloy (Hoeganaes Corp., Riverton, NJ) are powders in which the alloying elements of molybdenum, nickel, and copper are added as finely divided elements or oxides to the iron powder. They are then coreduced with the iron powders at an annealing step, resulting in the firm attachment and partial diffusion of the elements to the iron. This partial alloying increases hardenability compared to elemental mixtures, yet these powders exhibit good compressibility. Bonding of the alloying elements also reduces the tendency toward powder segregation.

The sintered structures exhibit ferrite, pearlite, and nickel-rich regions such as those described previously for the elemental mixes, and the nickel-rich regions have all the benefits noted above. With added copper, additional partial hardening during sintering occurs. In Europe, this is used to advantage by producing medium-carbon alloys that are sold in the pressed, sintered, and sized conditions, but have good strength and impact resistance. This procedure avoids the distortions that can occur during normal heat treating. Diffusion-alloyed structures are shown in Fig. 99, 100, and 101.

Sintered stainless steels are available in compositions that approximate AISI designations 303, 304, 316, 409, 410, 430, and 434. The austenitic materials display austenite grains and annealing twins. The most significant disadvantage may be decoration of the grain boundaries with chromium carbides, indicating loss of chromium from solution and reduction in corrosion resistance. The degree of pore rounding is the most important indication of strength and ductility. The materials are virtually always prepared from prealloyed powders; some variants contain added tin or copper for improved corrosion resistance. The 410 materials are often fabricated with 0.15% graphite mixed with prealloyed powders. This results in such high hardenability that the as-sintered structures are essentially all martensite and require tempering after sintering for optimal properties. Stainless steel P/M structures are shown in Fig. 102, 103, 104, 105, 106, 107, 108, 109, 110, 111, 112, and 113.

Powder metallurgy tool steels have long been used for tooling components such as punches and dies. These materials are produced by hot isostatic pressing of water-atomized, tool steel powders, resulting in a fully dense product with fine grain size and very fine, uniform carbide size. The product displays grindability that is superior to ingot-base tool steels. Such alloys as M2 and T15 are also available in molding grade powders. In addition to hot isostatic pressing, P/M tool steels can be fabricated by pressing to approximately 80% density, followed by vacuum sintering to full density. Tool steel powders of the M2 and T15 compositions can be cold pressed at 550 to 825 MPa (40 to 60 tsi), then liquid phase sintered to full density. For M2, sintering requires 1 h in vacuum at 1240 °C (2260 °F) at 100 to 1000 μ m nitrogen or argon; T15 takes 1 h at 1260 °C (2300 °F) in the same vacuum. Temperature control within 5 °C (9 °F) may be required for product uniformity. The as-sintered T15 structures contain retained austenite, because of the high amount of carbon in solution, as well as primary M_6C and fine MC (vanadium carbide). The M2 structures contain mainly M_6C of varying small sizes against a matrix of retained austenite. The martensite start, M_s , temperature for these materials with the high carbon in solution is below room temperature. Upon annealing, the carbon precipitates out of solution onto the M_6C phase, reducing the carbon in the matrix. This structure may then be heat treated at 1150 to 1205 °C (2100 to 2200 °F), but heating and cooling times must be minimized to avoid putting too much carbon back into solution. Upon furnace cooling or air cooling, the matrix then forms martensite with the proper distribution of fine carbides (Ref 12). Powder metallurgy tool steel structures are shown in Fig. 114, 115, and 116 (see also the article "Particle Metallurgy Tool Steels" in this Volume).

Nonferrous P/M Materials

As discussed in the Section "Metal Powder Production and Characterization" in this Volume, a great many nonferrous metals are also produced in powder form, including:

- *Copper*: by reduction of oxides, atomization, electrolysis, and hydrometallurgical processing
- *Tin*: by atomization
- *Aluminum*: by atomization
- *Magnesium*: by mechanical comminution and atomization
- *Nickel*: by carbonyl vapormetallurgy, hydrometallurgy, and atomization
- *Cobalt*: by carbonyl vapor metallurgy, hydrometallurgy, reduction of oxides, and atomization
- *Silver*: by chemical precipitation, electrolysis, and reduction of oxides
- *Gold, platinum, and palladium*: by chemical precipitation
- *Tungsten and molybdenum*: by reduction of oxides

- *Metal carbides*: by carburization, Menstruum process, and exothermic thermite reactions
- *Tantalum*: by reduction of potassium tantalum fluoride and a sequence of electron beam melting, hydriding, comminution, and degassing (dehydriding)
- *Niobium*: by aluminothermic reduction of oxides
- *Titanium*: by reduction of oxides and atomization
- *Beryllium*: by reduction of vacuum-melted ingots by comminution
- *Composite powders*: by diffusion (alloy coating)

This section reviews copper-, titanium-, and aluminum-base P/M materials.

Copper-base alloys include pure copper for high-density electrical applications; 90Cu-10Sn bronzes for bearings and structural parts; brasses with 10, 20, and 30% Zn; and nickel silver (Cu-18Zn-18Ni). The brasses and nickel silvers are used for structural parts that require ductility, moderate strength, corrosion resistance, and decorative value. Copper exhibits a single-phase structure with some annealing twins. The most significant feature is the particle boundaries or their absence. There should be virtual freedom from particle boundaries from the surface to the center of the part. Bronzes should display all α -bronze with no gray copper-tin intermetallic compounds. Optimal mechanical properties and machinability dictate a minimum of reddish copper-rich areas and small grain clusters of bronze. Mixes containing admixed graphite show the mottled gray flakes in the pores of the part. Bearings exhibit varying degrees of sintering, depending on the final application. In general, however, a well-sintered bearing results in greater ease of oil impregnation. Bronze P/M structures are shown in Fig. 117, 118, 119, and 120.

Brasses and nickel silvers are generally single-phase structures. They should display good pore rounding and almost no original particle boundaries. Some of the materials may contain up to 2% Pb within the particles as an aid to machinability; this will appear as a fine, rounded gray phase (Fig. 121 and 122).

Titanium and titanium alloys such as Ti-6Al-4V are produced from metal powders in several ways. The powders may be prealloyed or may be an elemental mix of titanium and a master alloy of vanadium and aluminum. The latter can be pressed and vacuum sintered to an impermeable state, which may then be hot isostatically pressed to full density without a can. The prealloyed materials may be vacuum hot pressed or preformed, canned, and hot isostatically pressed to full density. Titanium alloys can also be consolidated by metal injection molding. Titanium alloy P/M structures are shown in Fig. 123, 124, and 125.

Aluminum P/M alloys are pressed and sintered to 90 to 95% density. The common alloys are 201AB and 601AB. The alloys are prepared using low-alloy aluminum powder with additions of elemental or master alloy copper, magnesium, and silicon. During sintering, the additions cause a liquid phase to form that fluxes away the surface oxides and allows bonding between the aluminum particles. Sintering in nitrogen is performed at approximately 595 or 620 °C (1100 or 1150 °F) at a dew point of -50 °C (-60 °F) to prevent further oxidation of the aluminum. After sintering, the alloys are often solutionized and quenched, then repressed or coined before aging. The repressing densifies the material and establishes close dimensional tolerances. The materials may also be cold forged or rolled to varying reductions in thickness because of their favorable as-sintered ductility. Aluminum P/M structures are shown in Fig. 126, 127, 128, 129, and 130.

Representative Micrographs

This section includes a discussion of unusual and/or defective structures. Also included are examples of heat treated materials and those subjected to other finishing operations, such as steam blackening. Alternate consolidation processes, such as P/M forging, hot isostatic pressing, metal injection molding, and liquid-phase sintering, are also illustrated.

Sintered parts may be undersintered, which is evidenced by the presence of excessive numbers of original particle boundaries. Undersintering is related to the normal pressed-and-sintered structural materials and their mechanical properties as shown in MPIF standard 35 or the various ASTM materials standardized by the B-9 Committee in ASTM Volume 02.05. In general, for ferrous materials, a field of view at 200× would not be expected to show more than approximately five small segments of original particle boundaries. The presence of larger numbers of particle boundaries would necessitate verifying the sintering conditions and the strength of the part. Figures 27, 28, 29, 30, and 31 depict an increasing degree of sintering, as shown by the disappearance of particle boundaries.

High-temperature (1290 °C, or 2350 °F) sintered austenitic stainless steel does not exhibit particle boundaries, and the degree of rounding of the pores must be examined to compare sintering (Fig. 102, 103, 104, 105, 106, 107, 108, 109, 110, 111). Injection-molded parts made of fine powders tend to sinter to a closed-pore state with no original particle boundaries (Fig. 131 and 132). Powder metallurgy forgings and hot isostatically pressed parts would not display such boundaries (Fig. 133 and 134).

In the etched condition, sintered steels may exhibit carburization or decarburization (Fig. 135 and 136). If parts of nonuniform section are pressed, density may vary, which may be noted and measured metallographically (Ref 15). If parts are overpressed, the particles will separate, showing microlaminations. Cracks may occur upon ejection, at the change in diameter between two sections of a part, such as between a hub and a flange (Fig. 137 and 138). Even in simple shapes, such as flat tensile bars, improper tool design can cause cracks, which then result in reduced mechanical properties (see Fig. 139).

Heat treated ferrous parts vary in structure from nearly all martensite at the surface to a mixture of martensite, ferrite, and 10 to 30% fine pearlite in the interior (Fig. 140, 141, 142). This fine pearlite improves tensile properties (Ref 16).

Microhardness testing must be limited to a particular phase when testing with the 100 gf Knoop indenter, for example, martensite. The heat treated structures may display retained austenite, carbides, and subsurface quench cracking (Fig. 143, 144, 145). Most P/M materials do not form a definite shallow case because of penetration of the carburizing gases. At densities above approximately 7.2 g/cm³, a definite case tends to form if the core contains less than 0.2% C, as shown in Fig. 146.

Powder metallurgy parts can be finished by steam blackening. The degree of blackening, which should be controlled, generally lowers impact and tensile properties (Ref 17). The gray Fe₃O₄ layer (Fig. 147, 148) penetrates the pores and increases compressive strength and abrasive wear resistance. The thickness of the oxide layer can be measured metallographically, 10 μm (0.0004 in.).

Most P/M parts that are to be plated are first impregnated with a resin to prevent the corrosive plating solutions from entering and remaining in the pores. The resin is visible using optical metallography. The various plated layers are also visible, but polishing should be limited to 3 μm and 1 μm diamond on a short-nap (DAC) cloth to prevent rounding of the plated edge. To examine the original resin in the pores, the part should be mounted in an epoxy resin of contrasting color, for example, red. Also, impregnation with the red epoxy of a specimen that has no existing resin in the pores, allows the epoxy resin to be easily seen. The gray epoxy resins are difficult to image in the light microscope. Often, unfilled pores look dark or filled with debris. An epoxy-filled pore allows one to look through the epoxy at 1000× and see a specular reflection off the bottom.

Powder metallurgy parts can be joined to others by brazing, welding, or adhesive bonding; special precautions are necessary to prevent penetration of the brazing materials. Brazing of sintered steel is done using a special material with a melting point near the normal sintering temperature of iron. When it begins to penetrate iron pores, some iron dissolves in the liquid braze. This raises the solidus or melting point of the liquid, freezing occurs, and penetration proceeds no further into the porous material.

Manufacturers of sintered parts have occasion to examine raw materials (powders) metallographically. This is important because different production methods can result in powders with the same nominal chemistry, but disparate properties. Typical powder structures are shown in Fig. 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45, 46, 47, 48, 49, 50, 51, 52, 149, 150, 151, 152, 153, 154, 155, 156, 157, 158, 159, 160, 161, and 162. These micrographs are intended to simplify the task of examining a sintered part and attempting to deduce which powder was used to prepare it.

Figures 163, 164, 165, 166, 167, 168, 169, and 170 depict various normal and abnormal structures. Among these are undersintered structures (as shown in Fig. 163 and compared with an average sinter in Fig. 164), wear-resistant steels (Ancorwear 500) with high carbon contents (Fig. 165), gravity-sintered bronze filter powders (Fig. 166 and 167), sintered parts that were blistered during heating to the sintering temperature (Fig. 168), and parts that exhibit varying density from die-wall friction and the location in the die (Fig. 169 and 170).

Sealed Surfaces. Powder metallurgy parts can have their surface pores closed, either intentionally or inadvertently. Figure 171 shows the outside diameter of a tumbled P/M part in which the surface pores were closed to a depth of 50 μm (0.002 in.). Such closure can interfere with intended flow of fluids through the pores. Powder metallurgy parts, for example, gears and sprockets, are deliberately worked on the surface to densify the surfaces and increase the fatigue resistance. Machining P/M parts also is known to close off surface pores.

Determination of Crack Origin, Green or Sintered State. If a fracture occurs in the green state and the part is then sintered, the particles on the fracture surface will be rounded. If a fracture occurs after sintering, the surfaces of the particles show ductile cups, cones, and asperities, as in the scanning electron micrograph (SEM) view in Fig. 34, 36, and 37. If an SEM is not available, one can plate the fracture surface with 25 μm (0.001 in.) electroless nickel, Edgemet (Buehler Ltd., Lake Bluff, IL), in about 2 h. The plating is done on a specimen that was sectioned perpendicular to the fracture surface. The specimen is then mounted in epoxy resin, ground, and polished. The plating saves the details of the fracture surface, which is viewed at right angles to the fracture plane. In this way, any asperities and cones can be seen in profile view, at 1000 \times . It is best to create a deliberate fracture through a sintered region to serve as a comparison with the questioned fracture. Figure 172 shows the fracture that occurred in a green part, and it has rounded particle surfaces. Figure 173 shows a fracture that occurred in a sintered and heat treated part, and the asperities where sinter bonds were broken are shown by the arrows.

The plating above keeps epoxy resin from filling pores during sample mounting. This creates some difficulty at polishing, in trying to open all the pores. This is best accomplished at final polishing with 0.05 μm alumina on microcloth with a succession of 15 s nital etchings and 2 to 3 min polishing with 1 N force. Several iterations may be required. Smeared pores are most easily viewed at 1000 \times and are seen as thin gray lines in the unetched structure.

Sinter Hardened Steels. The FLC-4608-XXHT alloys contain enough copper, molybdenum, nickel, and carbon to harden to a largely martensitic structure during typical cooling from the sintering temperature. The structures show martensite with 0 to 40% colonies of dark fine pearlite, as shown in Figures 140 and 141. Such structures can be distinguished from austenitized and oil-quenched structures by the distribution of the fine pearlite. The sinter-hardened structures tend to have the fine pearlite distributed rather uniformly from surface to interior. Oil-quenched parts tend to be all martensite on the surface, and any fine pearlite is mainly formed in the interior. Sinter-hardened parts with more than 70% martensite should be tempered for 1 h at 175 $^{\circ}\text{C}$ (350 $^{\circ}\text{F}$) in air to relieve brittleness and increase the tensile strength. Such tempering can double tooth strength, as compared with using the part in the as-sinter-hardened condition.

Fig. 26 Same as Fig. 25, but showing the view of the surface that was in contact with the die wall. Arrows show the boundary

between particles that must be eliminated during sintering. SEM . 750×

Fig. 27 Distaloy 4600 A (6.7 g/cm^3), pressed at 480 MPa, undersintered 5 min in dissociated ammonia in hot zone at 1120°C (2050°F). Arrows P: particle boundaries; arrows G: undiffused, gray flakes of graphite in pores. As-polished. 645×

Fig. 28 Same diffusion-alloyed steel as Fig. 27. Arrows P show the many original particle boundaries. Sintering longer will remove these low-strength boundaries. As-polished. 120×

Fig. 29 Same as Fig. 27, but sintered 15 min. Arrows P indicate persistence of original particle boundaries; arrows R, rounded pores (compare with Fig. 27). As-polished. 645×

Fig. 30 Same as Fig. 29. Arrows S show segments of original particle boundaries that are shorter and less numerous than those in Fig. 28. Arrows P indicate a row of pores that show how original particles break down into planes of small voids, which coalesce or disappear from diffusion. As-polished. 180×

Fig. 31 Same as Fig. 27, but sintered approximately 37 min, which is longer than average. Structure still shows a few segments of original particle boundaries (arrow S). Arrows P indicate a row of pores at which a particle boundary is disappearing. As-polished. 180×

Fig. 32 Fracture surface of Ancorsteel 1000 iron powder (6.4 g/cm^3) pressed without lubricant at 275 MPa (20 tsi). Structure shows no evidence of cold welding or bonding of adjacent particles. Arrow indicates a triple particle boundary that will disappear during sintering. SEM. 750×. Source: Ref 10

Fig. 33 Fracture surface of Atomet 28 iron powder pressed to 6.6 g/cm^3 and sintered 3 min in hot zone at 1120°C (2050°F) in dissociated ammonia. Arrows D show where a bond has broken. Arrows S outline the smooth, rounded surface of a particle that did not bond to the adjacent particle above it. SEM. 750×. (Ref 10)

Fig. 34 Same as Fig. 33, but sintered 10 min in hot zone (approximately 1 to 3 min at 1120°C , or 2050°F). Arrows D show the ductile cup-and-cone fractures that occurred when this particle was torn from the adjacent one above it. Arrows S show the smooth surface of the particle that had not sintered to any adjacent particle. SEM. 750×. (Ref 10)

Fig. 35 Same as Fig. 34, but sintered 10 min in the hot zone at 1120°C (2050°F). Arrow D indicates a ductile cup-and-cone fracture where this particle was joined to the one above it. Arrows N show necks forming between two adjacent particles. These necks (solid regions) replace particle boundaries as sintering progresses. SEM. 2850×. (Ref 10)

Fig. 36 Same as Fig. 33, but sintered 20 min in the hot zone. Arrows D show the development of ductile cup-and-cone fracture dimples formed when material was torn away from the adjacent particle. Arrows S indicate smooth surfaces where no adjacent particle bonding has occurred. SEM. 750 \times . (Ref 10)

Fig. 37 Same material (Atomet 28) and processing as described in Fig. 36, but shown at higher magnification. Most of the field of view shows the ductile cup-and-cone fractures that occur when the material is torn apart. SEM. 2850 \times . (Ref 10)

Fig. 38 Same as Fig. 33, but sintered 40 min in the hot zone. Approximately 50% of the area fraction is occupied by ruptured ductile bonds (arrows D). The remaining area consists of smooth surfaces of particles (arrows S) at which no bonding has occurred. SEM. 750 \times . (Ref 10)

Fig. 39 Pyron D63 sponge iron (6.2 g/cm³), pressed at 480 MPa (35 tsi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Mainly ferrite grain boundaries. Arrow O indicates a small, gray, unreduced oxide particle; arrows C, a few isolated carbide platelets. 2% nital. 645 \times

Fig. 40 Same as Fig. 39, but not etched. Arrows S surround a spongy particle having small, internal pores. Arrow P indicates a much larger pore between powder particles. Very few original particle boundaries are present. As-polished. 180 \times

Fig. 41 Pyron 100 sponge iron (6.2 g/cm³), pressed at 480 MPa (35 tsi) and sintered 30

min at 1120 °C (2050 °F) in dissociated ammonia. Average sinter, no residual particle boundaries. Dark areas are pores. 2% nital. 960×

Fig. 42 Same as Fig. 41, but increased density (6.4 g/cm^3). Arrows S surround a spongy particle having small internal pores. Arrow P indicates a larger pore between particles. As-polished. 180×

Fig. 43 MH-100 sponge iron (6.4 g/cm^3), pressed at 480 MPa (35 tsi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Arrows S indicate the various pore sizes in different particles. The larger pores (arrow P) are between the original particles. As-polished. 180×

Fig. 44 Same as Fig. 43, but at higher magnification. Arrows E show eutectoid (pearlite) indicating $<0.05\%$ combined carbon. Arrow P indicates a pore. Structure is mainly ferrite. 2% nital. 960×

Fig. 45 MP35 iron powder (6.6 g/cm^3), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Arrows S surround a spongy region having pores inside the powder particles. Arrow P shows a pore between particles. As-polished. 180×

Fig. 46 Same as Fig. 45. Structure is mainly ferrite. Arrow E shows a colony of eutectoid (pearlite) indicating $<0.05\%$ combined carbon. Arrow S indicates pores within a spongy particle; arrow P, a pore between particles. 2% nital, 15 s. 645×

Fig. 47 Atomet 28 iron powder (6.7 g/cm^3), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia. Arrows S surround a spongy region. Arrow P indicates pores between particles. As-polished. $100\times$

Fig. 48 Same as Fig. 47, but etched. Structure is mainly ferrite. Arrows E indicate eutectoid (pearlite); arrow C, isolated carbides or divorced eutectoid. Arrow P shows a pore between particles; arrow S, pores within a spongy particle. 2% nital. $545\times$

Fig. 49 Sponge iron blended with atomized low-carbon steel (6.4 g/cm^3), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia. Arrows A show an atomized

particle with gas porosity. Arrows S indicate particles with interior porosity. Arrow P shows a pore between particles. As-polished. $100\times$

Fig. 50 Ancormet 100 sponge iron (6.4 g/cm^3) with same processing as Fig. 49. Structure is mainly ferrite. Arrows E indicate eutectoid (pearlite). The region shown in this micrograph is less dense than average for the specimen. Arrow P shows a pore between particles. 2% nital. $960\times$

Fig. 51 Ancorsteel 1000 atomized iron powder (6.7 g/cm^3), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia. Arrows S indicate residual particle boundary segments. Dark regions (arrows P) are pores. Arrows A surround a solid atomized particle. Arrow G shows a pore inside a particle formed during atomization. As-polished. $120\times$

Fig. 52 Same as Fig. 51, but etched. Structure is mainly α -iron (ferrite). Dark regions (arrow P) are pores. Arrows E surround eutectoid (pearlite). Micrographs above 500 \times do not always show a representative area fraction of porosity and should not be used to estimate density. Micrographs of unetched structures at 180 to 200 \times are best suited for this purpose. 2% nital. 960 \times

Fig. 53 Atomized iron powder with 0.3% graphite added to yield 0.1 to 0.2% combined carbon (6.7 g/cm^3). Pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120 $^{\circ}\text{C}$ (2050 $^{\circ}\text{F}$) in dissociated ammonia. White regions are ferrite. Arrows E surround a colony of eutectoid (pearlite). Arrow P shows a pore. 2% nital. 545 \times

Fig. 54 Atomized iron with 0.4 to 0.5% C (6.7 g/cm^3). See Fig. 53 for processing. P/M steel with 138 MPa (20 ksi) minimum yield strength. Arrows E surround eutectoid (pearlite). White background consists of ferrite grains. Dark areas (arrow P) are pores. 2% nital. 545 \times

Fig. 55 Atomized iron with 0.8% C (6.7 g/cm^3). See Fig. 53 for processing. P/M steel with 207 MPa (30 ksi) minimum yield strength. Structure is mainly pearlite. Arrows E surround eutectoid (pearlite). Arrows F show a few grains of proeutectoid ferrite. 2% nital. 365 \times

Fig. 56 Atomized iron with 1.0% combined carbon (6.7 g/cm^3). See Fig. 53 for processing. P/M steel with 207 MPa (30 ksi) minimum yield strength. Structure is mainly pearlite. Arrows E surround eutectoid (pearlite). Arrows F show a few grains of proeutectoid ferrite. 2% nital. 310 \times

Fig. 57 Atomized iron with 1.3% graphite added to yield 1.1 to 1.2% combined carbon (6.7 g/cm^3). See Fig. 53 for processing. Structure is mainly eutectoid (pearlite), as shown by arrows E. Some pearlite etched very light (arrows L). Arrows C show areas of massive carbide from excessive graphite addition. 2% nital. 310 \times

Fig. 58 Pyron 100 sponge iron with 2% Cu (6.3 g/cm^3). See Fig. 53 for processing. P/M copper steel with 124 MPa (18 ksi) minimum yield strength. Arrows Cu indicate pores that were originally occupied by copper particles before their melting and diffusion into the iron. Arrows S surround a spongy region showing pores inside the original iron powder particles. As-polished. 100 \times

Fig. 59 Same as Fig. 58, but with 7% Cu added (6.7 g/cm^3 with 138 MPa, or 20 ksi, minimum yield strength). Arrows S surround the pores inside the sponge iron. Arrows Cu show pores that were once occupied by copper particles before they melted and filled other, smaller pores and diffused into the iron. As-polished. 310 \times

Fig. 60 Same as Fig. 58, but with 20% Cu added (6.3 g/cm^3). Arrows Cu show coarse pores formerly occupied by the copper particles. Arrows S indicate the few pores remaining that may have been present in the original iron particles. The coarse pore size facilitates oil flow in bearings. As-polished. 100 \times

Fig. 61 Same as Fig. 58, but with 10% Cu added (6.3 g/cm^3). White areas (arrows Cu) are melted Cu-rich phase. Arrows Co show coring in iron particles. Darker areas on particle surfaces are where the copper has diffused, then precipitated as a Cu-rich phase upon cooling. The interiors are lighter, indicating no copper diffusion. Arrow P shows a pore previously occupied by a copper particle. 2% nital. 100 \times

Fig. 62 Same as Fig. 61, but with 20% Cu added (6.7 g/cm^3). The copper is the white phase (arrows Cu). Note coring (arrows Co) as described in Fig. 61. These arrows indicate a string of four iron particles. Arrow P shows a large pore previously occupied by a copper particle. 2% nital. 100 \times

Fig. 63 Atomet 28 iron powder with 2% Cu and 0.5% C (6.7 g/cm^3 with 275 MPa, or 40 ksi, minimum yield strength). See Fig. 53 for processing. Arrows E show eutectoid (pearlite); arrow F, white ferrite grains. Arrows C indicate isolated or divorced eutectoid in the form of separate Fe_3C platelets. Arrows Co show coring from copper dissolving in the outer regions of iron particles. 2% nital. 310 \times

Fig. 64 Atomet 28 iron powder with 2% Cu

and 0.8% C (6.7 g/cm^3). See Fig. 53 for processing. Mostly eutectoid (arrows E) with a small amount of white ferrite (arrow F). The shading results from copper coring in the iron. See Fig. 66 and 67 for effects of increased copper content on the resulting properties and structure. 2% nital. 310 \times

Fig. 65 Same as Fig. 63, but with 5% Cu and 0.5% C (6.7 g/cm^3 with 344 MPa, or 50 ksi, minimum yield strength). At 5% Cu, some residual copper-rich phase is shown as thin, light-colored slivers (arrow Cu). Arrows Co show bands of coring from copper diffusion into the iron. Arrows E indicate eutectoid (pearlite). Arrow F shows ferrite grain. 2% nital. 330 \times

Fig. 66 Same as Fig. 63, but with 5% Cu and 0.8% C (6.8 g/cm^3 with 413 MPa, or 60 ksi, minimum yield strength). Arrows Cu show lenticular regions of melted copper-rich phase; arrows E, eutectoid (pearlite). Arrow F indicates a residual ferrite grain. Arrows Co show coring. 2% nital. 330 \times

Fig. 67 Copper-infiltrated steel with 10% Cu and 0.5% C, pressed to 6.65 g/cm³ and infiltrated with copper during 30 min sinter in hot zone at 1120 °C (2050 °F) in endothermic gas. Final density: 7.3 g/cm³. Minimum yield strength: 276 MPa (40 ksi). Arrows Cu show copper phase; arrows E, eutectoid (pearlite); arrow F, white ferrite grain. Picral. 330×

Fig. 68 Copper-infiltrated steel with 10% Cu and 0.8% C (7.3 g/cm³ final density with 344 MPa, or 50 ksi, minimum yield strength). See Fig. 67 for processing. Arrow Cu shows copper-rich region. Arrows E indicate eutectoid (pearlite); arrows Co show coring from partial diffusion of copper in the iron. Arrow Fe shows white ferrite grain. Picral. 330×

Fig. 69 Copper-infiltrated, hydrogen-reduced sponge iron with 20% Cu (7.3 g/cm³ final density with 172 MPa, or 25 ksi, minimum yield strength). See Fig. 67 for processing. Arrows Cu show copper phase outlined against the white ferrite matrix. Arrow Ox indicates an unreduced oxide particle, and arrow P a residual pore. 2% nital. 330×

Fig. 70 Copper-infiltrated steel with 20% Cu and 0.8% C (7.3 g/cm³ final density with 413 MPa, or 60 ksi, minimum yield strength). See Fig. 67 for processing. Arrow Cu shows the light-colored, melted copper-rich phase; arrows E, the eutectoid. Arrow P indicates residual pore. Picral, 30 s. 330×

Fig. 71 Copper-infiltrated, H₂-reduced sponge iron with 10% Cu (7.3 g/cm³ final density). Same processing as Fig. 67, but austenitized 60 min in endothermic gas at 845 °C (1550 °F), oil quenched, and tempered 1 h at 175 °C (350 °F). Arrow Cu shows melted copper-rich phase. Arrows Co indicates a cored region. Arrows M show mixed transformation products present 0.25 mm (0.010 in.) from the surface. Bainite (arrow B) may also be present. Picral. 330×

Fig. 72 Copper-infiltrated steel with 10% Cu and 0.8% C, infiltrated as per Fig. 67 and heat treated as per Fig. 71. Typical structure for interior of 5-mm (0.2-in.) diam tensile bar (minimum ultimate tensile strength of 758 MPa, or 110 ksi). Arrows M show martensite platelets; arrows Co, coring. Arrow C indicates copper-rich region. Arrows A show flecks of retained austenite. Picral. 585×

Fig. 74 Same as Fig. 73, but with 0.5% C. Note that the eutectoid (arrows E) now covers most of the field of view and that the distinction between eutectoid and white proeutectoid ferrite is not clear. 2% nital. 545×

Fig. 73 Prealloyed low-alloy steel (Fe-0.42Ni-0.62Mo-0.2C, 6.7 g/cm³), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Arrows E surround eutectoid region (background is white ferrite). Arrow P shows a pore. See also Fig. 74 and 75 for effects of increasing carbon content. 2% nital. 545×

Fig. 75 Same as Fig. 73, but with 0.8% C. Arrows E show the typical eutectoid product. Dark areas are pores. Note that the density of carbide platelets in the eutectoid is higher than for Fig. 74. 2% nital. 545×

Fig. 76 Prealloyed, low-alloy steel (Fe-1.85Ni-0.60Mo-0.2C, 6.7 g/cm³), processed as per Fig. 73. Matrix is white ferrite (arrow F). Eutectoid is found in colonies (arrows E).

Arrow P shows a pore. Separation of eutectoid and ferrite is distinct, making it possible to estimate carbon content. 2% nital. 545×

Fig. 77 Same as Fig. 76, but with 0.5% C. Arrows E outline the eutectoid product, which is so mixed with ferrite that it is difficult to distinguish proeutectoid ferrite. Arrow F shows one small grain that is probably white ferrite. 2% nital. 365×

Fig. 78 Same as Fig. 76, but with 0.8% combined carbon. The increasing carbon content alters the appearance of the eutectoid (compare with Fig. 77). The carbide platelets in the eutectoid colonies (arrows E) are more numerous and more closely spaced than in Fig. 77. 2% nital. 545×

Fig. 79 Prealloyed steel (Fe-1.85Ni-0.6Mo-0.5C, 6.7 g/cm³), with an impurity particle of unalloyed free ferrite (outlined by arrows FF), which has a carbon content of 0.3 to 0.4%. It is a mixture of proeutectoid ferrite (arrow F) and normal eutectoid (arrows E). Compare this eutectoid with the matrix eutectoid. Arrow P indicates a pore. 2% nital. 365×

Fig. 80 Same as Fig. 79, with a similar unalloyed iron particle. Arrows FF outline the free ferrite, which has a carbon content of approximately 0.6%, judging by its pearlite (arrows E) and its white proeutectoid ferrite (arrow F). 2% nital. 365×

Fig. 81 Iron-phosphorus alloy (atomized iron mixed with Fe_3P to yield 0.45% P) for soft magnetic applications (6.7 g/cm^3). Pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia. Phosphorus forms a liquid phase that causes pore rounding during sintering. As-polished. $180\times$

Fig. 82 Same as Fig. 81, but etched. Arrows E show fine two-phase eutectoid or eutectic of Fe-C-P. Arrows P indicate isolated phosphorus-rich phase in grain boundaries. Matrix is all white ferrite. 2% nital. $545\times$

Fig. 83 Water-atomized iron powder with 0.5% MnS blended for increased

machinability. See Fig. 81 for processing (6.7 g/cm^3 with 103 MPa, or 15 ksi, minimum yield strength). The MnS is the gray material (see arrows M) inside the darker pores. 2% nital. $330\times$

Fig. 84 Sponge iron powder with 0.27% S and 0.9% Mn added to the melt before particle formation. See Fig. 81 for processing (6.7 g/cm^3 with 103 MPa, or 15 ksi, minimum yield strength). Arrows S show gray MnS inclusions within the iron particles and also in the spongy areas. 2% nital. $330\times$

Fig. 85 Carbon-reduced sponge iron powder with 0.5% S blended as elemental fines. See Fig. 81 for processing (6.4 g/cm^3 with 103 MPa, or 15 ksi, minimum yield strength). Arrows S show two-phase sulfide mixtures of MnS and FeS, which lie within the pores. 2% nital. $330\times$

Fig. 86 Nickel steel (elemental mix of atomized iron, 2% Ni, and 0.8% combined carbon, 6.7 g/cm³), pressed at 410 to 480 MPa (30 to 35 tsi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Arrows S indicate short segments of original particle boundaries. See also Fig. 87, 88, 89, and 90. As-polished. 180×

Fig. 87 Same nickel steel as shown in Fig. 86, but with 1% Cu added. A few short segments of original particle boundaries remain (arrows S). It is difficult to distinguish any microstructural effect of the copper. As-polished. 180×

Fig. 88 Same nickel steel as shown in Fig. 86, but with 2% Cu added. The additional copper helped to eliminate original particle boundaries, round the pores, and eliminate small pores. As-polished. 180×

Fig. 89 Same as Fig. 87, but etched. Arrows N show nickel-rich region, inside which are martensite platelets. The effect of the 1% Cu is indicated by shading or coring of the ferrite (arrows Co). Arrows E show eutectoid; arrows L, an underetched region of eutectoid. Arrow F indicates a white ferrite grain. 2% nital. 310×

Fig. 90 Same as Fig. 88, but etched. The 2% Cu causes the nickel to dissolve, eliminating the nickel-rich regions. Arrows ? surround regions where the nickel probably was. These regions are darkened by the coring caused by copper dissolving there and contain carbide platelets. Another cored region is marked Co. Arrows E mark unresolved eutectoid, and arrow F indicates a white ferrite grain. 2% nital. 310×

Fig. 91 Nickel steel (atomized iron mixed with 2% elemental nickel and 0.2% combined carbon). See Fig. 86 for processing (6.7 g/cm^3 with 137 MPa, or 20 ksi, minimum yield strength). Arrows N outline a nickel-rich region. The austenitic light-colored center is approximately 12% Ni. The outer edges are lower in nickel and higher in carbon. Dark regions are pores. 2% nital. 545 \times

Fig. 92 Same as Fig. 91, but with 0.5% C. Arrows N outline nickel-rich regions. The fine structure within these regions is martensite and bainite. Arrows E outline a eutectoid region. Arrow F indicates a white ferrite grain. Arrow D shows a white diffusion layer between the eutectoid and the nickel-rich areas. 2% nital. 310 \times

Fig. 93 Same as Fig. 91, but with 0.8% C. Structure is nearly all eutectoid (arrows E), with some nickel-rich regions (arrows N) and isolated ferrite (arrow F). See also Fig. 94 for higher magnification of this structure. 2% nital. 310 \times

Fig. 94 Same as Fig. 93, but at higher magnification. Arrows N outline a nickel-rich region running through the structure along the pore surfaces, which probably forms a continuous three-dimensional network within the steel. Martensite needles are visible on the surface of the region. Arrows E show eutectoid; arrow D, white diffusion layer. 2% nital. 550 \times

Fig. 95 Nickel steel (4% elemental carbonyl nickel admixed with atomized iron and 0.2% C, 6.7 g/cm^3). See Fig. 86 for processing. Arrows E show a small colony of eutectoid, but most of the carbon is tied up in the nickel-rich regions (arrows N). Background is white ferrite grains. 2% nital. 330 \times

Fig. 96 Same as Fig. 95, but with 0.5% C. As-sintered part would have a minimum yield strength of 207 MPa (30 ksi) or 723 MPa (105 ksi) if hardened and tempered at 260 °C (500 °F). Arrows N show a nickel-rich region. Arrows E indicate eutectoid, and arrow D shows a white diffusion layer between nickel-rich regions and the eutectoid. 2% nital. 330×

Fig. 97 Same as Fig. 95, but with 0.8% C. Minimum yield strength: 276 MPa (40 ksi). Arrows N outline nickel-rich regions. Arrows E indicate eutectoid. Very little ferrite is present. 2% nital. 330×

Fig. 98 Same as Fig. 97, but at higher magnification. A nickel-rich region is

bounded by arrows N. Martensite platelets (40 to 50 HRC) are visible on the periphery of this region (arrows M). These convey extra wear resistance in the as-sintered condition. The remaining structure is eutectoid. 2% nital. 585×

Fig. 99 Diffusion-alloyed steel (Fe-1.75Ni-0.5Mo-1.5Cu-0.5C, 6.7 g/cm³), pressed at 410 to 480 MPa (60 to 70 ksi) and sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia. Arrows N show nickel-rich regions containing martensite or bainite platelets; arrows E, a eutectoid colony with a white diffusion layer on the periphery. Arrow F indicates ferrite. 2% nital. 330×

Fig. 100 Same as Fig. 99, but with 0.8% C. Arrows N show nickel-rich areas containing platelets of martensite or bainite. Arrow L indicates a light-etching eutectoid region, and arrow P a pore. Arrows E outline a colony of eutectoid containing thin carbide platelets. 2% nital. 330×

Fig. 101 Same as Fig. 99, but with 4% Ni. Structure shows extensive nickel-rich areas (arrows N), with light-colored austenite at their interiors and gray martensite at their peripheries. Unresolved eutectoid is shown by arrows E, and a diffusion layer by arrows D. Arrow F indicates white ferrite. Arrows M outline a residual, spongy, undiffused molybdenum particle. 2% nital. 365×

Fig. 103 Same as Fig. 102, but sintered 60 min at 1290 °C (2350 °F) in dissociated ammonia (7.15 g/cm³). Many of the small pores have disappeared, and few particle boundary segments remain (see arrows). Specimen from tensile bar with a tensile strength of 432 MPa (62.7 ksi) and elongation in 25 mm (1 in.) of 11 %. As-polished. 180×

Fig. 102 Type 316 stainless steel (6.96 g/cm³), pressed at 830 MPa (60 tsi) and sintered 30 min at 1150 °C (2100 °F) in dissociated ammonia. Structure is a tensile bar with tensile strength of 393 MPa (57 ksi) and elongation in 25 mm (1 in.) of 1%. Arrows show original particle boundaries. As-polished. 180×

Fig. 104 Same as Fig. 102, but vacuum sintered at 1290 °C (2350 °F) for 60 min (7.26 g/cm³). Pores are more rounded than the dissociated ammonia sinters in Fig. 102 and 103. Specimen from tensile bar with a tensile strength of 355 MPa (54.4 ksi) and elongation in 25 mm (1 in.) of 25%. As-polished. 180×

Fig. 105 Same as Fig. 102, but etched, showing the precipitated grain-boundary carbides (arrow C), which cause the irregular grain boundaries. Arrow A shows a normal austenite grain boundary, arrow T a twin boundary, and arrow P a pore. Glyceregia. 365×

Fig. 106 Same as Fig. 103, but etched. Note that the austenite grain boundaries and twin boundaries (arrow T) are free of carbides due to the decarburizing effect of the high-temperature dissociated ammonia sinter. Glyceregia. 545×

Fig. 107 Same as Fig. 104, but etched. Structure is free of grain-boundary carbides. Arrow T points to a typical twin boundary. Glyceregia. 180×

Fig. 108 Same as Fig. 107, but at higher magnification. Grain boundaries show no carbide precipitates. Arrow T shows an annealing twin. Glyceregia. 545×

Fig. 109 Type 303 stainless steel (7.06 g/cm³), pressed at 830 MPa (60 tsi) and sintered 60 min at 1120 °C (2050 °F) in dissociated ammonia. Residual chromium carbides are in the austenite grain boundaries (arrow C). Arrow A shows an austenite grain boundary free of carbides. Glyceregia. 360×

Fig. 110 Same as Fig. 109, but sintered 60 min at 1190 °C (2350 °F) in dissociated ammonia (7.23 g/cm³). No carbides are present at grain boundaries. Arrows S

indicate gray MnS inclusions added for machinability. Arrow T shows a typical annealing twin boundary. Glyceregia. 365×

Fig. 111 Same as Fig. 109, but vacuum sintered at 1290 °C (2350 °F) for 60 min (7.29 g/cm³). Arrow S shows a MnS particle. Glyceregia. 365×

Fig. 112 Type 410 stainless steel with added 0.15% graphite (6.77 g/cm³), pressed at 830 MPa (60 tsi), sintered 60 min at 1150 °C (2100 °F) in dissociated ammonia, and tempered 1 h at 175 °C (350 °F). Arrows S indicate original particle boundaries. Glyceregia. 120×

Fig. 115 P/M T15 tool steel, pressed at 550

Fig. 113 Same type 410 stainless steel and pressing conditions as described in Fig. 112, but sintered 30 min at 1120 °C (2050 °F) and etched. Structure is all martensite (arrows M). Glyceregia. 545×

Fig. 114 Wrought T15 steel. Arrow shows large primary M₆C carbide (compare with P/M tool steels in Fig. 115 and 116). Fine precipitate is vanadium carbide; matrix is martensite. 5% nital. 365×. (Ref 12)

MPa (40 tsi), and vacuum sintered 1 h at 1260 °C (2300 °F) to full density (8.25 g/cm³). Arrow indicates primary M₆C carbide (compare with Fig. 114). 5% nital. 500×. (Ref 12)

Fig. 116 P/M M2 tool steel (8.12 g/cm^3) pressed at 550 MPa (40 tsi) and vacuum sintered 1 h at 1240°C (2260°F). Arrow indicates small M_6C particle. Other small MC precipitates can be seen in the matrix of retained austenite, which also contains martensite. 5% nital. $400\times$. (Ref 12)

Fig. 117 Bronze (Cu-10Sn, 6.4 g/cm^3) pressed at 140 to 205 MPa (10 to 15 tsi), sintered (conditions not known), and sized for tolerances. Mostly all α -bronze grains. Gray areas are pores. Arrows surround slip line from cold working during sizing. $\text{K}_2\text{Cr}_2\text{O}_7$. $180\times$

Fig. 118 Same material and processing as described in Fig. 117. Arrows indicate

clusters of small grains that have not grown into larger α grains. Compare with Fig. 119, which shows the effects of a 4% graphite addition on the resulting structure. $\text{K}_2\text{Cr}_2\text{O}_7$. $180\times$

Fig. 119 Cu-10Sn bronze (6.4 g/cm^3) with 4% graphite. Pressed at 165 to 205 MPa (12 to 15 tsi), sintered 15 min at 845°C (1550°F), and sized. Arrows GP show graphite in pores surrounded by darker gray epoxy resin; arrow G, graphite flake in the matrix. Arrows S surround a small grain cluster; arrow P indicates a pore. $\text{K}_2\text{Cr}_2\text{O}_7$. $120\times$

Fig. 120 Inner diameter (left) of a sized Cu-10Sn bronze bearing (see Fig. 119 for processing). Note that the pores on the ID have been closed by the sizing operation. As a result, oil would not have easy access from the interior to the ID. $\text{K}_2\text{Cr}_2\text{O}_7$ $180\times$

Fig. 121 Leaded brass (Cu-20Zn-2Pb, 8.1 g/cm³), pressed and sintered 30 min at 870 °C (1600 °F), then re-pressed. Structure is all single-phase α -brass with a few annealing twins. Dark spots are well-rounded pores. 5 mL NH₄OH, 5 mL H₂O, and 3 drops 30% H₂O₂. 180×

Fig. 122 Same as Fig. 121, but at higher sintering temperature and/or longer time, which results in much larger grains. The pores (dark areas) are coarser and more rounded than those in Fig. 121. Etchant: same as Fig. 121. 180×

Fig. 123 Ti-6Al-4V, cold isostatically pressed and vacuum sintered to dissolve the master alloy additions of vanadium and aluminum (94% dense). Rounded pores indicate adequate sintering. As-polished. 180×. (Ref 13)

Fig. 124 Same as Fig. 123, but etched. Dark areas are residual rounded pores. Matrix is transformed β -titanium. 85 mL H₂O, 5 mL HNO₃, and 10 mL HF. 180×. (Ref 13)

Fig. 125 Ti-6Al-4V, cold isostatically pressed, vacuum sintered, then hot isostatically pressed to 99.6% density. Structure shows all transformed β . 85 mL H₂O, 5 mL HNO₃, and 10 mL HF. 180×. (Ref 13)

Fig. 126 Aluminum alloy powder (Al-4.4Cu-0.8Si-0.4Mg), pressed and sintered 30 min at 595 °C (1100 °F) in nitrogen. Typical as-sintered structure. Keller's reagent. 100×. (Ref 14)

100×. (Ref 14)

Fig. 129 Same alloy and processing as Fig. 128, but reduced 25% in thickness by forging, which closed up most of the porosity. Keller's reagent. 100×. (Ref 14)

Fig. 127 Same alloy and processing as Fig. 126, but at higher magnification. Keller's reagent. 500×. (Ref 14)

Fig. 130 Same as Fig. 128, but pressed, sintered at 620 °C (1150 °F), and reduced 50% in thickness by forging or rolling to eliminate porosity. Keller's reagent. 100×. (Ref 14)

Fig. 128 Aluminum alloy powder (Al-1.0Mg-0.6Si-0.25Cu), pressed, sintered, and solution heat treated. Typical structure. Dark areas are pores. Keller's reagent.

Fig. 131 Nickel steel (carbonyl Fe, 2% carbonyl Ni, and 0.3% C) injection molded and sintered (1120 °C, or 2050 °F) to 97% density. Structure shows fine isolated

porosity (gray dots). At surface (bottom left) there is a 0.05 mm (0.002 in.) thick layer that exhibits no apparent porosity. As-polished. 180×

Fig. 132 Same as Fig. 131, but etched. The nickel has diffused into the iron, resulting in complete homogeneity. The eutectoid (arrows E) is similar to that found in 4600 prealloyed steel (Fig. 78). Arrow P indicates an isolated rounded pore. 2% nital. 365×

Fig. 133 Prealloyed steel powder (Fe-2Ni-0.5Mo-0.5C) pressed to 6.6 g/cm³, sintered 30 min at 1120 °C (2050 °F), induction reheated, and hot forged (1095 °C, or 2000 °F) at 830 MPa (60 tsi) to over 99% of theoretical density. Arrows E show typical eutectoid; arrows FP, fine pearlite from rapid cooling of forged part. 2% nital. 545×

Fig. 134 Powder-forged gear (Fe-2.0Ni-0.5Mo-0.2C). See Fig. 133 for processing. Arrows E show eutectoid; arrows F, white ferrite grains and grain boundaries. Dark spots are pores. Part is 99% dense. 2% nital. 365×

Fig. 135 Copper steel (Fe-2.0Cu-0.8C, 6.8 g/cm³) that has formed blisters during delubrication and sintering. Arrows C indicate stringer (grain-boundary) carbides resulting from carburization. Some light-colored copper is evident (arrow Cu). Arrow L shows a light-etching eutectoid region. 2% nital. 585×

Fig. 136 Same as Fig. 135, but pressed at 480 MPa (35 tsi), sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia, and

decarburized. White ferrite grains near the surface (right) indicate loss of carbon. The interior (left) is a darker eutectoid, containing approximately 0.8% C; the surface is $\sim 0.1\%$ C. 2% nital. 30 \times

Fig. 137 Pressed and sintered sprocket gear (composition unknown). Arrow OD shows the outer edge of the tooth, and arrow U the underside. A chamfer has broken off the tooling, resulting in a reverse chamfer (arrow C) on the part. Arrow P indicates original particle boundary resulting from particle separation during part ejection. As-polished. 110 \times

Fig. 138 View at the radius between a flange (arrow F) and a hub (arrow H) in a pressed and sintered part (composition unknown). The relative motion between the hub and flange was not adjusted correctly during pressing, resulting in a shear crack (arrows C). As-polished. 120 \times

Fig. 139 A corner of an MPIF tensile bar (Fe-2Ni-0.8C , 6.8 g/cm^3) pressed at 550 MPa (40 tsi) and sintered 30 min at 1115°C (2040°F) in endothermic gas. Arrows indicate microlaminations that occurred during part ejection. These reduce the tensile strength of the bar by 30 to 40%. As-polished. 120 \times

Fig. 140 Fe-0.8C , pressed at 550 MPa (40 tsi) and sintered 30 min at 1120°C (2050°F) in dissociated ammonia (DA). Heat treated structure showing mixture of 50% fine pearlite (dark phase) and 50% martensite (lighter phase). 4% picral. 960 \times

Fig. 141 Copper steel (Fe-2Cu-0.8C , 6.7

g/cm³) pressed at 480 MPa (35 tsi), sintered 30 min at 1120 °C (2050 °F) in dissociated ammonia, austenitized 1 h at 870 °C (1600 °F), and oil quenched. Surface of part shows a thin, white layer of carbide (arrow C). The structure interior consists of 35% fine pearlite (arrows FP) and balance martensite (arrows M). Picral. 120×

Fig. 142 Fe-0.37Mn-1.80Ni-0.63Mo alloy powder with added 2% Cu and 0.8% C. Pressed at 480 MPa (35 tsi), sintered 30 min at 1120 °C (2050 °F) in a nitrogen-base atmosphere, and tempered 1 h at 175 °C (350 °F) to 6.85 g/cm³. Structure shows fine pearlite (arrows P) and small amounts of white ferrite (arrow F) in a martensite matrix (arrows M). 2% nital. 365×

Fig. 143 Nickel steel (Fe-2Ni-0.8C, 6.7 g/cm³). Pressed and sintered (normal processing) in endothermic gas, austenitized 1 h at 870 °C (1600 °F), oil quenched, and tempered 1 h at 260 °C (500 °F). Arrows C indicate carbide particles. Arrows M show a typical martensite platelet, Arrows N surround a nickel-rich region. Arrows A show light-colored regions of retained austenite. Picral. 645×

Fig. 144 Prealloyed steel (Fe-1.8Ni-0.5Mo-0.4C, 6.83 g/cm³), pressed and sintered (normal processing) in dissociated ammonia, austenitized 1 h at 870 °C (1600 °F), oil quenched, and tempered 1 h at 175 °C (350 °F). Matrix (white areas) is retained austenite (excessive, 65 vol%). Arrows M indicate martensite platelets. Picral. 960×

Fig. 145 Fe-1.5graphite (6.7 g/cm³), pressed and sintered under normal processing conditions and heat treated as described in Fig. 144. Structure shows massive carbides (sharply delineated light phase). Picral. 960×

Fig. 146 Atomized iron powder, pressed to 6.8 g/cm³, sintered in dissociated ammonia, austenitized 30 min in vacuum, gas carburized less than 5 min, and oil

quenched. The 0.1 mm (0.004 in.) thick case is the dark martensite on right. Interior is all white ferrite. 2% nital. 180×. (Ref 18)

Fig. 147 Steam-blackened Fe-2Cu-0.8C part that was undersintered. Arrow O shows a spongy pore that has been filled with gray Fe₃O₄ during the steam process. Arrows P indicate original particle boundaries, which were filled by the steam process. As-polished. 180×

Fig. 148 Pressed and sintered Fe-0.8C steel (6.4 g/cm³), which was steam blackened. The pores are nearly all filled with gray Fe₃O₄ (arrows O). Arrow P shows a pore not filled with oxide. Arrows E surround a eutectoid region. White areas are ferrite. 2% nital. 365×

Fig. 149 Pyron D63, hydrogen-reduced mill scale, sponge iron powder (-100 mesh). Particles contain fine, internal pores and some coarse pores. As-polished. 180×

Fig. 150 Same as Fig. 149, but at higher magnification, showing details of the internal porosity and some unreduced oxides. As-polished. 615×

Fig. 151 MH-100 carbon-reduced sponge iron powder (-100 mesh). A few ferrite grain boundaries are shown, but no iron carbides. Arrows P surround a particle having extensive internal porosity. As-

polished. 960×

Fig. 152 Atomet 28 iron powder (granulated and oxidized, hydrogen reduced), showing particles of varying degrees of porosity. As-polished. 645×

Fig. 153 Ancorsteel 1000 water-atomized, annealed iron. Solid particle with some gas porosity (arrow G) and some surface porosity (arrows S) caused the reduction of oxides picked up during atomization. As-polished. 645×

Fig. 154 Ancorsteel 1000 water-atomized

iron (-80 mesh), Arrows indicate fine particles agglomerated to coarser ones during annealing. As-polished. 960×

Fig. 155 Same as Fig. 154, but etched. Grain boundaries are ferrite, indicating low carbon content. Some particles do not etch. Note irregular surface of particle at upper left caused by agglomeration of smaller particles. 2% nital. 615×

Ferrous Powder Metallurgy Materials

W.B. James, Hoeganaes Corporation; G.T. West, National Sintered Alloys Inc.

Introduction

FERROUS POWDER METALLURGY processing is a net or near net-shaped production technology, which in many instances eliminates the need for secondary machining operations. Ferrous P/M offers a wide range of engineered materials for structural applications and satisfies close dimensional tolerance requirements for parts with complex geometries.

Figure 1 illustrates the continued growth of iron powder shipments in North America. From 1985 to 1995 the North American iron powder market grew at a compounded annual rate of 6.1%. In 1996, iron powder shipments were 318,227 metric tons (350,603 short tons). The ferrous P/M industry in North America has experienced sustained growth in the 1990s with growth projected to continue through the year 2005 (Ref 1). In comparison, for Japan, the total iron powder production in 1996, including exports, reached 157,356 metric tons (173,406 short tons), a decline of 4.6% (Fig. 2). At 103,258 metric tons (113,790 short tons), iron powder shipments during 1996 in Europe showed a marginal increase of 416 metric tons (459 short tons) compared with shipments in 1995. Figure 2 illustrates a comparison of international iron and steel powder shipments.

Fig. 1 Iron powder shipments in North America. Source: Ref 1

Fig. 2 International iron and steel powder shipments. Source: Ref 1

Automotive applications currently represent 69% of the ferrous structural parts market (Fig. 3) (Ref 1). The typical family vehicle contains 14 kg (31 lb) of P/M parts, and industry experts forecast that the P/M content in cars will reach 22.6 kg (50 lb) by the end of the decade. There are some models that already contain up to 18.1 kg (40 lb) of P/M parts. Other major markets are represented by household appliances; hardware; industrial motors/controls and hydraulics; and recreation, tools, and hobby applications.

Fig. 3 Applications for ferrous P/M structural parts. Source: Ref 1

When selecting a material for an intended application it is important that a "systems" approach, as illustrated in Fig. 4, is followed (Ref 2). Part designers need to involve part fabricators, tool designers, and material engineers from the outset of an application development program. Performance targets for the part need to be defined, as well as the application environment. The part fabricator can suggest design changes that will lead to a more robust P/M part, and the designer

can assess the impact of the proposals on the anticipated performance of the part. It is important to determine from the outset whether the fabricator can make a net shaped part or whether secondary machining operations will be needed. This will have a major influence on the material selection for any proposed part processing sequence.

Fig. 4 "Systems" approach to P/M part development. Source: Ref 2

In addition, ferrous powder metallurgy also encompasses several production technologies other than traditional press and sinter operations. These include copper-infiltrated steels, powder forged steels, and injection molded steels, which are discussed in detail in separate articles in this Section. Various other options are also used to increase the performance of P/M parts. This may include additional processing (Fig. 5a) or alloying (Fig. 5b). This article briefly summarizes the general classification, mechanical properties, and applications of ferrous P/M materials for parts production. More detailed coverage on major alloys and processing methods are discussed elsewhere in this Volume and in Ref 4 and 5.

Alloying Methods

There are four principal alloying methods used in ferrous powder metallurgy:

- Admixed alloys
- Partial alloys (diffusion alloys)
- Prealloys
- Hybrid alloys

Each method will be described, and the benefits and disadvantages of each method will be reviewed along with the effect of processing on the microstructure and properties of the materials. In general, comments made with respect to sintering will relate to sintering at a temperature of 1120 °C (2050 °F) unless specified otherwise.

Admixed Powders. Alloying additions, in elemental form or as ferroalloys, such as Fe₃P, FeMn, or FeCr, can be mixed with an iron powder. This is generally the least expensive and most commonly used alloying method in ferrous powder metallurgy. When the mix is pressed, the additions are not alloyed with the iron powder; admixed materials therefore retain most of the compressibility of the base iron powder. The degree of alloying during sintering is limited by the diffusivity of the alloying elements in the iron at the sintering temperature. The resulting microstructures can be chemically and microstructurally heterogeneous.

Direct reduced sponge iron or water atomized iron powders can be used as the base powder for admixed materials. The density required to achieve the desired mechanical properties generally will dictate which type of powder is used. Sponge powders are selected typically for the density range of 6.4 g/cm³ and lower, while atomized iron powders are used for parts with a density of 6.7 g/cm³ and higher. Either type of powder can be used for the intermediate density range; the choice generally depends on the part geometry and the available compaction press tonnage.

Partially Alloyed Powders. In partially alloyed powders, also known as diffusion alloyed powders, the alloy addition or additions are metallurgically bonded to either an elemental iron powder or to a prealloyed powder base (see the section "Prealloyed Powders" for an explanation of prealloyed powders). The diffusion alloying of the additions is controlled to provide adequate bonding of the additions to the base powder while limiting the extent of diffusion of the additives so they do not reduce the compressibility of the base powder appreciably.

While there is a wide range of diffusion alloyed powders available in Europe (Ref 6), there are only two grades in widespread commercial use in North America, South America, and Canada. Both are based on a highly compressible iron powder, contain nominally 1.5 wt% Cu and 0.5 wt% Mo, and differ with respect to their nickel contents. One powder contains 2 wt% Ni, while the other has a nickel content of 4 wt%. Parts made from partially alloyed powders have a complex as-sintered microstructure consisting of areas of martensite, bainite, fine unresolved pearlite, nickel-rich ferrite containing blocky carbides, as well as dispersed nickel-rich areas of retained austenite (Fig. 6). This complex microstructure provides a combination of good tensile strength and tensile ductility as well as a material with excellent impact energy.

Fig. 6 As-sintered microstructure of a part made from a partially alloyed powder FD-0405: B, bainite; P, pearlite; UP, unresolved pearlite; NR, nickel rich region; NRF, nickel rich ferrite; M, martensite

Prealloyed Powders. Prealloyed, low-alloy steel powders are particularly useful in the manufacture of P/M parts designed for high performance applications. Combinations of molybdenum, manganese, and nickel are added to molten iron during the steelmaking process to produce a chemically uniform powder. Practices are followed during melting and atomization to ensure the production of powders with nonmetallic inclusion contents suitable for the most stringent requirements. The reactivity of carbon, in the form of graphite, with the prealloyed powders is excellent, enabling close control of the combined carbon content during sintering.

These powders are used in a wide range of applications. Varying performance requirements are satisfied through a combination of alloy selection, carbon additions, and processing conditions. In general, the compressibility of prealloyed powders is lower than that of admixed or partially alloyed powders. However, prealloyed powders in which molybdenum is the principal alloy addition have compressibilities that are comparable to those of iron powders (Ref 2).

The hardenability of the prealloyed materials is controlled by the amount and type of alloying employed and can be tailored to fit specific applications. Prealloyed materials have homogeneous microstructures with uniform apparent hardness. Unlike admixed, partially alloyed, and some hybrid alloys, alloying is not primarily dependent on diffusion processes. Just as with admixed, partially alloyed, and hybrid alloys (see the section "Hybrid Alloy Powders"), higher sintering temperatures ($>1120^{\circ}\text{C}$, or 2050°F) and longer sintering times (greater than 20 min at temperature) will, however, influence the number of pores that are present in the microstructure as well as their size and their shape. Pore coalescence occurs as sintering temperature and time are increased; large pores grow at the expense of the smaller pores. Increased time and temperature also lead to an increased amount of pore rounding.

Certain applications may require supplemental alloy additions via admixing to enhance the hardenability and mechanical properties of the material. Such materials are termed hybrid alloys.

Hybrid Alloy Powders. Hybrid alloys consist of either prealloyed or partially alloyed base powders to which elemental or ferroalloy additions are made to achieve the desired chemical composition. The practice of making nickel or copper additions to prealloyed powders has become widespread since the introduction of the highly compressible, prealloyed powders with molybdenum as the principal alloy addition (Ref 2, 7). These prealloyed powders are also particularly suitable for the addition of high-carbon ferroalloys to produce chrome-molybdenum, manganese-molybdenum, and chrome-molybdenum-manganese steels (Ref 8). Elemental nickel additions can be made to partially alloyed powders to provide even greater impact properties (Ref 9, 10). The compressibility and hardenability of hybrid alloy materials depends primarily on the compressibility and hardenability of the base powder employed. Hybrid materials generally have a heterogeneous microstructure with nonuniform apparent hardness. Higher sintering temperatures and longer sintering times generally lead to greater diffusion of the alloy additions and to more homogeneous microstructures.

Ferrous Powder Metallurgy Materials

W.B. James, Hoeganaes Corporation; G.T. West, National Sintered Alloys Inc.

Ferrous Powder Materials

Material code designations for ferrous P/M materials are found in MPIF Standard 35, *Materials Standards for P/M Structural Parts*. Similar designations have been adopted by ASTM and are summarized in specification B 783 (Ref 11). These standards are subject to periodic review, and users are cautioned to refer to the latest edition. Ferrous material designations have various prefixes:

- F, iron
- FC, iron-copper or copper steel
- FD, diffusion alloyed steel (partially alloyed)
- FL, prealloyed ferrous material except stainless steel
- FN, iron-nickel or nickel steel
- FX, copper infiltrated iron or steel
- SS, stainless steel (prealloyed)

Figure 7 provides examples of material designations. The designation FN-0205-35 (Fig. 7a) refers to a nickel steel with nominally 2 wt%Ni, 0.3 to 0.6 wt% combined carbon, and a guaranteed minimum 0.2% offset yield strength of 240 MPa (35 ksi). The FN prefix designates an admixed nickel steel, and the 02 following the prefix indicates that there is 2 wt% of the major alloy addition (nickel). The 05 refers to the combined carbon content of the material. The code designations for various combined carbon contents are:

Combined carbon range, wt%	Code designation
0-0.3	00
0.3-0.6	05 ^(a)
0.6-0.9	08

(a) The 05 designation for the FL materials (prealloyed) refers to 0.4 to 0.7 wt% combined carbon.

The designation FL-4405-175HT in Fig. 7(b) refers to a quench-hardened and tempered, prealloyed steel with a combined carbon content of 0.4 to 0.7 wt% and a guaranteed minimum ultimate tensile strength of 1210 MPa (175 ksi).

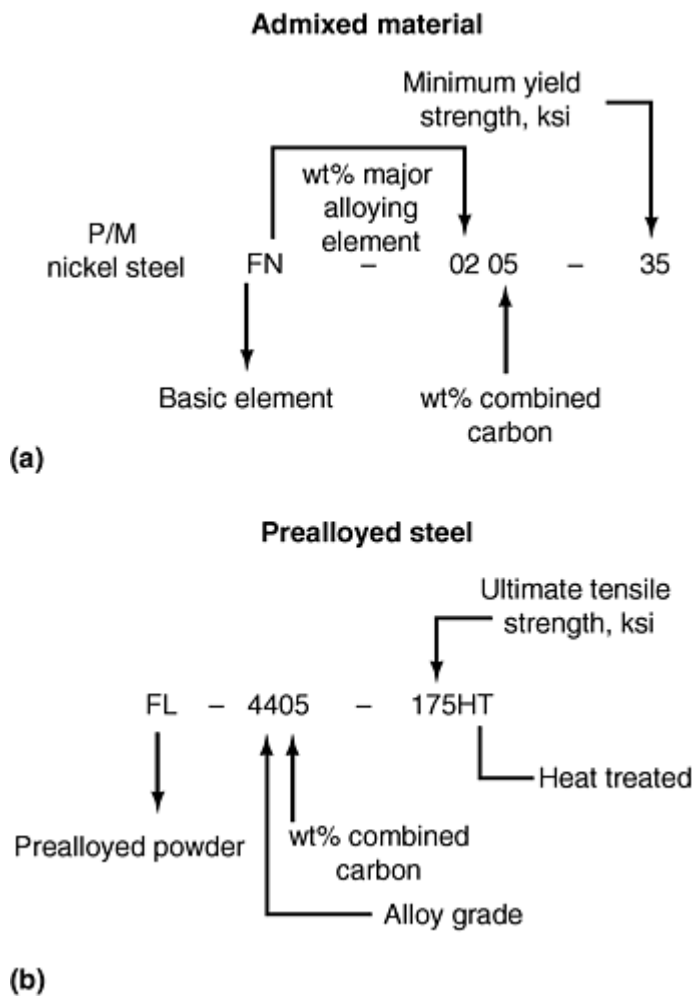

Fig. 7 Examples of ferrous P/M material designations. (a) FN-0205-35 and (b) FL-4405-175HT

For as-sintered materials the material designation suffix refers to the guaranteed minimum 0.2% offset yield strength in thousands of pounds per square inch. For example, FC-0208-50 refers to an admixed copper steel with nominally 2 wt% Cu, a combined carbon content of 0.6 to 0.9 wt%, and a guaranteed minimum 0.2% offset yield strength of 340 MPa (50 ksi).

For heat treated materials the material designation suffix refers to the guaranteed minimum ultimate tensile strength in thousands of pounds per square inch. For example, FN-0205-130HT refers to an admixed nickel steel with nominally 2 wt% nickel, a combined carbon content of 0.3 to 0.6 wt%, and a guaranteed minimum ultimate tensile strength of 900 MPa (130 ksi).

Admixed Powders

Admixed materials are in widespread use throughout the ferrous P/M industry. They generally contain sufficient graphite to provide the desired carbon content after sintering because the typical base powders used are essentially carbon free. Base powders generally have low carbon contents because carbon forms an interstitial solid solution with iron and reduces the compressibility of the powder significantly. In addition to graphite, the mixes contain a lubricant that aids particle rearrangement during the initial stages of compaction. The principal purpose of the added lubricant is, however, to reduce the friction between the powder particles and the compaction tooling members (die wall, core rods, and punches) and make ejection of the compacted part easier. Lubricant additions vary from 0.5 wt% to sometimes >1 wt%, depending on the part geometry, part density, and the surface area of the compact at the die-wall and core rod interfaces. Lubricant additions of 0.75 wt% are quite common. The lubricants used are generally metallic stearates (e.g., zinc stearate) or ethylene bisstearamides. They are white solids with pycnometric densities of $\sim 1 \text{ g/cm}^3$. Because of their low density relative to that of iron, while they are added typically in quantities of about 0.75 wt%, they occupy $\sim 5.5 \text{ vol\%}$ in the mixture. This has particular significance when parts are compacted at high pressures (Ref 12, 13, 14).

Because the various powders that comprise the admixed alloys have differing particle size and density, admixed alloys are particularly susceptible to dusting and segregation during handling and transfer to the die cavity. Numerous opportunities exist during the P/M process for dusting and segregation to occur (Ref 15). Compositional variations, which result from these demixing phenomena, cause inconsistencies in the green and sintered properties of P/M parts. The tendency for mixes to dust and segregate can be reduced significantly through the use of binder treated mixes (Ref 16, 17, 18, and 19). In addition to reducing dusting and segregation, binder treated mixes improve powder flow and die filling characteristics during part manufacturing. This results in more consistent part sectional densities and improved control of part mass. Improved flow and die fill uniformity result in reduced press cycle times and more consistency throughout the entire part manufacturing process.

Improved retention of alloy additions provides an economic advantage in terms of reduced amounts of green scrap, enhanced alloy efficiency, and a more pleasant and easier to maintain work environment. Plant cleanliness is dramatically improved, and the amount of respirable dust in the immediate vicinity of the compaction press is reduced by an order of magnitude (Fig. 8) (Ref 2). Binder treated premixes are produced using a proprietary mixing process that utilizes patented binders (Ref 16, 17, 18, and 19).

Iron and Carbon Steels. Table 1 summarizes the chemical compositions of the iron and carbon steels listed in MPIF Standard 35.

Table 1 Chemical composition of iron and carbon steels

Material designation	Chemical composition, wt%		
	Fe	C	Element
F-0000	97.7	0.0	min.
	100.0	0.3	max.
F-0005	97.4	0.3	min.
	99.7	0.6	max.
F-0008	97.1	0.6	min.
	99.4	0.9	max.

Other elements: Total by difference equals 2.0 wt% maximum, which may include other minor elements added for specific purposes.

Unalloyed iron (F-0000) materials are used for lightly loaded structural applications and structural parts requiring self lubrication where strength is not critical. The combined carbon content of these materials can be from 0 to 0.3 wt%. Iron parts that are essentially carbon free are often used, particularly at higher part densities, for their soft magnetic properties (Ref 20, 21, 22).

P/M carbon steels with 0.3 to 0.6 wt% combined carbon (F-0005) possess moderate strength and apparent hardness. They are used where such properties combined with machinability are desired.

Higher carbon P/M steels (F-0008) have moderately higher strength compared with F-0005 materials, but are more difficult to machine. In the as-sintered condition carbon steels have a ferrite/pearlite microstructure (Fig. 9). Both F-0005 and F-0008 steels can be heat treated to increase tensile strength, improve apparent hardness, and enhance wear resistance. Heat treated carbon steels have a martensitic microstructure (Fig. 10). Table 2 summarizes the mechanical properties of various carbon steels.

Powder metallurgy carbon steels often are steam treated to improve shelf life; close interconnected porosity; and increase compressive yield strength, apparent hardness, and wear resistance. Steam treatment, however, significantly degrades the tensile properties (Ref 23).

Copper is added to increase strength, apparent hardness, and wear resistance. Copper steels (FC-0205 and FC-0208) are used in medium-strength structural applications. Copper steels with combined carbon contents of greater than 0.5 wt% are more difficult to machine than copper steels with lower combined carbon contents. In the as-sintered condition copper steels have a ferrite/pearlite microstructure. The FC-0208 material shown in Fig. 11 is almost of the eutectoid composition and is mostly pearlitic.

Fig. 11 Ferrite/pearlite microstructure of an as-sintered P/M copper steel (FC-0208)

Copper steels can be heat treated to increase strength, apparent hardness, and wear resistance. Table 4 summarizes the mechanical properties of various copper steels.

Table 4 Mechanical properties of various iron-copper and copper steels

HT, heat treated; N/A, not applicable. Suffix numbers represent minimum strength values in 10³ psi; yield in the as-sintered condition and ultimate in the heat treated condition. Mechanical property data derived from laboratory prepared test specimens sintered under commercial manufacturing conditions. Tempering temperature for heat treated materials: 177 °C (350 °F).

Source: MPIF Standard 35

(a) Yield and ultimate tensile strength are approximately the same for heat treated materials.

Heat treated copper steels have martensitic microstructures (Fig. 12). Higher copper contents can be used for increased wear resistance when heat treatment is not practical.

Fig. 12 Tempered martensitic microstructure of a quench-hardened and tempered P/M copper steel (FC-0208)

Copper melts at 1082 °C (1980 °F), leaving a pore at the site of the prior copper powder particle. Admixed copper powders typically are -270 mesh (-53 μm). This is considerably coarser than the size of admixed nickel powders (8 μm), and the pore structure of copper steels is considerably different from that of admixed nickel steels (Fig. 13) (Ref 24). Sintered copper steels with 2 wt% Cu generally show little or no undissolved copper. At higher percentages, the copper will be seen as a separate phase. The form of the copper phase indicates whether the material has been heated to a temperature in excess of 1082 °C (1980 °F) (Fig. 14). When copper has precipitated from solid solution, there is a considerable difference in the shape and distribution of the copper. The copper is no longer in the form of discrete particles; typically, it follows grain boundary contours and fills small pores (Fig. 15).

	96.4	5.5	0.9	2.0	max

Other elements: Total by difference equals 2.0 wt% maximum, which may include other minor elements added for special purposes.

Typical admixed nickel additions in P/M nickel steels range from 2 to 4 wt%. Nickel does not diffuse very rapidly in iron at the typical sintering temperature of 1120 °C (2050 °F) and the sintered microstructure of these materials contains nickel-rich regions that improve toughness significantly, particularly in the heat treated condition (Fig. 16). P/M nickel steels are used mainly for heat treatable structural parts that need a combination of strength, wear resistance, and good impact toughness. Table 6 summarizes the mechanical properties of various nickel steels.

(a) Carbon, on basis of iron only, may be a metallographic estimate.

Infiltration is the process of filling the interconnected pores of a P/M part with an alloy of lower melting point than the base material. The lower melting point alloy is drawn into the pores by capillary force (Fig. 17). Infiltrants are generally alloys of copper with iron, zinc, and manganese (Ref 25). Infiltrant slugs can be placed on top of the P/M compact, beneath the compact, or both on top and beneath the compact. The mass of the infiltrant slug is calculated to fill the interconnected pore volume of the compact. The infiltration process can be either a single step or double step. In the single step process, the parts are infiltrated at the same time as they are sintered. It is extremely important for the green compact to be properly delubricated prior to reaching the high heat zone of the sintering furnace. Improper delubrication will lead to problems with infiltration. In double step infiltration, parts are sintered and cooled to room temperature under a protective atmosphere. Infiltrant slugs are then positioned, and the parts are subjected to a second sintering operation during which infiltration of the interconnected porosity occurs. Some parts have selected areas infiltrated to enhance properties in critical areas, a process known as selective infiltration.

Fig. 17 Schematic of copper infiltration

Infiltration leads to higher and more uniform densities which in turn results in enhanced mechanical properties. Filling the interconnected porosity makes parts pressure tight for medium-pressure hydraulic applications. Infiltrated parts have improved machinability, better electrical and thermal conductivity, and can be plated. Infiltration can also be used as a joining process to make multicomponent P/M assemblies during the sintering process.

Copper infiltrated parts can be used in the as-infiltrated condition, or they can be heat treated to improve strength, apparent hardness, and wear resistance. Table 8 summarizes the mechanical properties of various copper infiltrated irons and steels. More information is contained in the article "Copper Infiltrated Steels" in this Volume.

(a) Yield and ultimate tensile strength are approximately the same for heat treated materials.

Phosphorus irons are admixed alloys made by adding fine (<20 μm and preferably close to 10 μm) ferrophosphorus particles to high compressibility iron powders (Ref 26, 27, 28). These alloys exhibit a good combination of tensile strength, ductility, and impact absorption energy. However, their primary use is for parts requiring superior soft electromagnetic performance. Compared with parts made from pure, high-compressibility iron powders, those made from phosphorus irons have higher resistivity, permeability, and induction and reduced coercive force. The presence of phosphorus also decreases the susceptibility of a P/M part to nitrogen aging (Ref 22). The typical soft magnetic properties and mechanical properties of phosphorus irons with two levels of phosphorus (0.45 and 0.80 wt%), sintered under various conditions, are summarized in Table 9 from ASTM A 839-96. Typical applications for parts made from the phosphorus irons include anti-lock brake sensors, magnetic solenoids, and plungers. More information on typical applications is found in the article "Magnetic Materials and Properties for Part Applications" in this Volume.

Partially Alloyed (Diffusion Alloyed) Powders

Table 10 summarizes the chemical compositions for various partially alloyed (diffusion alloyed) steels listed in MPIF Standard 35. These materials are based on a highly compressible iron powder to which the alloy additions have been diffusion alloyed. While the dusting and segregation tendencies of the alloy additions are reduced through diffusion alloying, partially alloyed materials typically contain sufficient admixed graphite to provide the desired combined carbon content during sintering and lubricant to facilitate compaction. These additives are susceptible to dusting and segregation and, hence, mixes of partially alloyed powders are improved by binder treatment. The complex microstructures of these materials (Fig. 6) lead to a good combination of tensile strength, ductility, and toughness. Diffusion alloyed materials can be heat treated to improve strength, apparent hardness, and wear resistance. Table 11 summarizes the mechanical properties of various partially alloyed materials.

Table 10 Chemical composition of various partially alloyed (diffusion alloyed) steels

Material designation	Chemical composition, wt%

HT, heat treated; N/A, not applicable. Suffix numbers represent minimum strength values in 10^3 psi; yield in the as-sintered condition and ultimate in the heat treated condition. Mechanical property data derived from laboratory prepared test specimens sintered under commercial manufacturing conditions. Tempering temperature for heat treated materials: 177 °C (350 °F).

Source: MPIF Standard 35

(a) Yield and ultimate tensile strength are approximately the same for heat treated materials.

Prealloyed Powders

Table 12 summarizes the chemical compositions of various prealloyed, low-alloy steels listed in MPIF Standard 35, and the mechanical properties of materials made from prealloyed powders are summarized in Table 13. Prealloyed powders generally are used for parts that require heat treatment. The hardenability of the prealloyed materials is controlled by the amount and type of alloying employed. Nickel-molybdenum prealloyed powders have lower compressibility than prealloyed powders that use molybdenum alone as the principal alloying agent (Fig. 18). Parts made from prealloyed powders have a homogeneous microstructure and uniform apparent hardness. In the as-sintered condition, the carbides that form are not lamellar in nature (compare Fig. 19 with Fig. 9). In the as-sintered condition, prealloyed materials can be identified by this characteristic carbide morphology. In the heat treated condition, parts made from prealloyed powders exhibit a uniform tempered martensitic microstructure (Fig. 20).

Hybrid Alloy Powders

Hybrid alloy powders consist of prealloyed or partially alloyed (diffusion alloyed) powders to which elemental or ferroalloy additions have been made to produce the desired composition. In MPIF Standard 35 the term "hybrid alloy" is not currently used. However, some hybrid-alloy materials are covered in the sections covering low-alloy steels and sinter-hardened steels. The chemical composition of those hybrid alloys referenced in MPIF Standard 35 is summarized in Tables 12 and 14, and their mechanical properties are summarized in Tables 13 and 15.

HT, heat treated. Suffix numbers represent minimum strength values in 10³ psi; ultimate in the heat treated condition. Mechanical property data derived from laboratory prepared test specimens sintered under commercial manufacturing conditions. Tempering temperature for heat treated materials: 177 °C (350 °F).

Source: MPIF Standard 35

(a) Yield and ultimate tensile strength are approximately the same for heat treated materials.

The compressibility of hybrid alloys depends on the compressibility of the base powder used to constitute them. While many hybrid alloys are suitable for sintering at conventional temperatures (1120 °C, or 2050 °F), the mechanical properties of parts made from these materials often can be enhanced by high temperature sintering (>1150 °C, or 2100 °F) (Ref 7, 8, 29).

Ferrous Powder Metallurgy Materials

W.B. James, Hoeganaes Corporation; G.T. West, National Sintered Alloys Inc.

Mechanical Properties of Ferrous P/M Materials

The mechanical properties listed in MPIF Standard 35 relate to guaranteed minimum values and typical values.

Not all commercially available ferrous P/M materials are covered by current material standards. It takes time for the independent testing and review that is required before new materials can be added to the existing standards. When selecting materials for various applications, it is important therefore that P/M parts fabricators and design engineers discuss options with their material suppliers.

The mechanical properties of ferrous P/M materials are a function of part density and microstructure. The manner in which the P/M alloy is constituted has a direct influence on the hardenability of the material and hence, for a given process sequence, on the resulting microstructure. Figure 21 ranks the hardenability of various P/M steels at a density of 7.0 g/cm^3 . In general, hardenability increases with density, as shown in Fig. 22 for two P/M steels. Prealloyed steels also attain greater hardenability than diffusion alloyed steels of comparable composition (Ref 30).

Fig. 21 Relative hardenability of various P/M alloy steels (70 g/cm³). (a) Admixed powders. (b) Prealloyed powders. Based on data from Ref 30

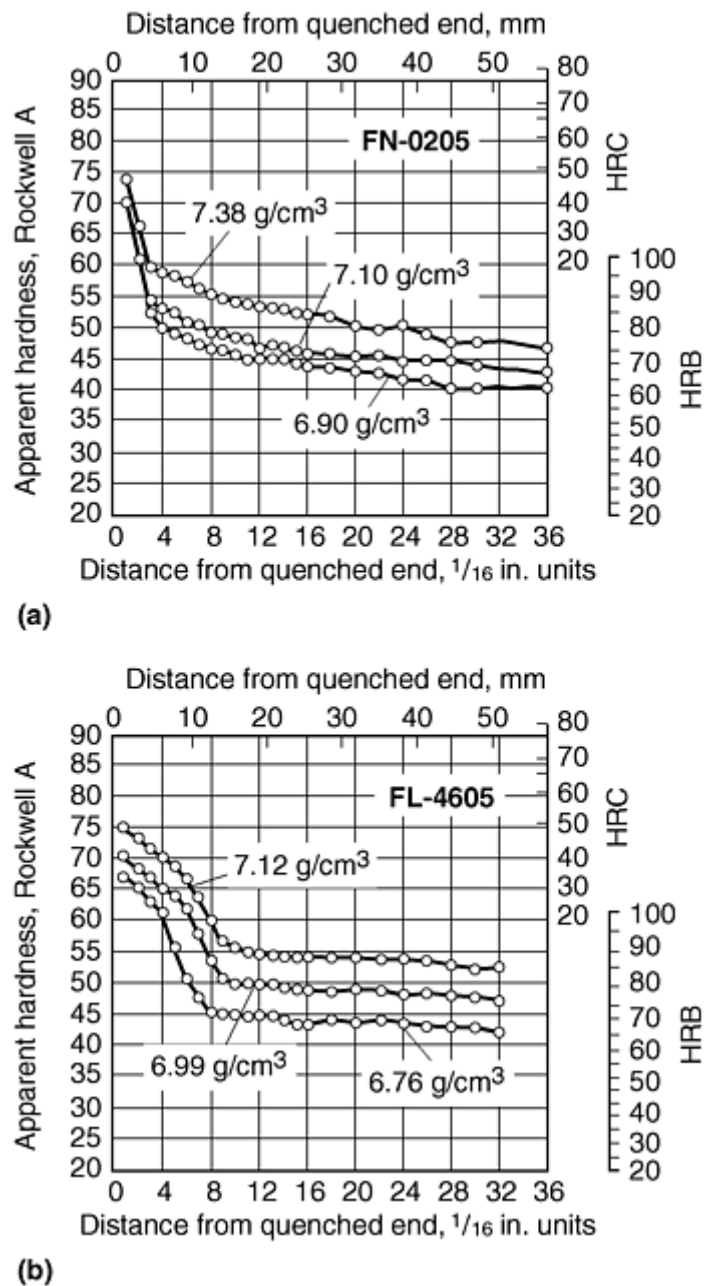

Fig. 22 Effect of density on hardenability of (a) FN-0205 P/M alloy and (b) FL-4605 P/M alloy. Source: Ref 30

For a given microstructure the mechanical properties improve as density is increased. Tensile strength increases linearly with increase in density, while properties such as tensile ductility, impact energy, fatigue performance, and fracture toughness increase exponentially when the level of porosity reaches low levels. Various methods are used to achieve high densities for high-performance P/M parts, as described in the article "Mechanical Properties of High-Performance Powder Metallurgy Parts" in this Volume, for ferrous parts with densities $>7.4 \text{ g/cm}^3$ for iron and low-alloy steel parts.

Figure 23 shows the effect of density on the tensile strength and tensile elongation of several P/M steels, from two different published sources (Ref 5 and 31). These typical values illustrate the linear dependence of strength on density and the exponential increase in elongation with density.

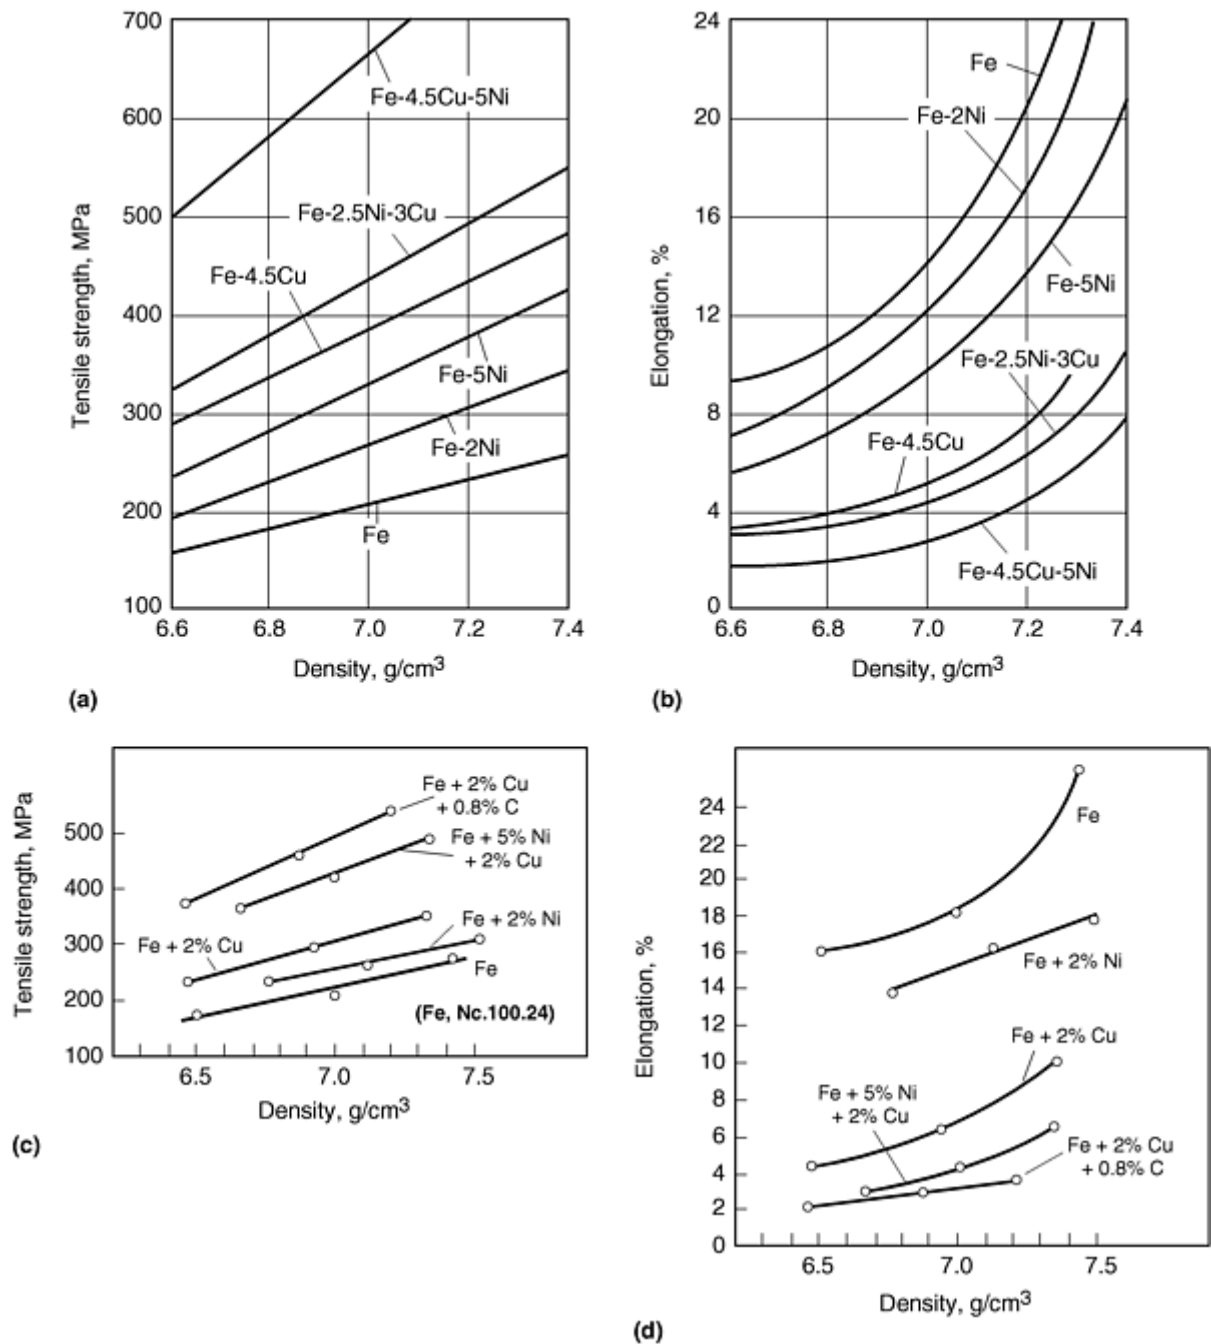

Fig. 23 Dependence of the tensile strength and elongation of sintered steels on density. (a) and (b) Source: Ref 5. (c) and (d) Source: Ref 31

Strength and Toughness. If the yield strength of various P/M materials is plotted against their impact energy, as illustrated in Fig. 24(a) to 24(f), some interesting trends become apparent. Successive data points for each material represent a higher sintered density; the data from MPIF Standard 35 were used to construct the plots shown in Fig. 24.

Fig. 24 Tensile strength versus impact energy for various ferrous P/M materials (MPIF Standard 35). (a) Compare carbon, copper, and nickel steels in the as-sintered condition. (b) Compare carbon, copper, and nickel steels in the quenched-hardened and tempered condition. (c) Compare nickel steels and diffusion alloyed steels in the as-sintered condition. (d) Compare nickel steels and diffusion alloyed steels in the quenched-hardened and tempered condition. (e) Compare prealloyed materials in the as-sintered condition. (f) Compare prealloyed materials in the quenched-hardened and tempered condition

In Fig. 24(a), the as-sintered copper steel (FC-0208) exhibits a higher tensile strength than the carbon steel (F-0008) over a similar range of impact energy. Increasing the combined carbon content of the copper steel increases the tensile strength and reduces the impact energy very slightly at the lower density level (FC-0208 versus FC-0205). The nickel steel (FN-0408) matches the tensile strength of the copper steel (FC-0208) but has better impact properties for a given level of tensile strength. The various nickel steels have the best impact energy values. For the nickel steels, increasing the combined carbon content improves the tensile strength at the expense of impact performance (FN-0208 versus FN-0205, and FN-0408 versus FN-0405). After quench hardening and tempering, carbon steel and copper steels have much lower tensile strength and impact properties than nickel steels (Fig. 24b).

Figure 24(c) and 24(d) compares the yield strength and impact energy of various nickel steels and partially alloyed (diffusion alloyed) materials. In the as-sintered condition, the diffusion alloyed materials have higher yield strengths than the nickel steels while maintaining comparable impact performance. In the quench hardened and tempered condition (Fig. 24d) tensile strength is increased at the expense of impact energy.

The modest yield strength and impact properties of the prealloyed materials (Fig. 24e) reflects why such materials are rarely used in the as-sintered condition. Quench hardening and tempering these materials increases their tensile strength at the expense of impact energy (Fig. 24f), although at higher density levels the FL-4405-HT and FLN-4205-HT materials maintain a good combination of tensile strength and impact energy.

Hardness. It should be noted that, for ferrous P/M materials, macroindentation hardness measurements result in a measure of apparent hardness. The hardness indentation reflects a composite of both matrix and porosity. Apparent hardness is thus a function of part density. A ferrous P/M material with an apparent hardness of 35 HRC may in fact have a matrix hardness of 60 HRC. The matrix hardness of materials with homogeneous microstructures, or the hardness of various constituents of heterogeneous microstructures, can be measured using microindentation hardness methods.

The Effect of Sintering Temperature on Mechanical Properties. A detailed review of the sintering of ferrous P/M materials is discussed in the article "Production Sintering Practices" in this Volume. During the sintering process any lubricant admixed to aid the compaction and ejection process is removed from P/M compacts in the preheat zone of the furnace. The time at temperature and the sintering temperature determine the extent to which diffusion occurs during the sintering process. Admixed, partially alloyed, and hybrid alloys depend on diffusion processes to alloy their various constituents during sintering. Sintering also generally serves to reduce any residual oxides and to effect solution of any admixed graphite. When compacts reach the end of the high-heat section of the sintering furnace, the hardenability of ferrous P/M material is determined by the extent of the diffusion that occurred during sintering. In the case of parts made from prealloyed powders, the hardenability is not primarily determined by the extent of diffusion processes but by the composition of the prealloyed powder and the sintered carbon content of the compact. For each alloying method the sintering time and sintering temperature will influence the number, the size, the size distribution, and the shape of the porosity present in the microstructure (Ref 24).

The mechanical property data for ferrous P/M materials that are summarized in MPIF Standard 35 relate to sintering at 1120 °C (2050 °F). Sintering at higher temperatures often enhances the mechanical and soft magnetic properties of materials (Ref 21, 22, 24, 29, 31, and 32). For example, the tensile strength and elongation of samples compacted from the hybrid alloy FLN6-4405 reach 1240 MPa (180 ksi) and greater than 2% respectively when the samples are sintered at 1315 °C (2400 °F) for 45 min at temperature in a 75 vol% to 25 vol% dissociated ammonia atmosphere (Ref 29).

Figure 25 illustrates the effect of sintering temperature on the ultimate tensile strength and elongation of a variety of ferrous P/M materials (Ref 32). For each material the data points represent compacting pressures of 415, 550, and 690 MPa (30, 40, and 50 tsi), respectively. In general, tensile strength and elongation both increase with higher compacting pressure for sintering at both 1120 °C (2050 °F) and 1260 °C (2300 °F). The data for the higher sintering temperature are, in most instances, almost a direct extension of the data from the lower sintering temperature.

Fig. 25 Effect of sintering temperature on the ultimate tensile strength and elongation of various ferrous P/M materials. Source: Ref 33

Sinter Hardening. The mechanical properties of ferrous powder metallurgy (P/M) materials are directly related to their density and microstructure. Many P/M parts are heat treated, in a secondary operation, to develop a tempered martensitic microstructure either in a surface layer, or throughout the part. The need for a secondary quenching operation can be avoided by "sinter hardening" the parts (Ref 9, 10, 33, 34, 35, 36, 37, 38, and 39).

Ferrous P/M materials with sufficient hardenability will develop microstructures containing significant percentages of martensite in the as-sintered condition. Accelerated cooling techniques for sintering furnaces have been developed, which

permits larger parts to be sinter hardened, or materials with lower hardenability to be used to produce sinter-hardened parts with smaller cross sections.

Conventionally sintered copper and nickel steels such as FC-0208 and FN-0205 usually yield microstructures consisting of ferrite and pearlite. More highly alloyed materials such as partially alloyed low-alloy steels (FD-0205, FD-0208, FD-0405, and FD-0408) can form some bainite and even some martensite in addition to ferrite and fine unresolved pearlite (Fig. 6). Sinter-hardened parts have been made from FLC-4608 using conventional sintering furnaces for many years. This is possible because of the hardenability of this material. If the sintering furnace is modified to permit the cooling rate to be increased, it is possible to sinter harden P/M materials with less hardenability than FLC-4608. The current trend is toward lower cost, leaner alloys with good compressibility such as FLNC-4408. In addition to being essential for the sinter hardening of parts made from materials with less hardenability, furnaces with additional cooling capacity are beneficial for parts made from more highly alloyed materials as they permit sinter hardening of larger parts.

The tensile strength and apparent hardness of sinter-hardened materials are directly related to the percentage of martensite in the microstructure (Ref 33). In selecting materials, it is extremely important to understand all of the functional requirements of the intended application. Does the part need to meet a minimum hardness for an application in which wear is of primary concern? Does the part need to meet a specified tensile strength, elongation, fatigue strength, or impact energy value as well as a minimum hardness? Understanding whether the need is for hardness alone, or in combination with mechanical property requirements, is critical to selection of an appropriate material and process.

While it is possible to perform limited machining on sinter-hardened parts, they will, for the most part, be designed as net-shape parts. Typically, sinter-hardened parts need tempering to relieve stresses and improve toughness. The high apparent hardness of sinter-hardened parts makes sizing difficult if not impractical.

The Effect of Density on Mechanical Properties. The mechanical properties of ferrous P/M materials are directly related to their density. Mechanical properties improve as the amount of porosity is reduced. Tensile strength is almost a linear function of density while ductility, toughness, and fatigue strength increase significantly at low levels of porosity (Fig. 23). Increased density is generally achieved through the use of higher compacting pressures. However, there is a practical upper limit to the density that can be achieved through conventional compaction, and this is due to the presence of an admixed lubricant and the work hardening of the powder particles during compaction. Typically, to reach green densities of 7.1 g/cm³ and higher, ferrous P/M parts need to be either copper infiltrated, double pressed/double sintered, or powder forged. Recently, however, warm compaction processing has been developed to permit single compaction processing of parts to green densities of up to 7.3 g/cm³ (Ref 40, 41, 42, and 43) (see the article "Warm Compaction" in this Volume).

Applications of P/M Structural Parts

Automotive and off-highway vehicle applications dominate the ferrous P/M structural parts market (Fig. 3) (Ref 1). However, there are many other fields in which ferrous P/M parts are being used such as lawn and garden structural parts, parts for hand tools and hobby applications, parts for household appliances, lock hardware parts, parts for industrial motors, controls, and hydraulic applications, and parts for business machine applications. Each of these business segments

will be reviewed briefly with emphasis given to the largest application area, automotive parts. Various part applications are also illustrated in "Appendix 3: Examples of Powder Metallurgy Parts" in this Volume.

Automotive Applications

As previously noted, the typical family vehicle in North America contains 14 kg (31 lb) of P/M parts, and industry experts anticipate that this figure will reach in excess of 22 kg (~50 lb) by the end of the decade. Table 16 summarizes the application areas in which P/M parts are found (Ref 44, 45). Some major applications are noted in the following paragraphs.

Table 16 Automotive applications for P/M parts

Application area	P/M part
Steering	Power steering pump cam ring
	Power steering pump rotor
	Steering column collar
	Locking wedge
	Passive restraint locking pawls
	Tilt lever
	Column lock bolt
	Power steering pump side plates
	Power steering pump vanes/slippers
	Steering column gears
	Steering end plate
	Steering rack guide
	Steering shift lever
Suspension	Ball joint bearing
	Shock absorber piston

	Shock absorber strut rod guides
	Clips
	Shock absorber cylinder ends
	Shock absorber compression valve
	McPherson strut rod guides
Transfer case	Clutch housing
	Driven sprocket
	Drive sprocket
	Inner mode hub
	Main shaft hub
	Planetary gear carrier
	Planetary carrier housing
Automatic transmission	Direct clutch hub
	Drive sprocket
	Driven sprocket
	Forward clutch hub
	Governor counterweight and sleeve
	Parking pawl
	Parking gear
	Planetary carrier gears
	Planetary carrier housing

	Planetary carrier spacer/tube
	Ring gear hub
	Support hubs
	TCC sleeve
	TCC stator clutch cam
	Intermediate clutch hub
	One-way clutch inner cam
	One-way clutch inner race
	One-way clutch outer race
	One-way clutch outer cam
	Output shaft hub
	Pressure reaction plates
	Pump cam ring
	Pump gears/gerotor
	Pump rotors
	Pump stators
	Pump vanes
	TCC stator clutch race
	TCC turbine hub
Manual Transmission	Detent/guide plate
	Shift fork

	Synchronizer blocking ring
	Synchronizer housing
	Synchronizer hub
	Shift levers
Engine	Balance shaft sprocket, gears
	Camshaft lobes
	Camshaft bearing caps
	Camshaft holddown bracket
	Camshaft retainer
	Connecting rods
	Crankshaft bearing caps
	EFI timing sensor ring
	Oil pump gears and rotors
	Rocker arm ball
	Rocker arm fulcrum
	Tensioner back plate
	Tensioner pulleys
	Timing sprocket, gears: intermediate
	Timing sprocket, pulleys, gears: camshaft
	Timing sprocket, pulleys, gears: crankshaft
	Valve guides

	Valve seat inserts: intake and exhaust
	Water pump impeller
	Water pump pulley
	Water pump pulley hub or flange
Engine fuel system	Fuel injection sprockets
	Fuel injector components
	Fuel pump eccentric ring
	Fuel pump gears/gerotor
Engine-starter motor	Starter motor frame
	Starter motor pinions
	Starter motor plunger stop
	Starter motor pole piece
Platform body	Door hinges
	Electric remote mirror gears
	Headlight activator gears
	Instrument parts
	Windshield wiper drives
	Windshield wiper motor flux rings
Brake systems	ABS sensor ring
	Brake adjustor nuts
	Brake lock master cylinder

	Brake piston
Exhaust system	Exhaust flanges
	EGR base plate
	HEGOS bosses
HVAC	Air conditioner compressor clutch hub
	Air conditioner compressor swash plate
Interior fittings	Lock parts (striking plate/latch)
	Rearview mirror mounts
	Pinion gears (door windows)
	Seat safety belt locks
	Speedometer gear
	Airbag hardware
	Seat adjustment levers
	Seat adjustment racks
	Seat recliner parts
	Signal light lever
	Tachometer sensing ring

Powder forged connecting rods currently are used by Ford Motor Company, General Motors Corporation, and Chrysler Corporation. Among the first engines to use powder forged connecting rods were the Porsche 928 and the Toyota Camry engine. Powder forged rods have replaced both drop forged and cast rods in many applications because the use of powder forged rods significantly reduces the number of machining operations needed to produce a finished part ready for assembly (Ref 46, 47). Specifically, powder forged connecting rods can be fracture split rather than machined in order to separate the crank-end cap from the remainder of the rod. This process is needed to assemble the rod to the crankshaft, and fracture splitting allows easier processing and a better fit than machining. Another benefit of the powder

forged rods is very consistent distribution of part mass, which eliminates grouping of rods into various weight categories (as required for cast and drop forged rods). Balance pads also can be eliminated or reduced on many applications.

Currently, most powder forged connecting rods are made from copper steels (P/F-10C45 to P/F-10C60 or from materials such as P/F-11C45 to P/F-11C60 with manganese sulfide added to enhance machinability). These are admixed materials. The rods are used in the as-forged condition and have a ferrite/pearlite microstructure. The material used to make the powder forged rods has an ultimate tensile strength of ~ 830 MPa (120 ksi), a yield strength of 550 MPa (80 ksi), and a fatigue limit of 255 MPa (37 ksi). Some rods are produced from a prealloyed steel base powder and used in the as-forged condition. They have similar mechanical properties to the copper steel rods. Press and sintered (P/M) connecting rods have been developed with comparable performance to cast and drop forged rods (Ref 48, 49, 50). While engine tests have been satisfactory, no press-and-sintered rods are currently in commercial production. The advent of the warm compaction process with the possibility of machining the crank-end bolt holes in the "green" state offers promise for the production of P/M connecting rods.

P/M main bearing caps (Fig. 26) are currently used for some General Motors, Chrysler, and Honda engines in North America. Conversion and development programs are in progress at Ford Motor Company. The P/M bearing caps replace the traditional cast iron caps that are machined from a cast "loaf." The P/M caps are made from a modified FC-0205 material (an admixed material). The main bolt holes are designed into the P/M compact, while side holes are drilled and tapped in a secondary operation. Additional secondary machining operations include milling the surfaces of the feet of the caps and the snap width used to locate the caps. The P/M bearing caps have a sintered density of ~ 6.6 g/cm³, and the material used to make the caps has an ultimate tensile strength of ~ 450 MPa (65 ksi), 3% elongation, and a fatigue limit of 160 MPa (23 ksi).

Fig. 26 Main bearing cap and end cap for GM 3.8 liter V-6 engine. Source: Ref 51

P/M carriers for planetary pinion gears (Fig. 27) are used in four-wheel drive transfer cases. The carriers shown in Fig. 27 are made from a 2% Cu steel admixed alloy (FC-0208) (Ref 52). The carriers have a sintered density of ~ 6.7 g/cm³ and are made from two P/M parts that are sinter brazed together during the sintering operation. Selective copper infiltration is also carried out during sintering to enhance the strength, apparent hardness, and wear properties of the splines. The material used to make the carriers has an ultimate tensile strength of about 410 MPa (60 ksi) and an apparent hardness of 70 HRB. Powder metallurgy carriers are also used for transmission gears and, in conjunction with the helical pinion gears they contain, represent a major growth opportunity for ferrous powder metallurgy.

Fig. 27 Powder metallurgy carriers for planetary pinion gears. Source: Ref 52

Steering column tilt levers (Fig. 28) are made using powder metallurgy. The levers lock the steering column tilt mechanism in position, and the parts require a good combination of strength, apparent hardness, impact toughness, and wear performance for this demanding application. The P/M levers are made from a hybrid alloy, a diffusion alloyed material (FD-0405) to which an additional 2 wt% Ni has been added to improve the impact energy of the material. The P/M tilt levers are double pressed and double sintered to a density in excess of 7.3 g/cm^3 . They are subjected to a light surface carburizing treatment to enhance the wear characteristics of the grooved profile area.

Fig. 28 Steering column tilt levers made from a hybrid P/M alloy (diffusion alloyed FD-0405 material with 2 wt% Ni). Source: Ref 9

Camshaft Lobes. An assembled camshaft (Ref 53) may have powder forged camshaft lobes made from a P/F-4680 material. The assembled camshaft using a hollow tube provides for improved distribution of lubricating oil, reduces the overall mass of the camshaft, and provides an engineered materials solution to the manufacture of the camshaft. Numerous varieties of assembled camshaft are in production.

Sensor Parts. Powder metallurgy is used for production of automotive antilock brake systems (ABS) sensors and engine sensors (Ref 54). Some alloys are made from iron or an iron-phosphorus alloy. The iron-phosphorus alloy is made by admixing ferrophosphorus powder ($<20 \mu\text{m}$ particle size Fe_3P) to iron powder (Ref 22). Automotive ABS sensor rings (tone wheels) are also fabricated from P/M stainless steel (see the article "Powder Metallurgy Stainless Steels" in this Volume).

One-way clutch races (Fig. 29) (Ref 55) are powder forged. A dual material fill is used during compaction of the preforms used for powder forging. The inner portion of the race is made from P/F-4665, while the outer region is made from P/F-4615. Both materials are based on prealloyed powders to which an appropriate amount of graphite has been added. The races are quench hardened and tempered, and the use of dual materials results in a tempered martensitic microstructure with different hardness levels in the inner and outer regions of the heat treated forged parts. The races have a mass of 450 g and a forged density of 7.82 g/cm^3 .

Fig. 29 Powder forged one-way clutch races. Source: Ref 55

Other Applications

Lawn and Garden Applications. Application areas include power steering metering pumps, rockshaft servo cam and followers, engine oil pump gears, picker bar drive gears for cotton pickers, picker bar pivot studs, floating cams, dual sprocket assemblies, idler arms, feed rolls and shutoffs for grain drills, planetary gear assemblies, inner and outer 45° cams for combines plus auger bevel gears and hydraulic wheel motor manifolds, power take-off cams and followers for lawn and garden tractors, idler pivots, mower hubs, front-mounted mower neutral arms, fourth reduction gears, and rototiller gear assemblies. Several parts are illustrated in "Appendix 3: Examples of Powder Metallurgy Parts" in this Volume.

Recreation, Hand Tools, and Hobby Applications. Ferrous P/M parts are used in a wide variety of power hand tools. Figure 30 shows examples of some warm compacted parts, which include P/M power tool gears (Ref 56).

Fig. 30 Examples of warm compacted parts (FD-0405). Densities from 7.2 to 7.5 g/cm³. Source: Ref 56

Household Appliances. Ferrous P/M parts used in appliances such as washers and dryers include eccentric gears and rack gears. Washing machine water pump impellers are made from stainless steel P/M powders. Powder metallurgy parts enjoy wide usage in domestic appliances, particularly washers and dryers, to reduce costs and increase service life of various components. These parts, which have solved strength, wear, and corrosion problems, fall into three general categories: stainless steel structural parts, iron-copper-graphite structural parts, and copper-tin bronzes used for bearings. Parts made from structural plastics compete with P/M parts in this market segment.

Hardware Applications. Many of the P/M parts used in lock hardware applications are made from nonferrous or stainless powders.

Business Machine Applications. Many of the P/M parts once used in business machines have been replaced by parts made from plastics, and many of the mechanical devices in business appliances have been replaced by solid state electronics. This segment currently represents just over 1% of the market for ferrous P/M structural parts.

Copper-Infiltrated Steels

Prasan K. Samal, OMG Americas; Erhard Klar, Consultant

Introduction

THE CONVENTIONAL P/M PROCESS of cold compaction and sintering of metal powder parts generally results in materials that contain pores. Typically, such materials contain 12 to 18% pores, and most of these pores are interconnected. For some applications, such as the self-lubricating bronze bearings, this level of porosity is desirable, and for many other applications it is quite well acceptable. Presence of porosity, however, makes these materials substantially weaker than their wrought counterparts. The pores give rise to areas of stress concentration within the body, thus degrading the dynamic mechanical properties (e.g., fatigue and impact strength) and ductility of the material (Ref 1, 2).

Reduction or elimination of porosity in a P/M material usually requires the application of one of the relatively expensive nonconventional processes, such as hot isostatic pressing, P/M forging, metal injection molding, or hot pressing. These processes lead to fully or near fully dense (less than 2% porosity) materials that usually equal or exceed their wrought counterparts in mechanical properties and metallurgical structure. A recently developed process known as warm compaction can produce P/M steel parts having substantially reduced porosity (8 to 10%) while utilizing a modified, yet economical press-and-sinter technique (Ref 3). The more expensive double-press, double-sinter technique is also capable of producing these higher densities.

An alternative approach to producing substantially pore-free materials is based on molten metal infiltration. In this process, a porous metallic body, having a substantial degree of interconnected porosity (commonly known as the matrix), is infiltrated with another metal of lower melting point (commonly known as infiltrant) by means of a suitably designed heat treatment. The infiltrant is drawn into the interconnected pores of the matrix by capillary action, and upon its solidification a highly or fully dense composite structure is produced. The two most important classes of materials that are manufactured via infiltration methods are copper- and silver-infiltrated refractory metals and refractory carbides, and copper-infiltrated steels. This article focuses on copper-infiltrated steels. Infiltrated refractory metals are discussed in the article "Powder Metallurgy Electrical Contact Materials" and the article "Infiltration" in this Volume.

In its widely practiced form, sintering of the steel part and its infiltration are combined into one process, known as one-step infiltration. From a practical point of view, the process is designed to produce parts with incomplete infiltration, typically to approximately 92 to 94% of theoretical density. This lower density reduces the tendency of the infiltrant residue to adhere to the steel part, yet it produces mechanical strengths that are much higher than those of uninfiltrated P/M steels, hence making the process commercially attractive.

In a more recent version of copper infiltration of steels, residual porosity after infiltration is reduced to less than 1%. Also, because this modified process employs powder forging grade iron powder, the dynamic mechanical properties of these materials are comparable to those of the lower range of wrought steels (Ref 4). The manufacturing cost of these materials is less than that of double-pressed, double-sintered steels.

Copper-Infiltrated Steels

Prasan K. Samal, OMG Americas; Erhard Klar, Consultant

Basic Requirements

The infiltration technique is only applicable to material systems that meet certain key requirements. In the most simple case, infiltration may involve only two metals, but it is possible for combinations of more than two metals to equally satisfy the basic conditions. One of the key requirements is that the two metals or metal phases have sufficiently different melting points. This allows the matrix to be kept as a solid, while the infiltrant is heated above its melting point. Secondly, there should be no or limited solubility between the two metals or metal phases. This ensures free flow of infiltrant into the pores without causing significant changes in the structure of the matrix or the properties of the infiltrant. In cases where some mutual solubility exists, it is desirable to minimize the dissolution of the matrix in the infiltrant by modifying the composition of the infiltrant to match the equilibrium composition to that of the matrix alloy at the infiltration temperature. This minimizes the so-called erosion of matrix. In addition, it is generally desirable to limit the effects of mutual solubility by keeping the infiltration time period short and temperature of infiltration sufficiently low. For example, minimization of diffusion of copper into the grain boundaries of the steel matrix enhances the ductility and heat treatability of the copper-infiltrated steel. Additionally, it is essential that the two metals or metal phases do not form an intermetallic phase that may hinder the flow of the molten infiltrant into the pores. It is extremely important that the surface of the matrix be well wetted by the molten infiltrant during the infiltration process. This, in turn, requires that the process be well controlled to help maintain clean, oxide-free, and soot-free surfaces on the matrix. Wetting behavior of the molten infiltrant is also a function of its fluidity, and this is enhanced by good reducing conditions and by proper selection of infiltration temperature and infiltrant composition. Molten infiltrant is drawn into the interconnected pores of the matrix by capillary action (Ref 5). Capillary pressure (ΔP) varies with the inverse of pore diameter (d) as follows:

$$\Delta P = 2 \gamma \cos \theta / d$$

where γ is the surface energy of the infiltrating liquid and θ is the contact angle between infiltration liquid and solid matrix. Hence for a given liquid, the capillary pressure can vary widely, depending on θ (the contact angle) and d (the pore diameter). With increased wetting the contact angle θ is lowered, increasing $\cos \theta$. Small-diameter pores have greater capillary force and hence are filled more completely than large-diameter pores.

Infiltration can be either combined with the sintering step (one step) or can be carried out separately (two steps), where sintering of the matrix is carried out separately prior to infiltration.

Copper-Infiltrated Steels

Prasan K. Samal, OMG Americas; Erhard Klar, Consultant

Conventionally (Partially) Infiltrated Steels

The conventional, that is, partial, infiltration of steel utilizes a matrix made by compaction of an iron powder graphite mix, in a manner similar to that used in the conventional P/M steel process. During the combined sintering/infiltration heat treatment carbon diffuses and alloys with iron to form the steel matrix prior to the melting and infiltration of the copper-base infiltrant. Because iron is partially soluble in copper at the infiltration temperature, commercial infiltrants almost always contain a small amount of iron (2 to 5%, typically), which minimizes dissolution of the matrix in the molten infiltrant.

(a) Suffix numbers represent minimum strength values in ksi; yield in the as-sintered condition and ultimate in the heat treated condition.

(b) Mechanical property data derived from laboratory prepared test specimens sintered under commercial manufacturing conditions.

(c) Tempering temperature for heat treated (HT) materials: 177 °C (350 °F).

(d) Yield and ultimate tensile strength are approximately the same for heat treated materials.

Fig. 1 Increase in transverse rupture strength of sintered steel due to infiltration as a function of amount of graphite added

Materials

Matrix. A mixture of iron powder, graphite, and a solid lubricant is used as the matrix material. Graphite provides the carbon content required to convert the iron powder into steel. There are two families of iron powders that are currently in use: oxide-reduced and atomized iron powder. The oxide-reduced powder particles tend to possess noninterconnected internal pores that cannot be infiltrated and often contain hard-to-reduce oxide inclusions. The atomized iron powders are cleaner (fewer inclusions) and possess none or few internal pores. As a result, atomized powders exhibit superior infiltrated properties compared to the reduced powders. The higher compressibilities of atomized powders also produce higher-density matrices that require less copper. Graphite powder added must be sufficiently fine and well dispersed so that it completely dissolves in the iron matrix during heating to the sintering temperature. Molten copper does not wet graphite, and hence if any graphite is present in the undissolved form at the time of infiltration, it can prevent infiltration. The amount of graphite added is dictated by the desired composition of the steel. It also affects the dimensional change of the infiltrated component. As shown in Fig. 2, low-carbon-containing steel matrices swell if they come in contact with copper during sintering. This is attributed to the greater wettability of molten copper with pure iron matrices and rapid diffusion of copper atoms along the grain boundaries (Ref 7). Most commercial practices employ graphite additions of 0.80 to 1.0%. If an application requires a smaller amount of graphite, possibly in the interest of a more ductile pearlitic structure, the dimensional change behavior of such a material needs to be taken into account in the designing of tooling. The matrix iron powder mix should contain sufficient amount of a solid lubricant, such as lithium stearate or Acrawax, to aid in the compaction process.

Fig. 2 Effect of amount of graphite added on the dimensional change of copper infiltrated and uninfiltrated sintered steel

The pore volume and the pore structure of the matrix govern its capillarity and hence have a strong influence on the completeness of pore filling. Iron powders with different particle size and different particle size distributions can have very different performance even when processed at the same green density.

The infiltrant consists of mainly copper (more than 90% by weight) and small amounts of iron and other additives such as manganese. The iron content typically ranges from 2 to 5% and is intended to form a saturated solution in molten copper prior to infiltration (Ref 8). This minimizes dissolution of iron from the matrix in the molten copper, which erodes the surface of the matrix in the vicinity of the infiltrant slug. Iron may be present in the infiltrant either in alloyed or admixed form. The former is usually preferred because it is not prone to variations in composition due to powder segregation and also due to the fact that with an alloy there is no risk of any iron-free molten copper coming in contact with the matrix.

Commercial infiltrants contain various other additives, some proprietary. Their functions are mainly to enhance fluidity of molten copper and to aid in the formation of a nonadhering residue. Most commercial infiltrants are designed to form residues of varying sizes. The residue holds the molten copper during infiltration, allowing the matrix to gradually draw in the liquid. This prevents the molten copper from running off the edges of the part, into narrow crevices such as the teeth of a gear or lightning holes in gears. After infiltration, a small amount of the copper alloy is usually left in the residue due to the capillarity of the spongy residue mass. Also, if a part is supplied with any excess infiltrant, either due to part-to-part weight variation or density variation, the excess infiltrant is retained by the residue. The residue formed should be easily removable from the matrix and should drop off the infiltrated part when the part is tumbled.

There are a few commercial infiltrants that do not produce a residue. Their use requires precise control of infiltration conditions, particularly infiltration temperature, because of the change of solubility of iron in copper with temperature. Lack of control results in inferior infiltration and excessive erosion. The residue-forming property of manganese derives from its greater tendency for oxidation. However, if the dew point of the sintering atmosphere is very low (<13 °C, or 55 °F) some or all manganese may remain in the metallic form, in solution in molten copper, and find its way into the iron matrix. This can result in the sticking of the residue as well as excessive hardening of the steel matrix.

The infiltrant is conveniently used in a powder form, so as to permit a slug to be designed to match the geometry of the part and also to help promote the formation of a spongy residue.

The Process

The infiltrated density is determined by the green density of the matrix and the amount of the infiltrant used. The latter is often expressed as slug-to-matrix ratio. For each grade of infiltrant, the ideal slug-to-matrix ratio for a given final infiltrated density can be determined from its nomograph, which is usually supplied by the infiltrant manufacturer. Figure

3 is an example of such a nomograph (Ref 9). The infiltrant slug is most commonly compacted to a density of 6.5 to 6.8 g/cm³. This range of density promotes the formation of an optimally porous spongy residue that also minimizes adhesion.

Fig. 3 Guidance chart to determine infiltrating slug weight required to achieve the desired infiltrated density. Solid lines, IP-174 and IP-190; dashed lines, IP-195-LD/HD and IP-204. To find the appropriate slug-to-matrix ratio (S/M), draw a line across the figure at the desired infiltrated density. Then draw a line at the matrix density. The proper S/M is where the lines cross. Multiply the slug-to-matrix ratio (S/M) by the matrix weight to estimate slug weight.

The location of the slug on the matrix is determined by a number of factors: criticalness of surface finish of the component, distance of travel of infiltrant, and density distribution of green matrix.

The matrix-slug green assemblies are heat treated in a continuous belt furnace for sintering and infiltration, either in a single operation or two. In a two-step operation, the green matrix is first sintered without the infiltrant and then passed through the furnace a second time with the infiltrant. The one-step process is the most commonly practiced process because it is more economical, and it does produce satisfactory results for a large variety of components.

The time-temperature requirements are quite critical in an infiltration process. Proper delubrication of the matrix is essential. Large parts require more care in delubrication. Typically, the green parts should remain for at least 10 min in the 425 to 650 °C (800 to 1200 °F) temperature range for effective delubrication.

Another key event that must occur prior to melting of the infiltrant is the dissolution of admixed graphite in the iron matrix. This occurs at temperatures above 980 °C (1800 °F). If the admixed graphite is not dissolved in the iron matrix prior to melting of the infiltrant, it will affect wetting of the pore surfaces by the molten infiltrant, thus resulting in incomplete infiltration. When the temperature of the assembly is at or above the melting point of the infiltrant, the actual infiltration process occurs. The process takes several minutes for completion, depending on the size of the part, fluidity of infiltrant, and the density and pore structure of the matrix. Most infiltrants are designed for use at a temperature of 1120 °C (2050 °F) and most often the time at this temperature is from 20 to 30 min. If a higher temperature is used, erosion of matrix near the location of slug placement occurs. If a lower temperature is used, infiltration may be incomplete and also strong adhesion of the slug may result.

The dew point of the sintering atmosphere plays a critical role in the process. Generally, a specific dew point range is recommended for each infiltrant. If an infiltrant is used in an atmosphere having a lower dew point than recommended, it may not form the desired residue and can cause sticking of residue. Also, low dew points can lead to soot formation,

which in turn can prevent wetting and result in the formation of copper balls. Very high dew points lead to decarburization of the matrix and incomplete sintering of the matrix.

Evaluation of Infiltrated Parts

Several criteria are used to judge the performance of an infiltration process. Depending on the application, some may be more critical than others. Some of the major criteria are described in the following paragraphs.

Completeness and Uniformity of Infiltration. In conventional infiltration, matrix pores are infiltrated to attain an infiltrated density of about 93 to 94% of theoretical. Areas of low green density, which usually contain large pores, remain uninfiltrated because of their weak capillarity. Parts possessing significant density gradients, therefore, possess wide hardness ranges after infiltration. Lower-than-expected hardness along with low efficiency can also be experienced if infiltration is carried out below the recommended temperature or for not long enough time or if poor wetting of the matrix by molten copper occurs due to oxidation, incomplete dissolution of graphite, or soot formation; or if fluidity of the infiltrant is low.

Adhesion of Residue. Strongly adherent residues may require machining, grinding, or chipping to remove them. Common causes of residue adhesion are excessive amount of infiltrant used, unsatisfactory oxidation of residue-forming constituents, shrinkage of residue around any kind of a projection on the surface of matrix, excessive amount of iron in the infiltrant in relation to infiltration temperature, incomplete infiltration, and incorrect matrix density.

Efficiency of infiltration is a measure of how well the infiltrant supplied was actually utilized to infiltrate the pores in the matrix. Hence, any amount of the infiltrant alloy that is left behind as copper balls or as a constituent of the residue directly accounts for a loss in efficiency. Based on its composition and infiltrating conditions, each infiltrant is expected to yield a specific efficiency. Infiltrants that contain large amounts of residue-forming elements typically are rated to have an efficiency of 90 to 92%, whereas a low residue infiltrant may have a rated efficiency of 99%. If a process yields a lower efficiency than what the infiltrant is rated for, then it is indicative of process deficiencies.

Process variables that commonly cause low efficiency are soot formation, leading to copper ball formation; too low a sintering temperature or too short an infiltration time, leading to incomplete infiltration; and use of an excessive slug-to-matrix ratio.

A simple way to determine efficiency is to compare the mass of the infiltrant slug used and mass of residue formed. This, however, requires that the residue be recovered wholly and weighed accurately, which is not always feasible. Hence, efficiency determinations are based on the mass of the green matrix, mass of green slug, and mass of the infiltrated matrix. In that case, calculation of efficiency must take into account the weight loss of the matrix due to lubricant burnoff, reduction of oxides in the matrix material, and other volatiles. This is conveniently achieved by sintering a test sample (called a blank) in the infiltration heat treatment cycle without an infiltrant slug placed on it. Infiltration efficiency can thus be calculated by the following equation:

$$\text{Efficiency, \%} = \frac{M_I - M_G (M_{BS}/M_{BG})}{I_G} \times 100$$

where M_G is the mass of the green matrix test sample; I_G is the mass of green infiltrant slug (placed on matrix test sample), M_I is the mass of infiltrated test sample, without residue; M_{BG} is the mass of matrix blank sample before sintering; M_{BS} is the mass of matrix blank sample after sintering.

Erosion refers to localized dissolution of the matrix material in the infiltrant that results in the formation of microscopic grooves and pits on the surface of the matrix. These grooves are often large enough to be seen with the naked eye. Erosion can lead to loss of mechanical strength, especially impact strength, besides being cosmetically undesirable. Erosion is commonly caused by inadequate concentration of iron in the molten infiltrant, too high an infiltration temperature, or the use of a relatively small contact area between the slug and matrix. Infiltrants that contain iron in the admixed form tend to produce more erosion compared to prealloyed infiltrants because the freshly melting copper dissolves some iron from the surfaces of matrix simultaneously with the dissolution of iron powder present in the slug.

Surface Appearance. In some applications, the surface appearance of the infiltrated part can be quite important. Typical unacceptable surface appearances are copper flashing, dirty or sooty surface, oxidized surface, and a steel gray color instead of the copper color.

Integrity of Residue. The residue formed may be a hard mass or a soft porous body. In some applications, a hard residue is undesirable because the residues can get entrapped in a crevice (such as between gear teeth or lightening hole), leading to problems in the final assembly of the part. Although a soft porous residue is generally preferred, if the residue tends to become too crumbly and fine it could lead to excessive dust generation in the manufacturing facility.

Selection of an infiltrant and infiltration process parameters (matrix materials, green densities, slug-to-matrix ratio, furnace atmosphere, dew point, temperature, and time, etc.) are based on specific performance requirements and overall process economics. The process parameters and infiltrant selected are often influenced by the geometry and size of the part because of their effect on density distribution and uniformity of part heat-up and on the availability of suitable location for slug placement.

Copper-Infiltrated Steels

Prasan K. Samal, OMG Americas; Erhard Klar, Consultant

Fully Infiltrated Steels

Properties similar to those of the lower range of wrought steels can be obtained if the infiltration process is conducted so that practically all pores are infiltrated. This technique bridges the gap in terms of both economy and properties between pressed-and-sintered and fully dense steels. Conventional state-of-the-art powders, compaction presses, and sintering equipment are used. Critical aspects include control of defects through:

- Selection of high-purity powders and erosion-free copper infiltrants
- Processing that controls maximum pore size
- Processing that ensures complete infiltration of the largest pores present
- Heat treatments which produce microstructures that give rise to ductile fracture (dimple rupture)

Residue adherence is minimized by selecting an infiltrant/matrix ratio that provides for full infiltration without an excess of copper.

Mechanical properties as well as fracture toughness and fatigue strength data of these fully infiltrated steels are shown in Table 3 (Ref 4). Figures 4(a) and 4(b) show the microstructures of a conventionally and a fully infiltrated steel, respectively.

Powder Metallurgy Stainless Steels

E. Klar and P.K. Samal, OMG Americas

Introduction

COMMERCIAL PRODUCTION of sintered stainless steels in North America began in the late 1950s. After a typical steep initial expansion, growth from 1970 settled to an average compound growth rate of $\sim 4.6\%$. In 1996, ~ 4500 short tons (4100 metric tons) of stainless steel powders were used. This represents only a small fraction of wrought stainless steels. As powder producers develop improved stainless steel powders (see the article "Production of Steel Powders" in this Volume), growth is expected to continue. Optimum sintering parameters are also being developed, as stainless steel parts producers continue to improve the control of their sintering operations (see the article "Production Sintering Practices" in this Volume). P/M companies and end users of P/M parts are working on the development of specifications and corrosion tests for sintered stainless steels. This article briefly reviews major applications of sintered stainless steel with a view toward the improvement of P/M stainless steel technology with respect to corrosion resistance. This is followed by processing characteristics and properties of sintered stainless steels. The last section of this article is a brief summary of the uses and properties of fully dense P/M stainless steels.

Powder Metallurgy Stainless Steels

E. Klar and P.K. Samal, OMG Americas

Applications

Stainless steel P/M parts are produced from powders in both the 300 (austenitic) series and the 400 (ferritic) series. The 300 series austenitic alloys are typically used in applications that require good corrosion resistance, while ferritic grades are used in applications that require magnetic properties or good thermal conductivity and/or durability in applications that involve thermal cycling (like automotive exhaust systems).

Automotive components are the most significant application sector, and three major automotive applications are briefly described in the following paragraphs. Substantial quantities of stainless steel powders also are used to make parts possessing controlled interconnected porosity features for filtration, metering of liquids and gas, and sound attenuation in telephones, microphones, and hearing aids. Substantial quantities of sintered stainless steel parts are also used in hardware, appliances, and electrical systems (Table 1). Figure 1 shows a few examples of sintered stainless steel parts from various industries.

Fig. 1 Examples of P/M stainless steel parts for various applications

Rearview Mirror Bracket. The first major automotive application of a sintered stainless steel was the rearview mirror bracket (Fig. 2). It was developed in the 1960s and today still accounts for $\sim 15\%$ of all P/M stainless steel parts in North America. These brackets are made mainly from 430L and 434L by sintering in dissociated NH_3 or in H_2 . Sintered density is $\sim 7.1 \text{ g/cm}^3$. As might be expected, there are no demanding requirements regarding corrosion resistance. However, the thermal expansion coefficient of the bracket must be similar to that of glass as the metal bracket is glued to the windshield window.

Fig. 2 Stainless steel bracket for automotive rear-view mirror

Antilock brake system (ABS) sensor rings (Fig. 3) comprise the second major automotive application of sintered stainless steel parts. The application was developed in the 1980s and presently accounts for $\sim 25\%$ of the total volume of sintered stainless steel parts. As shown schematically in Fig. 4, a sensor ring constitutes an integral part of an ABS. Rotating at the same speed as the car, a sensor ring generates voltages in a stationary induction coil. The frequency of the induced voltage depends on the rotational speed of the ring or the wheel. The voltage signal is used to control brake and ignition functions via a computer to prevent locking of the car wheels. Thus, in addition to adequate mechanical strength, ductility, and dimensional accuracy, the ring must possess adequate magnetic characteristics and sufficient corrosion resistance to survive their exposure to the elements of the road.

Fig. 3 Sensor rings for anti-lock brakes

Fig. 4 Schematic of sensor system for anti-lock brakes

Various steel compositions and P/M techniques have been developed to achieve the previously mentioned objectives. Sensor rings made from mild steel require a protective coating to resist abrasion and corrosion (Ref 1). The majority of ABS sensor rings are now made from 410L, 434L, and modified 434L (18Cr, 2Mo) stainless steel by hydrogen or vacuum sintering. Nitrogen contents are preferably <50 ppm to ensure good magnetic response and adequate chloride corrosion resistance. Sintered densities range from 7.0 to 7.2 g/cm³ (Ref 2). Stainless steel sensor rings processed in this manner can develop various amounts of rust as well as a small number of pits when subjected to a 100 h 5% NaCl salt spray test in accordance with ASTM B 117. However, extensive field testing in various locations across the United States and Canada has shown that these rings are still functioning properly after ten years and/or over 100,000 miles with only minor amounts of rust and no loss of mechanical strength and ductility (Ref 3). For aesthetic purposes, these rings can be nickel or chrome plated to give them a rust-free appearance.

Automotive Exhaust Systems. Because of stricter environmental concerns and consumer demands for extended service life, automotive exhaust systems are now increasingly made from stainless steel. For the connection of various components of an exhaust system (Fig. 5), as well as for measuring exhaust gas properties, flanges and sensor bosses (Fig. 6) are required, both of which can be manufactured advantageously by P/M technology. While some P/M stainless steel flanges are already in use in limited applications, the P/M industry is presently working on qualifying compositions and other properties to meet a number of specifications. Perhaps the most demanding of these specifications is a cyclic elevated temperature oxidation/corrosion test in which a part is heated in air to 650 °C (1200 °F), kept at this temperature for 90 min, then quenched in water for 1 min, and exposed for another 20 min in a humidity chamber (60 °C, or 140 °F; 85% relative humidity) for 200 cycles. Another critical test is a so-called "condensed corrosion test for welded parts" in which a flange that is welded to the exhaust pipe (typically of 409Cb composition) is soaked for 15 min in a solution of 5000 ppm sulfate plus 100 ppm chloride at a pH of 2.5. After drying in air for 75 min, the part is exposed for 20 h to 85% relative humidity at 60 °C (140 °F). This is followed by soaking for 90 min in air at 427 °C (800 °F). After 25 cycles, the P/M part is compared to a wrought welded 409Cb flange tested identically for signs of grain boundary corrosion due to sensitization.

Fig. 5 Exhaust system components

Fig. 6 Powder metallurgy flanges and sensor bosses for automotive exhausts

Flanges made from various 300 and 400 series stainless steel compositions initially passed the "condensed corrosion" test (the degree of sensitization was small and similar to that of wrought 409Cb), but failed the "elevated temperature oxidation/corrosion" test. In spite of a slower rate of oxidation of the P/M flanges, in comparison to wrought flanges (Fig. 7), the P/M flanges, after 60 to 80 cycles, developed hairline cracks that grew and led to complete fracture (Fig. 8). The greater oxidation rate of the wrought parts was due to the oxide spalling off from the flanges, particularly upon quenching, resulting in a weight loss. The slower oxidation rate of a sintered flange was due to the oxide becoming anchored and locked into place in the surface pore space, thus slowing the rate of oxidation due to the adhesion of the oxide layer. This mechanism caused the flange to increase weight. The failure of the P/M flanges was diagnosed as thermal fatigue, and due to the repetitive and cumulative effects of oxidation of surface-near pores and the stresses developed during quenching in water on account of different expansion coefficients of metal and metal oxide. Figure 9 shows a transgranular crack of a 410L flange after 100 cycles produced by this mechanism. This failure was overcome by increasing the density from a low range of 6.9 to 7.15 g/cm³ of the flange to a higher range of ~ 7.2 to 7.3 g/cm³, depending on composition. The higher density range further reduced the oxidation rate, kept the oxidation restricted to the outer surfaces of the flange, and also increased the strength of the flange.

Powder Metallurgy Stainless Steels

E. Klar and P.K. Samal, OMG Americas

Specifications and Properties

The selection of a P/M stainless steel alloy for a given application is based on a number of considerations. Corrosion resistance is a key property for the majority of uses, as is the case with wrought stainless steels. Additional reasons for selecting a P/M stainless steel are magnetic versus nonmagnetic characteristics, mechanical properties (room and elevated temperature), machinability, and hardenability. Ease of processing and raw material cost must also be taken into consideration. Table 2 summarizes the main characteristics of widely used P/M stainless steels. Composition ranges and properties of sintered stainless steels as standardized by the Metal Powder Industries Federation (MPIF) (Standard 35) in 1997, are shown in Tables 3 and 4, respectively. The information is practically identical to that of ASTM Standard B 783, published in 1993. The 1997 edition of MPIF Standard 35 features additional property values for higher sintered densities as well as property data for the ferritic alloys 430L and 434L.

Table 2 Characteristics of various grades of P/M stainless steels

Designation	Description	Characteristics
303L	Free machining austenitic grade	Designed for parts that require extensive secondary machining operations. It has high strength and hardness. This alloy has marginal corrosion resistance. Sulfur added for machinability
303LSC and	Enhanced corrosion	These are copper and tin-modified versions of 303L alloy having all the characteristics of

Ultra 303L	resistance version of 303L	303L, except for improved corrosion resistance. Hence, they combine machinability and moderate corrosion resistance.
304L	Basic austenitic grade	Most economical of austenitic grades. Used where material cost is large percentage of the total manufacturing cost. It has better corrosion resistance than 303L. Machinability is good. Copper and tin modified versions of 304L alloy (304LSC and Ultra 304L) are available for improved corrosion resistance.
316L	Standard austenitic grade	This alloy offers better corrosion resistance and machinability than 304L. With careful processing it can meet the corrosion resistance requirements of the more demanding applications. Copper and tin modified versions of 316L alloy offer even greater corrosion resistance than 316L alloy.
317L	Premium austenitic grade	It is a higher molybdenum content austenitic grade possessing excellent resistance to corrosion, especially to crevice corrosion (superior to 316LSC and Ultra 316L).
SS-100	Super premium austenitic grade	A highly alloyed austenitic grade superior to all other grades of P/M stainless steel in corrosion resistance. Its corrosion resistance equals to that of wrought 316L. In non-optimized sintering atmospheres it suffers a smaller loss of corrosion resistance, compared to other grades of P/M stainless steel.
409L	Weldable ferritic grade	A weldable grade of stainless steel containing niobium, which prevents sensitization. It is not recommended to make carbon additions to this grade. It is a magnetic alloy with good ductility and fair corrosion resistance.
410L	Standard ferritic/martensitic grade	This ferritic grade can be readily converted to a martensitic alloy by addition of small amounts of carbon prior to processing, which will also make it responsive to heat treatment. In the ferritic form the alloy is ductile and machinable, whereas in the martensitic form it is hard with reduced ductility. In the martensitic form it is used in wear resistant applications. Both forms of the alloy are magnetic. The martensitic form has the lowest corrosion resistance of all P/M stainless steel grades.
430L/434L	Premium ferritic grades	Used for applications requiring some corrosion resistance but where economics (or magnetic requirement) preclude use of austenitic grade. Within the specified levels of carbon and nitrogen of standard compositions (Table 3), these grades cannot usually be converted to a martensitic alloy. Color is compatible with chrome plate. Corrosion resistance is better than that of 410L. Machinability is slightly better than that of 410L.

Note: LSC and Ultra are proprietary grades of OMG Americas and Ametek, respectively

- (a) N1, nitrogen alloyed, good strength, low elongation, sintered at 1149 °C (2100 °F) in dissociated ammonia; N2, nitrogen alloyed, high strength, medium elongation, sintered at 1288 °C (2350 °F) in dissociated ammonia; L, low carbon, lower strength, highest elongation, sintered at 1288 °C (2350 °F) in partial vacuum, cooled to avoid nitrogen absorption. Suffix numbers represent minimum strength values in 10³ psi. Yield strength in the as-sintered condition. Ultimate strength in the heated treated condition

Corrosion resistance of sintered stainless steel depends on a number of factors, particularly those related to sintering. Figure 10 illustrates how different sintering conditions can produce widely differing levels of corrosion resistance for the grades listed in Table 2. The importance of avoiding contamination and minimizing the presence, in the microstructure, of precipitates of chromium carbide, chromium nitride, silicon oxide, as well as controlling the formation of surface oxides and/or nitrides on cooling, are discussed in the article "Production Sintering Practices" in this Volume. Extensive coverage on P/M stainless steel corrosion is also in the article "Corrosion-Resistant Powder Metallurgy Alloys" in this Volume. As standards relating to the corrosion resistance of sintered stainless steel are not yet available, it is recommended that users of sintered stainless steel parts use published data as guidelines and conduct their own application-specific tests with respect to corrosion resistance.

Fig. 10 Corrosion resistance of various P/M stainless steels. Hours of immersion by open beaker method in 5% NaCl solution until 1% of surface is covered by rust or stain

Mechanical properties of sintered stainless steels are determined by the powder characteristics, the sintered density, and the sintering parameters. Table 4 lists typical and minimum mechanical properties specified in MPIF Standard 35. Medium-density stainless steels (6.2 to 6.6 g/cm³) usually are produced by pressing at 415 to 825 MPa (30 to 60 tsi) and sintering at 1120 to 1150 °C (2050 to 2100 °F) in dissociated ammonia, hydrogen, or vacuum. Superior elongation, impact resistance, and corrosion resistance are obtained by sintering at 1260 to 1315 °C (2300 to 2400 °F). Higher sintering temperatures and long sintering times produce more pore rounding and grain growth, both of which

impart ductility and impact strength to the part. Lowering the carbon, nitrogen, and oxygen contents also improves ductility.

Mechanical properties of stainless steels depend on the atmosphere in which they are sintered. The most common commercial atmosphere for sintering stainless steel is dissociated ammonia (75 vol% hydrogen and 25 vol% nitrogen). Sintering in nitrogen-containing atmospheres results in the absorption of significant amounts of nitrogen, which produces increased strength and hardness, reduced ductility, and much less shrinkage in comparison to sintering in hydrogen or under vacuum. This effect of sintering atmosphere is shown in Table 5 for austenitic 316 (Ref 6) and in Table 6 (Ref 7) for two martensitic steels.

(a) Reaustenitized at 1010 °C (1850 °F), quenched and tempered at 315 °C (600 °F).

Figures 11, 12, 13, and 14 summarize mechanical properties as well as dimensional changes of an austenitic (316L) and a ferritic (434L) stainless steel for various sintering temperatures and sintering atmospheres over a broad density range. The high sintering temperature (1232 and 1316 °C, or 2250 and 2400 °F) data were obtained from commercial sintering furnaces. The low temperature (1149 °C, or 2100 °F) data were obtained from a laboratory furnace. Sintering in hydrogen atmospheres with lower dewpoints increases densification and ductility.

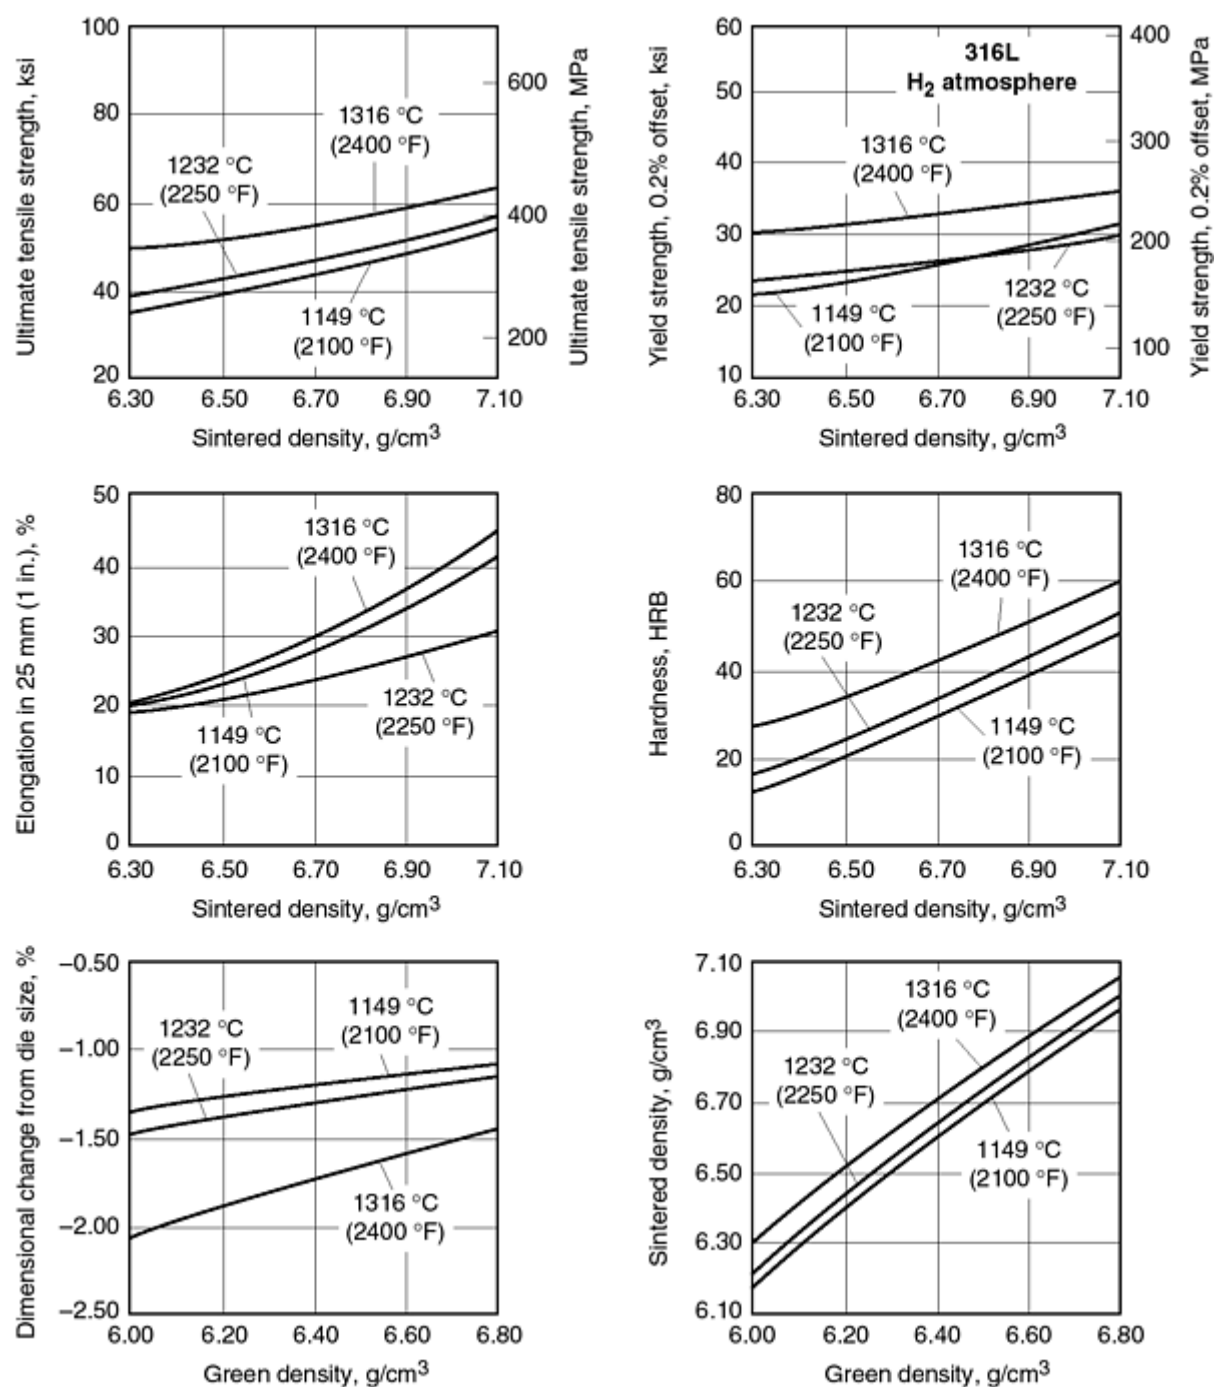

Fig. 11 Mechanical properties and densification behavior of sintered 316L as a function of sintering temperature and density. Sintered for 45 min in hydrogen atmosphere with dew point of approximately -45 °C (-50 °F)

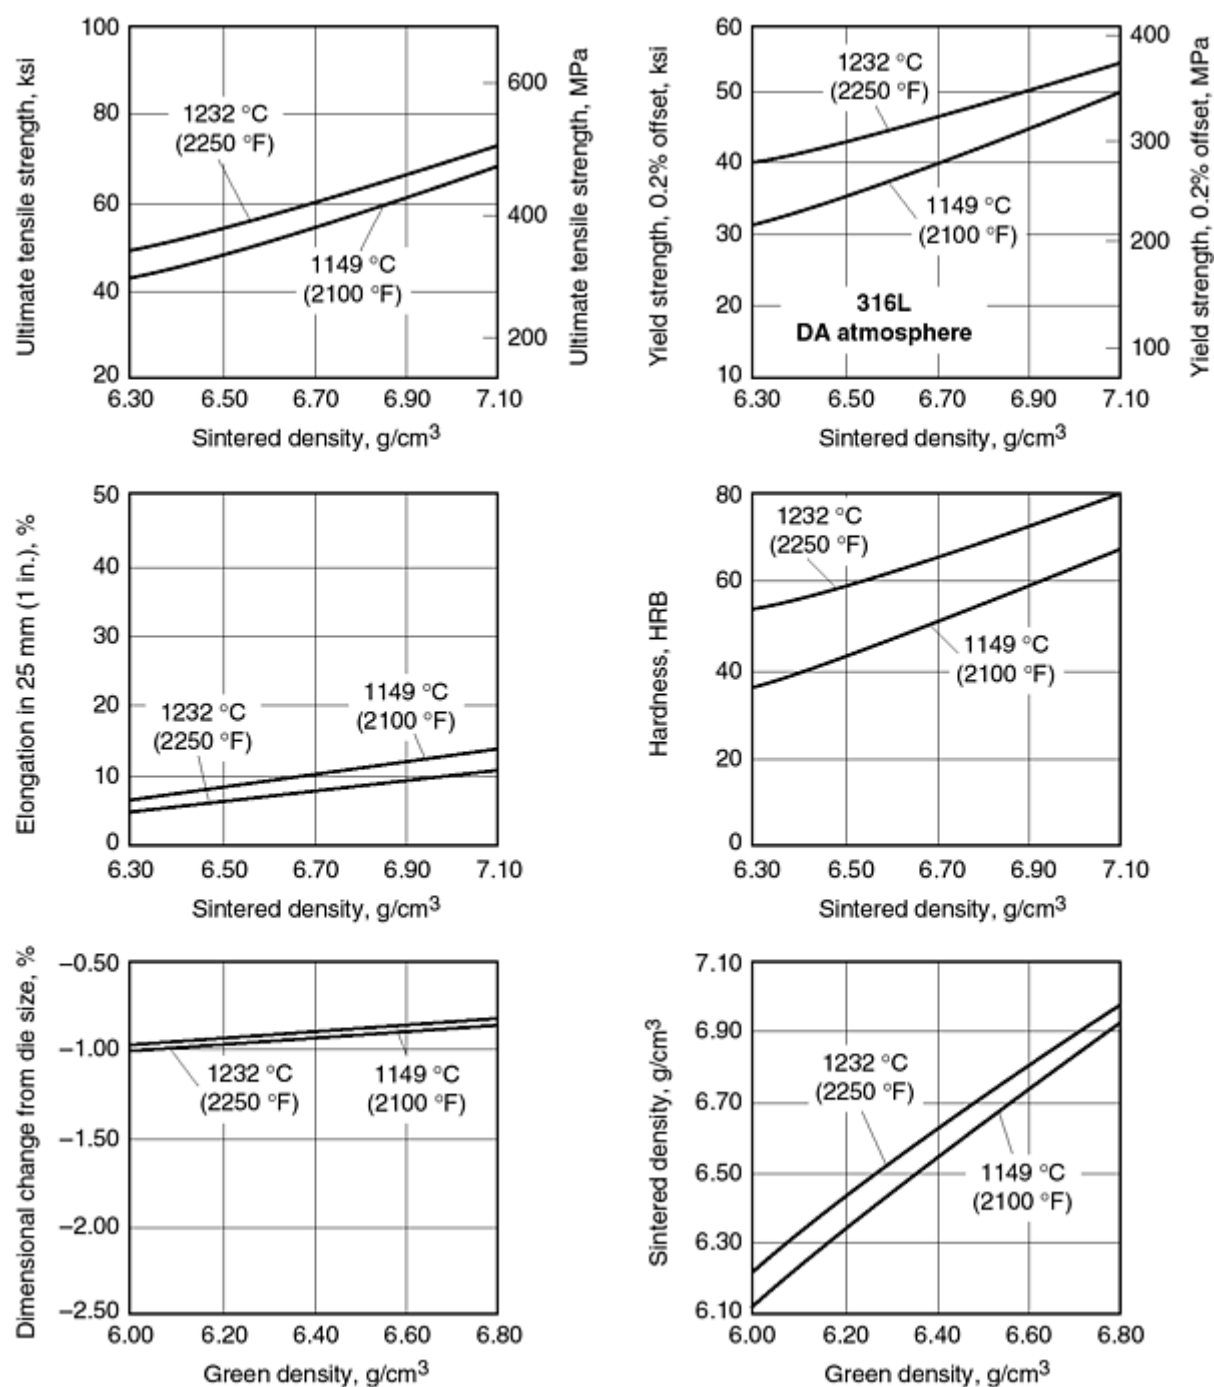

Fig. 13 Mechanical properties and densification behavior of sintered 316L as a function of sintering temperature and density. Sintered for 45 min in dissociated ammonia (DA) atmosphere with dew point of approximately -45 °C (-50 °F)

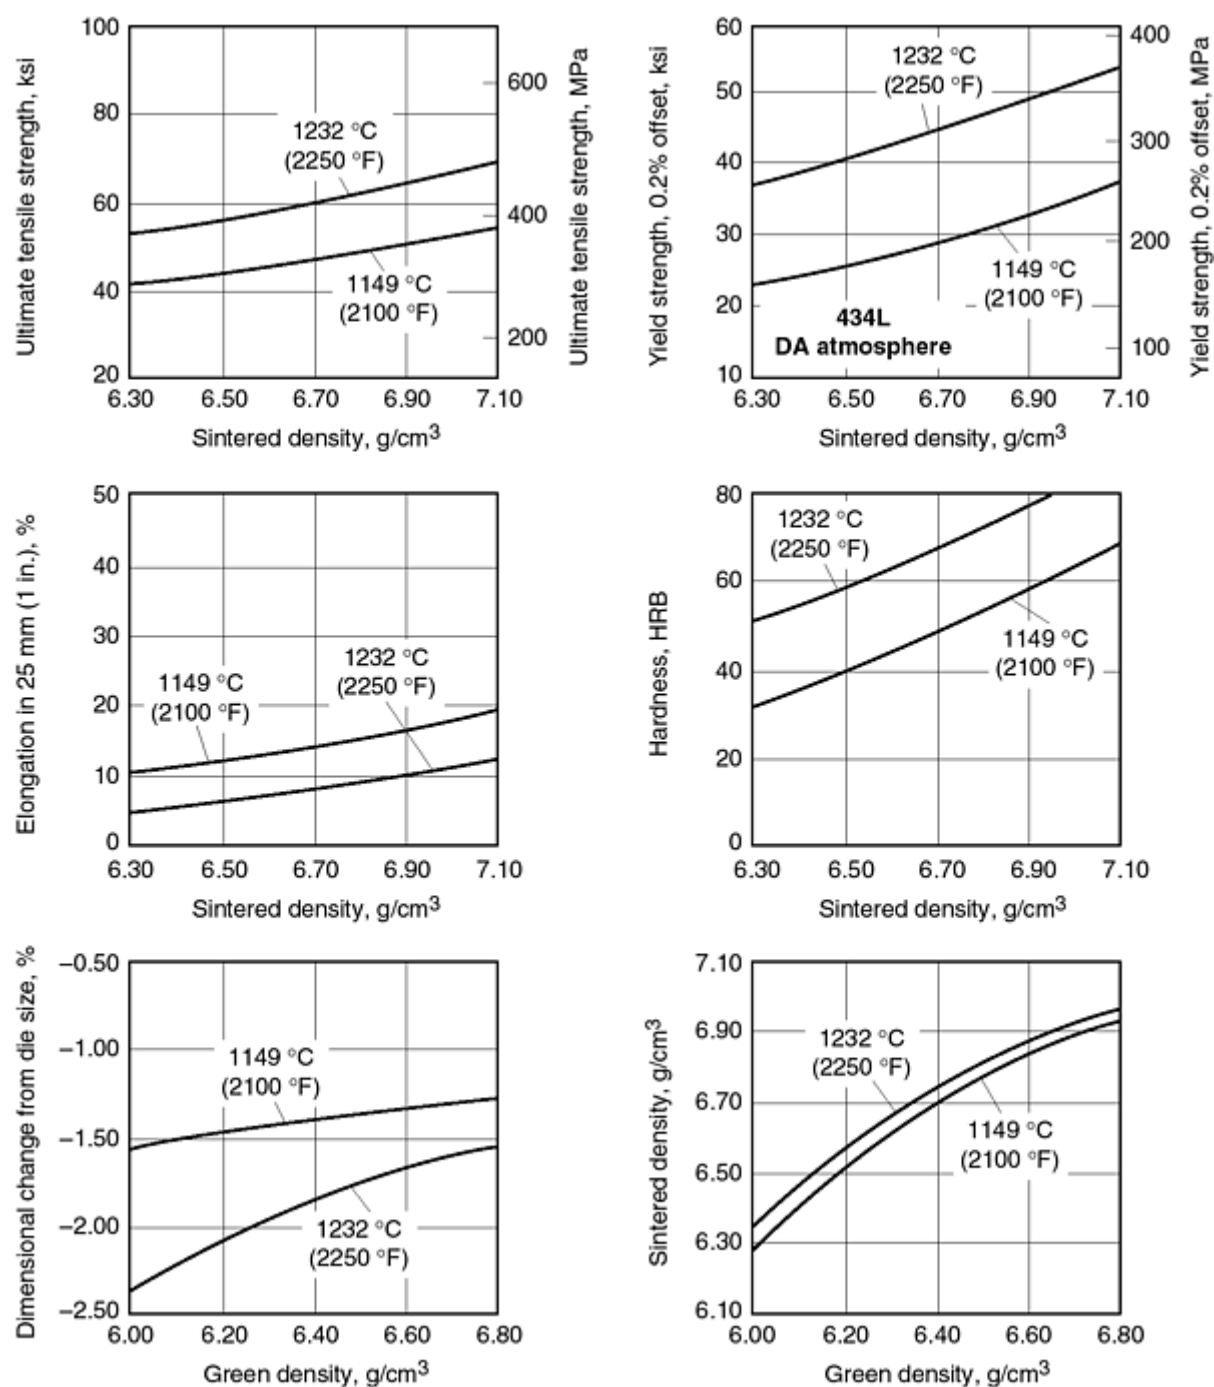

Fig. 14 Mechanical properties and densification behavior of dissociated ammonia (DA) sintered 434L as a function of sintering temperature and density. Sintered for 45 min, -45 °C dew point

The mechanical properties of vacuum-sintered stainless steels are similar to those of hydrogen-sintered stainless steels. If vacuum sintering is done with optimized additions of graphite (Ref 8, 9), low oxygen contents of 600 to 800 ppm will result with improved ductility and toughness. For minimizing interstitials (oxygen, carbon, nitrogen), high-temperature vacuum sintering (with a partial pressure of hydrogen) is superior to high-temperature hydrogen sintering.

Ferritic Stainless Steels and Magnetic Properties. The soft magnetic properties of powder metal (P/M) components are essentially dictated by the level of impurities, the resultant density, and the sintering practice. The optimum properties for soft magnetic performance are obtained by maximizing density and sintering temperatures and minimizing the contamination levels of carbon, nitrogen, and oxygen.

Tables 7 and 8 compare magnetic and mechanical properties of two stainless steels under various sintering conditions (Ref 10). Vacuum sintering produces the best product with regard to soft magnetic properties. This is attributed to the fact that both nitrogen and carbon were maintained below 50 ppm, while oxygen levels were below a few hundred ppm.

Sintering of low-chromium ferritic alloys in nitrogen-containing atmospheres promotes the formation of martensite upon cooling, resulting in low ductility, high hardness, and lower magnetic properties. High-temperature vacuum sintering (with a partial pressure of hydrogen) improves the mechanical and magnetic properties of ferritic stainless steels (Table 9) (Ref 11, 12).

Dimensional Shrinkage. Stainless steels exhibit greater shrinkage during sintering than do P/M irons. Figure 15 shows the dimensional change for type 304L sintered in dissociated ammonia, in which it can be seen that shrinkage increases with increasing temperature.

Fig. 15 Dimensional changes for type 304L stainless steel. Dimensional changes were determined on transverse-rupture bars sintered for 45 min in -40 °C (-40 °F) dew point dissociated ammonia and were calculated from die size.

Sintering in either hydrogen or vacuum results in greater shrinkage. Sintering of low- and medium-density parts in hydrogen or under vacuum (particularly at the higher sintering temperatures and even more so for ferritic stainless steels) produces significant shrinkage, which in turn impairs the dimensional accuracy of a part. For this reason, such parts are often sized after sintering.

Machinability. With respect to machinability, sintered stainless steels are similar to wrought stainless steels. High-temperature sintering and sintering in hydrogen or vacuum result in improved machinability (Ref 13), whereas sintering in nitrogen-containing atmospheres impairs machinability on account of the greater hardness due to absorption of

nitrogen. The addition of manganese sulfide to 304L has been used in the industry for improving the machinability. This approach, however, is at the expense of corrosion resistance. Tin-modified 303L has a good combination of machinability and corrosion resistance.

Elevated temperature properties of sintered stainless steels have recently become available in connection with the development of P/M flanges for automotive exhausts (Ref 14, 15). Figure 16 shows room and elevated temperature ultimate tensile strength, yield strength, and elongation results for three hydrogen-sintered ferritic stainless steels at 7.17 g/cm^3 , compared with the same properties of the corresponding wrought steels. Figure 17 shows 676°C (1250°F) creep rupture strength data for two ferritic and two austenitic stainless steels at densities from 7.04 to 7.15 g/cm^3 .

Fig. 16 Tensile properties of wrought (W) and hydrogen sintered (H) 409Cb and 434L stainless steels

Fig. 17 Creep strength at 675 °C (1250 °F) of 304L, 316L, 434L, and 409Cb P/M stainless steels, hydrogen sintered

A systematic study of eight P/M stainless steels has also identified several key factors for successful application in automotive exhaust systems (Ref 14). A key factor is the importance of density in the specification of P/M stainless steel components. Low density alloys do not survive the cyclic elevated temperature oxidation/corrosion testing that simulates automotive exhausts. Testing indicates that a minimum density of 7.2 g/cm³ for 400 series alloys is strongly recommended in thermal cyclic conditions for exhaust system components.

Alloy selection is also a key factor when specifying materials for cyclic applications involving thermal shock. In general, 400 series (ferritic) stainless steels at minimum 7.2 g/cm³ density perform quite well in such cyclical applications. Austenitic 300 series alloys, on the other hand, are highly susceptible to cracking and failure in cyclical applications above 260 °C (500 °F).

Austenitic 300 series alloys maintain higher strength at elevated temperatures (Fig. 18) in comparison to 400 series alloys (Fig. 16a, b, c). However, ferritic grades have better thermal shock resistance than austenitic grades. This is due to the higher thermal conductivity of ferritic grades. The ductility of austenitic grades also decreases with temperature (Fig. 18c), while ductility of 400 series grades increases above ~500 °C (930 °F) (Fig. 16d).

Processing

All commercial compacting-grade stainless steel powders are produced by atomization. Water atomized powders (with irregular particle shapes) are typically used for conventional pressed-and-sintered parts, while gas atomized powders (with spherical shapes) are used for high-density consolidation. Table 10 lists chemical compositions, physical properties, and screen analysis of widely used powders.

Type 830 is used for the manufacture of P/M parts where superior resistance is of primary consideration. Parts made from type 830 exhibit improved resistance to oxidizing media and sulfuric acid. This grade is not recommended for conditions involving unstable chlorides.

- (a) 0.2% sulfur added for machinability.
- (b) 3.5% copper also present

Compaction. Design and processing of stainless steel P/M parts are subject to the same basic considerations as are other P/M materials. However, compared with low-alloy ferrous powders, stainless steel powders require higher compacting pressures and have lower green strength. Figure 19 shows typical compaction characteristics of austenitic and martensitic grades (Ref 6). Compaction pressures ranging from 550 to 830 MPa (40 to 60 tsi) are common in commercial practice. Carbide tooling is generally required.

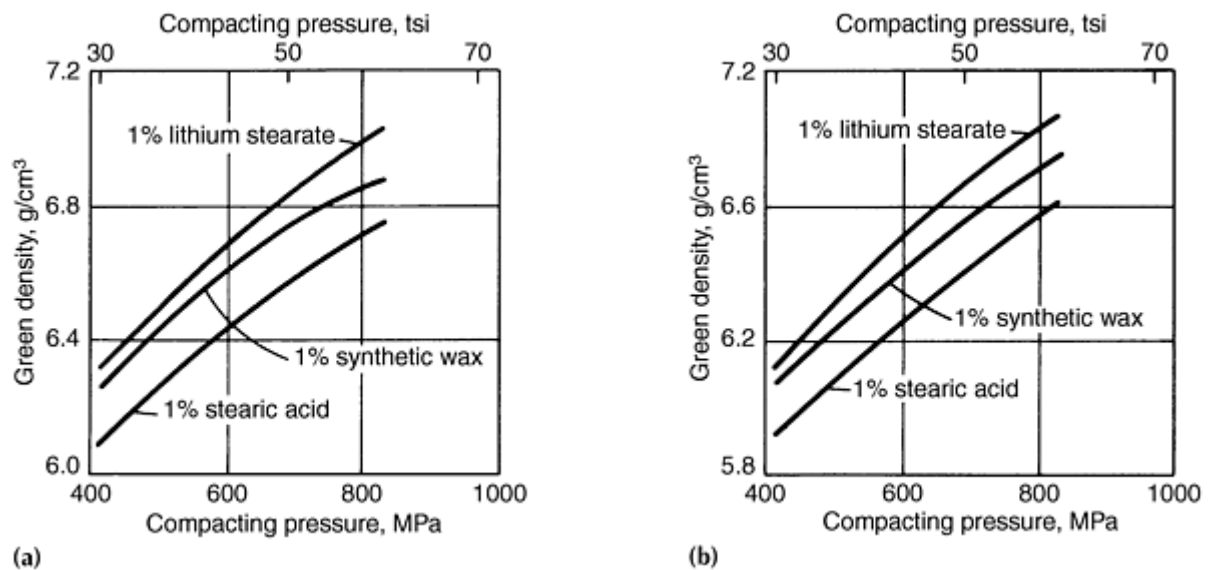

Fig. 19 Compactibility of stainless steel powders. (a) Type 316L austenitic stainless steel. (b) Type 410L martensitic stainless steel

The green strength of stainless steel compacts, which is about half that of P/M iron, is influenced by compaction pressure and the type of lubricant. Lubricants that provide high green strength, such as stearic acid (see Fig. 20), generally cause lower compactibility (Fig. 19). Therefore, lubricant selection is an important factor in determining successful application and fabrication of P/M stainless steels.

Fig. 20 Effect of lubricant and compacting pressure on green strength of stainless steel powder. (a) Type 316L austenitic stainless steel. (b) Type 410L martensitic stainless steel

Stainless steel powders with lower carbon and nitrogen contents also improve compressibility and compactibility (green strength). In Japan, for example, over 1800 tonnes/year of stainless steel powder are used in P/M applications, of which 60% is 400 series powder without nickel. This volume of powder demand and the need for better mechanical properties has led to a 410L powder with lower carbon + nitrogen levels and better compactibility (Fig. 21). Powder annealing also improves green strength at similar carbon + nitrogen levels (Fig. 22) (Ref 16).

Fig. 21 The green densities of 410L mixed with 1% zinc stearate. HGD, high green density grade with lowered carbon and nitrogen levels

Fig. 22 Effect of annealing on the green density of 410L-HGD mixed with 1% zinc stearate, compacted at 490 MPa

Sintering is the most important step in processing stainless steel P/M parts. Because carbon lowers corrosion resistance, the lubricant must be removed to prevent carbon diffusion into the part. As previously noted, medium-density stainless steels are sintered typically at ~ 1120 to 1150 °C (2050 to 2100 °F), except when improved mechanical properties and corrosion resistance are required. Higher sintering temperatures up to 1315 °C (2400 °F) are used for improved mechanical properties and corrosion resistance. More information on sintering of stainless steels is covered in the article "Production Sintering Practices" in this Volume.

Fully dense P/M stainless steels are made predominantly from spherically shaped, inert gas atomized stainless steel powders by extrusion, hot isostatic pressing, and metal injection molding (MIM). These techniques are often preferred for applications where high dynamic mechanical properties are important and/or where shape complexity (MIM) is a factor. A Swedish manufacturer of stainless steel uses substantial quantities of gas atomized stainless steel powder to make seamless tubing by extrusion. Stainless steel flanges, fittings, valve bodies, and pump components are made by hot isostatic pressing.

The mechanical properties, as well as corrosion resistance of parts produced by these techniques, are generally similar to those of their conventional wrought counterparts. In highly alloyed compositions, superior fatigue strength and superior corrosion resistance, particularly pitting resistance, have been reported and attributed to the more uniform microstructure, as well as to low sulfur content and spherical sulfide morphology (Ref 17) in comparison to ingot metallurgy (Ref 18).

High-density stainless steels can be produced by P/M forging, but high-temperature sintering is the preferred fabrication method. At high temperatures (1315 to 1425 °C, or 2400 to 2600 °F), austenitic and ferritic stainless steels densify during sintering. With minor variations in composition, near theoretical density can be achieved in pressed and sintered parts. Table 11 (Ref 19) provides typical mechanical property data for nearly dense ($>98\%$ of theoretical density) stainless steels.

Table 11 Typical mechanical properties of nearly dense P/M stainless steel

Based on high-temperature sintering.

As noted, another form is tubing. Powder is packed in cans, sealed, cold isostatically pressed to reduce bulk, and extruded into tubing. The cold isostatically pressed cans can be hot isostatically pressed to full density, thus eliminating extrusion. Table 12 gives mechanical property data for extruded and hot isostatically pressed materials compared to wrought (ingot metallurgy) materials.

Metal Injection Molding. Stainless steels are the most common material used in MIM components, followed closely by iron-nickel steels. The MIM process is used to produce quantities of precision parts with complex shapes not conducive to production by the normal P/M method of pressing metal powder followed by sintering. The MIM process is also predictable because the green parts shrinks linearly upon binder removal and sintering. Shrinkage is ~20%, depending on the exact mixture used, and is precise from part to part. The standard part-to-part dimensional tolerance is ±0.003 in./in. The part surface is smooth and fine, thereby eliminating secondary machining operations in most cases.

Most MIM parts are required to have a density of 97 to 98% of theoretical to achieve the strength needed in their application. These high densities are made possible by using extremely fine spherical powders and by sintering at high temperature. Sintering can be incorporated directly onto a thermal, catalytic, or solvent debinding cycle. It is typically performed in a protective atmosphere or vacuum at a peak temperature that causes rapid elimination of the pores previously filled with binder. For steels and stainless steels, these temperatures are in the 1120 to 1350 °C (2050 to 2460

°F) range for times of 30 to 120 min, with linear shrinkages of 12 to 18% (Ref 20). The austenitic stainless steels such as Type 316, often specified for orthodontic braces and medical instruments, achieve highest density by sintering at 1350 °C (2460 °F).

As with traditional P/M, carbon control is critical in achieving good properties for MIM stainless steel parts. After molding, binders can add up to 5% C to the part, while the maximum allowed carbon in the final sintered part can be 0.03% or less for sintered stainless steel. Oxygen control is also critical during debinding and subsequent sintering.

During binder extraction (at ~500 °C, or 930 °F), oxygen assists in carbon extraction through formation of CO and CO₂. However, the grain surfaces can become oxidized by the binder. These oxides are reduced again at sinter temperatures by carbon diffusing to the surface oxide. The oxide can be reduced by hydrogen at a temperature of 400 °C (750 °F). This temperature is lower than that needed for rapid reaction with carbon. Retention of nearly all the carbon can be achieved by introducing small quantities of hydrogen at 400 °C (750 °F).

Particle Metallurgy Tool Steels

R.B. Dixon, W. Stasko, and K.E. Pinnow, Crucible Research Center, Crucible Materials Corporation

Introduction

PARTICLE METALLURGY processing of tool steels was first introduced commercially by the Crucible Materials Corporation in 1970, and it is currently the primary manufacturing method used for the development and production of high-performance high-alloy tool steels and tooling composites. The term *particle metallurgy* applies exclusively to powder metallurgy (P/M) processes where gas-atomized and prealloyed powders are consolidated to full density by hot isostatic pressing (HIP). Particle metallurgy (PM) is used to distinguish such processing from traditional powder metallurgy techniques that typically employ mechanical pressing and high-temperature sintering to achieve varying degrees of densification in relatively small net-shape parts.

Particle metallurgy tool steels are produced and distributed internationally by a number of specialty steel manufacturers using various tradenames. Table 1 lists several of the major suppliers of these materials and the corresponding product tradename prefixes generally recognized in the marketplace. Some of the PM tool steel compositions are patented and are only available from a single supplier. Others not so protected are available from multiple producers or distributors often using registered tradenames. To avoid confusion concerning the use of multiple tradenames for similar PM tool steel compositions, an attempt is made in the balance of this article to use comparable AISI grade designations or nominal alloy descriptions wherever possible. Additional information on tool steel powders is also provided in the article "Production of Steel Powders" in this Volume.

Table 1 International suppliers of PM high-alloy tool steels

Company	Location	Tradename prefixes
Crucible Materials Corporation	United States	CPM

Particle Metallurgy Process and Product Forms

As shown in Fig. 1, the basic PM process consists of induction melting of a prealloyed tool steel composition (with or without secondary refining), gas atomization to produce a rapidly solidified spherical powder, screening and encapsulation of the powder, and consolidation by HIP. There are a few select applications where it may be practical or technically necessary to use as-HIP product forms directly (e.g., large diameter hollows or composite bars). However, the more common practice is to HIP a large cylindrical "compact" that is then hot worked to round or rectangular billets for subsequent hot rolling and finishing to round bar, flat bar, or plate and sheet products; that is, the same product forms in which conventionally produced

tool steels are stocked for resale to tooling or equipment component manufacturers. Starting compact sizes typically range from 36 to 51 cm (14 to 20 in.) in diameter by 152 to 254 cm (60 to 100 in.) in length, and they weigh approximately 909 to 2727 kg (2000 to 6000 lb). Consolidation by hot extrusion or other forging techniques is technically feasible, but generally not practical due to size limitations. It is also possible to produce PM tool steel near-net shapes using HIP technology, but it is usually more economical to machine directly from the solid. For special applications requiring unique material property combinations, or where it is not practical to fabricate the entire component from the PM tool steel, composites can be supplied by HIP-cladding a high-alloy PM tooling material to a technically different or less expensive substrate material.

Characteristics of Particle Metallurgy Microstructures

The distinguishing characteristic of wrought PM high-alloy tool steels compared to conventionally ingot cast and wrought materials of similar compositions is the uniform distribution and small size of the primary carbides that form in the PM tool steels during rapid solidification of the powder particles during atomization from the melt. Figure 2 shows the primary carbide distributions observed in the heat treated microstructures of 51 mm (2 in.) diam wrought PM and conventional T15 high-speed steel (1.5C-12W-5V-5Co), where the primary carbides are a combination of vanadium-rich MC and tungsten-rich M_6C types. The PM microstructure shown would appear essentially the same for all product cross sections, while larger cross sections of high-alloy conventional tool steels exhibit inherently coarser carbides and a more pronounced carbide network due to slow ingot solidification and insufficient hot working to break up the as-cast structure.

Fig. 2 Primary carbides in heat treated PM T15 (left) and conventional T15 (right) high-speed steels. 500×

For the same reasons that the primary carbides are uniformly distributed and very small in PM tool steels, so too are any sulfides that form during solidification. Examples of the sulfides observed in polished longitudinal cross sections of conventional and PM M35 high-speed steel containing about 0.10 and 0.22% S, respectively, are shown in Fig. 3. The ability to resulfurize to very high levels without detrimentally affecting hot workability or transverse toughness properties is a distinct advantage for PM processing, and it is done routinely for PM tool steel applications requiring good machinability.

Fig. 3 Typical longitudinal sulfide distributions in PM (left, 0.22% S) and conventional (right, 0.10% S) high-speed steels. 500×

Grindability and Toughness Improvements

The microstructural refinements achieved through PM processing of high-alloy tool steels provide potential benefits to both the tooling (or component) manufacturer and to the end user of the finished product. The two most important physical property and fabricating characteristics that have set high-alloy PM tool steels apart from conventional high-alloy tool steels are (a) good grindability in the heat treated condition and (b) excellent toughness properties in service. Although these characteristics apply to all PM tool steels, they are particularly evident in the wear-resistant high-vanadium tool steel compositions where conventional ingot metallurgy results in heavily segregated microstructures containing large, irregularly shaped, vanadium-rich MC primary carbides.

Figure 4 schematically illustrates why the PM tool steels exhibit improved grindability compared to conventionally produced tool steels with the same composition. In conventionally produced T15 high-speed steel, the large vanadium-rich MC carbides present in the heat treated microstructure are harder than the Al_2O_3 grains in the grinding wheel. These carbides, along with any other large carbides present, significantly impede the cutting action of the grinding wheel. The uniformly small carbide size inherent in PM T15 high-speed steel results in significantly less resistance to the cutting action of the much larger Al_2O_3 grains.

Fig. 4 Beneficial effect of fine carbide size on the grindability of PM tool steels

For tooling that is subjected to extremely abrasive wear conditions in service, it can be argued correctly that poor grindability characteristics would be beneficial for abrasive wear resistance. However, in most tooling applications the service conditions are typically a combination of sliding (adhesive) and mildly abrasive wear. Under these conditions, the PM tool steels have exhibited wear resistance at least comparable to conventional tool steels having the same composition and heat treated hardness. Figure 5 shows laboratory crossed-cylinder wear test results for M2, M4, and T15 high-speed steels, which contain increasing amounts of the MC carbide and therefore increasing wear resistance. As shown, the PM tool steels have at least comparable metal-to-metal wear resistance compared to the conventional steels, despite their excellent grindability.

Fig. 5 Crossed-cylinder wear test results for M2, M4, and T15 high-speed steels

Good toughness characteristics are critical to the successful application of high-alloy tool steels in many industrial operations. Low toughness or strength can cause catastrophic tool failures, or it can have a more subtle negative effect on cutting edge retention due to fine microchipping. To illustrate the potential benefit of PM processing for edge retention, Fig. 6 compares high-magnification scanning electron microscopy (SEM) photos of the edge "wear" experienced by conventional and PM high-speed steels in a machining operation. The relatively uniform wear observed on the cutting edge of the PM tool steel would be expected to result in more consistent tool performance and a better surface finish on the part. These edge retention benefits apply equally to high-speed machining and cold-work cutting operations and are particularly important when upgrading to higher-alloyed tool steel compositions is being considered to improve tool life. Table 2 lists longitudinal bend fracture strength and impact toughness test results for M2, M4, and T15 high-speed steels, which contain increasing amounts of vanadium-rich primary carbides for increased wear resistance. The data clearly show the toughness advantage of the PM steels for a given alloy composition and also indicate that the toughness penalty generally associated with upgrading to the higher-vanadium high-speed steel compositions can be avoided by using a PM tool steel. The better toughness of the PM tool steels is attributed to elimination of alloy segregation, carbide banding, coarse carbide size, and carbide angularity that are inherent in ingot-cast high-alloy tool steels.

Table 2 Longitudinal toughness comparison for M2, M4, and T15

Material	Hardness, HRC	Charpy C-notch impact, J (ft · lbf)	Bend fracture strength, MPa (ksi)
Conventional M2	65	18 (13)	3819 (554)
Conventional M4	64	14 (10)	3585 (520)
CPM M4	65	33 (24)	5377 (780)
Conventional T15	66	5 (4)	2151 (312)
CPM T15	67	19 (14)	466 (676)

Additional Processing Benefits

In addition to improving the grindability and toughness of high-alloy tool steels, PM processing results in other benefits that very often enable the tool manufacturer to economically supply higher-quality tools that are capable of more consistent tool performance. These benefits include:

- Better machinability in the annealed condition (enhanced with high sulfur additions)
- Consistent and more uniform heat treat response in larger cross sections
- Predictable size change (important for accurate unground tools as well as for high-temperature coating operations such as chemical vapor deposition and thermal diffusion)
- Greater capability to finish form grind or hard turn directly from solid
- More efficient and consistent electrodischarge machine (EDM) processing, with better surface finishes
- Better substrate quality for coating (plasma vapor deposition, chemical vapor deposition, thermal diffusion, etc.), nitriding, and plating

Particle Metallurgy Tool Steels

Particle Metallurgy Tool Steel Development

Particle metallurgy processing has also enabled the development of new and advanced tool steel compositions with unique properties that could not be manufactured economically by conventional ingot metallurgy. Examples include the following: super-high-speed steels with 30% or more total alloy content, cobalt-free super-high-speed steels, highly resulfurized tool steels for enhanced machinability, wear-resistant cold-work steels containing 3 to 18% V, wear/corrosion-resistant tool steels containing a combination of high-chromium and high-vanadium, and hot (warm) work tool steels for specialized applications. Several of these materials are discussed in later sections of this article.

Particle Metallurgy Tool Steels

Industrial Applications for Particle Metallurgy Tool Steels

Particle metallurgy tool steels are used in a wide range of applications within the traditional tool-and-die industry, as well as for equipment components and other nontooling wear parts. The general application categories for PM tool steels can be separated as follows:

- High-speed cutting and machining operations
- Cold working
- Processing and molding of engineering plastics
- Hot (warm) working and die casting
- Precision wear parts (nontooling)

The selection of a particular PM tool steel for a given application depends on a number of factors: the service life required, the operating conditions anticipated, compatibility with coating operations, material availability, cost, and so forth. The following sections describe the properties of the different classifications of PM tool steels and the types of applications where they are used.

Particle Metallurgy Tool Steels

R.B. Dixon, W. Stasko, and K.E. Pinnow, Crucible Research Center, Crucible Materials Corporation

Particle Metallurgy High-Speed Steels

Particle metallurgy tool steels used in the cutting tool industry are high-speed steel compositions capable of both achieving high room-temperature hardness for wear resistance (at least 64 HRC after heat treatment) and maintaining high hardness when exposed to the frictional heating encountered at the tool/workpiece interface during the cutting operation (commonly referred to as "red hardness").

The relative performance of the PM high-speed steels is strongly influenced by the alloy composition and heat treatment. The principal alloying elements found in varying amounts in high-speed steels are carbon, tungsten, molybdenum, vanadium, and cobalt. All high-speed steels also contain about 4% Cr to provide good hardenability in larger cross sections during heat treatment. Carbon is necessary for heat treat response, and it combines with the carbide-forming elements to form wear-resistant primary carbides. Tungsten and/or molybdenum are essential alloying elements for developing sufficient temper resistance to enable these materials to perform at "high speed" in cutting operations. Both elements form wear-resistant M_6C primary carbides that partially dissolve during heat treatment to provide a strong precipitation or "secondary" hardening response on tempering. In high molybdenum compositions (e.g., containing 9 to 10% Mo), it is also possible to form some M_2C carbides. Recognizing that tungsten and molybdenum can often be used interchangeably for alloying on an atomic basis and that their atomic weights differ by a factor of two, the combined effects of tungsten and molybdenum are often compared by calculating a "tungsten equivalency" (W_{eq}) equal to the tungsten content plus twice the molybdenum content ($W + 2 Mo$). Vanadium also contributes to secondary hardening during heat treatment, but its main function is to form primary MC carbides for wear resistance. Niobium would be expected to have an effect similar to that of vanadium, but it is not a commonly used alloying element for high-speed steels. Cobalt does not form carbides in tool steels, but significantly contributes to the hot hardness and tempering resistance of the matrix in compositions containing 5 to 8% Co and higher.

Table 3 lists a number of the commonly recognized PM high-speed steel compositions that are currently produced internationally. The table also includes the calculated W_{eq} and the attainable hardness capability for each alloy. Some of the compositions listed are PM modifications of traditional high-speed-steel grades (e.g., M3, M4, and T15) that are also produced conventionally. Notably absent from this table are the 1 to 2% V commodity high-speed steels such as M1, M2, M7, and M42. Although several of the latter materials have been periodically produced in PM form for specialized applications, the general trend in the cutting tool industry has been to take advantage of the grindability and toughness properties resulting from PM processing to upgrade to higher-performance higher-vanadium alloy compositions. Thus, the base alloy compositions listed are PM M3 and PM M4, which are essentially high-carbon and high-vanadium modifications of M2. With the exception of PM M35 (M2 + 5 Co), the balance of the compositions listed are generally classified as "super-high-speed" steels, which have high attainable hardness capability (66 HRC minimum) and excellent temper resistance for a combination of good wear resistance and high red hardness properties. The selection of a particular PM high-speed steel for a cutting or machining operation depends on the tool life requirements, the operating conditions (high wear, high frictional heating, or a combination of both), and whether or not the tool is to be coated (TiN, TiCN, etc.).

Table 3 Nominal compositions of PM high-speed steels

Note: All of the PM high-speed steels contain about 4% Cr for hardenability in large sections. Silicon, manganese, and sulfur contents are typically 0.50%, 0.30%, and 0.03% maximum, respectively. For select applications requiring improved machinability, sulfur contents are increased to 0.10 or 0.22% with corresponding increases in the manganese contents.

The wear resistance of a PM high-speed steel is determined by the heat treated hardness and by the amount and type (hardness) of primary carbide present in the heat treated microstructure. As discussed earlier, all of the PM high-speed steels contain significant amounts of tungsten and/or molybdenum as well as vanadium, which combine with carbon to form tungsten or molybdenum-rich M_6C (occasionally some M_2C) and vanadium-rich MC primary carbides, respectively. The approximate microhardnesses of these complex carbides, as well as the chromium-rich M_7C_3 -type primary carbide found in some cold-work die steels, which are discussed later, are given in Table 4. It follows that for a given heat treated hardness and a similar total primary carbide volume fraction, a high-speed steel with a higher percentage of the harder vanadium-rich (or niobium-rich) MC carbide exhibits better wear resistance. It is therefore very often possible to rank the PM high-speed steels in Table 3 in order of increasing wear resistance by simply looking at the relative vanadium contents. Thus, the PM high

speed steels with 4% V generally outwear PM or conventional high-speed steels with 2 to 3% V, and steels with 5 to 6% V generally outwear the materials with 4% V. Exceptions to this vanadium content "rule of thumb" are special cases where the alloying results in a significant increase in the total volume fraction of primary carbides as well as the attainable hardness capability. An example of the latter is PM M48 (1.5C-10W-5Mo-3V-8.5Co), which contains about 33% total alloy content. This material is capable of attaining 67 to 69 HRC and also has a significantly greater volume fraction of primary carbides than the lower alloyed PM M3, PM M4, and PM M3 + 8Co grades. Other exceptions to this rule are the cobalt-free PM super high-speed steels, which by design also have significantly increased volume fractions of the M_6C primary carbide compared to the cobalt-bearing materials they were designed to replace. These materials are discussed in a later section.

Table 4 Microhardness of primary carbides in PM tool steels

Carbide type	Knoop hardness
$M(V,Nb)C$	2200-2800
$M(W,Mo)_6C$	1550-1750
$M(Cr)_7C_3$	1300-1600

The "red hardness" characteristic of a high-speed steel is dependent on the effect of alloying on the initial attainable hardness as well as on resistance to softening as the tempering or exposure temperature is increased. A measure of the relative red hardness capability is laboratory hot hardness, which is shown in Fig. 7 for a number of the PM high-speed steels. Note that the materials that exhibit higher initial attainable hardness also exhibit higher hot hardness as the testing temperature is increased. These same materials also exhibit greater resistance to tempering during heat treatment.

Fig. 7 Hot hardness of PM high-speed steels

A unique class of materials are the cobalt-free PM super-high-speed steels that were first developed by the Crucible Materials Corporation in the late 1970s in direct response to a serious curtailment in the worldwide availability of cobalt raw materials. PM M61 (1.8C-12.5W-6.5Mo-5V) and PM M62 (1.3C-6.25W-10.5Mo-2V) were simultaneously designed as cobalt-free substitutes for T15 (1.5C-12W-5V-5Co) and M42 (1.1C-1.5W-9.5Mo-1V-8Co), which have historically been two of the more important cobalt-bearing cutting tool materials used in the aerospace industry and elsewhere. Replacing the solid-solution effects of cobalt on heat treating response and elevated-temperature properties was accomplished primarily by alloying with tungsten and/or molybdenum to form a significantly greater number of alloy carbides in the annealed microstructure, which partially dissolve during austenitizing for heat treatment to provide a strong secondary or precipitation hardening response on tempering. Thus, the PM M61 composition with a $W_{eq} = 25.5$ and no cobalt has heat treat response and temper-resistance characteristics comparable to T15 with 5% Co, and also better wear resistance due to a greater volume fraction of primary carbides in the heat treated microstructure. Similarly, the PM M62 composition with a $W_{eq} = 27.25$ and no cobalt has about the same attainable hardness, somewhat better temper resistance, and significantly better wear resistance compared to M42 with 8% Co. These highly alloyed cobalt-free compositions could not be economically produced or fabricated into tools without the benefits of PM processing.

The relative effects of attainable hardness, vanadium carbide content, and total alloying on the properties of the PM high-speed steels are summarized in the qualitative comparison chart shown in Fig. 8. As illustrated in the graph, red hardness increases as the total alloy content and corresponding attainable hardness capability increase. Wear resistance also generally increases with total alloy content and attainable hardness, but the most wear-resistant materials in each classification of high-speed steels are the higher vanadium compositions, for example, PM M4 and PM T15. The graph also shows that as the alloy content increases, the relative toughness decreases. As discussed earlier, however, the generally improved toughness of the PM materials compared to conventionally produced high-speed steels often enables upgrading without serious concerns about the actual toughness in service.

Fig. 8 Graphical comparison of high-speed steel properties

Another consideration when selecting a PM high-speed steel for a cutting tool application is whether or not the tool is to be coated (or recoated as part of tool refurbishing in service). Where a super-high-speed steel may have been required for wear resistance and to prevent localized softening and chip welding in the absence of a coating, these problems are often avoided by the application of a coating. Thus, it may be possible for the end user to consider downgrading to a lower alloy and therefore less expensive substrate material such as PM M3 or PM M4, which have an excellent combination of wear resistance and strength characteristics. However, if the successful performance of the coated tool is dependent on having a combination of high hot hardness and high wear resistance in the substrate (or in any uncoated areas), then alloy selection for the substrate material follows the same criteria used for uncoated tools with the higher alloyed PM compositions offering higher attainable hardness and hot hardness capability.

Basic heat treatments for PM high-speed steels involve preheating to about 790 to 845 °C (1450 to 1550 °F), austenitizing at high temperatures to dissolve enough of the carbides to achieve the desired heat treat response after tempering (without overheating), quenching at sufficiently fast rates to prevent reprecipitation of the dissolved carbides (but uniformly and not too fast to cause excessive distortion or cracking), and multiple tempering usually at a minimum of 540 °C (1000 °F) to eliminate retained austenite and provide adequate stress relieving. The traditional method of heat treatment for high-speed steels is to use salt baths or atmosphere furnaces with associated salt or oil quench baths. However, for environmental and safety concerns, many captive and commercial heat treating operations have converted to rapid-gas-quenching vacuum hardening furnaces employing a combination of high pressure and high volumetric mass flow to achieve quench rates approaching those previously achieved in salt.

An example of the type of hardening and tempering response information supplied by the steel producers is shown in Fig. 9 for PM M4. For tooling applications requiring maximum hardness, the austenitizing temperature typically selected for PM M4 is 1190 to 1205 °C (2175 to 2200 °F) to optimize the tempering response at 540 to 550 °C (1000 to 1025 °F) when attempting to achieve 64 to 66 HRC or 65 to 67 HRC. For tooling applications requiring additional toughness, and where a lower hardness is acceptable, it is common practice to "underharden" from lower austenitizing temperatures to take fewer of the carbides into solution and thereby maintain finer prior austenite grain size for improved toughness properties. Thus, for PM M4 cutting tools requiring a minimum application hardness of 63 to 64 HRC, a typical underhardening treatment might be to austenitize no higher than 1175 to 1190 °C (2150 to 2175 °F) and to multiple temper at 550 °C (1025 °F). For cold-work punch and die operations, where the required application hardness might be no higher than 60 to 62 HRC, PM M4 is typically austenitized from no higher than 1120 to 1150 °C (2050 to 2100 °F) and multiple tempered at a minimum of 550 °C (1025 °F) to maximize the toughness. It is particularly important to multiple temper as high as possible, or at a minimum of 550 °C (1025 °F), whenever extensive wire EDM cutting is anticipated to guarantee that the part is thoroughly stress relieved and thereby to prevent stress cracking. These heat treating guidelines apply to all high-alloy tool steels, whether they are produced using PM processing or by conventional ingot metallurgy. However, because there can be slight differences in the composition of similar steels supplied by different manufacturers, it is always advisable to refer to the specific heat treating procedures recommended by the material supplier.

Tempering temperature		Heat treat response ± 1 HRC ^(a)					
°C	°F	1025 °C (1875 °F)	1080 °C (1975 °F)	1120 °C (2050 °F)	1150 °C (2100 °F)	1175 °C (2150 °F)	1205 °C (2200 °F)
As-quenched		59.5	62.5	64.5	65	65	63.5
540	1000	58.5	61	62.5	63.5	65	66
Optimum for maximum toughness and effective stress relieving

Cold-Work Particle Metallurgy Tool Steels

Many of the PM high-speed steels are also used in cold-work operations where a combination of good wear resistance and compressive strength (high hardness) is required. PM M3 and PM M4 are particularly well suited for cold-working applications because of their excellent combination of wear resistance, toughness, and grinding characteristics over a wide range of hardnesses.

Several of the international tool steel producers have also taken advantage of PM processing to develop new cold-work tooling materials alloyed primarily with high vanadium to maximize wear resistance. The first such material designed specifically for high-performance wear applications was Crucible particle metallurgy CPM 10V (hereafter referred to as PM

10V), which was introduced commercially in 1978. Also developed at about the same time was a lower-matrix carbon and slightly lower vanadium modification of PM 10V, called CPM 9V (hereafter referred to as PM 9V), which has lower attainable hardness but better toughness than PM 10V and can also be used in warm-working applications requiring resistance to heat checking. More recent PM tool steel development work has focused on the following: (a) even more wear-resistant ultrahigh vanadium compositions containing 15 to 18% V with up to 30% by volume of primary MC-type carbides, (b) low-to-intermediate carbide volume fraction materials moderately alloyed with vanadium and chromium to optimize the toughness properties while still maintaining good wear resistance, and (c) high-vanadium high-chromium compositions for wear applications that also require good corrosion resistance. The wear/corrosion-resistant PM tool steels are discussed in a later section.

Table 5 lists the nominal compositions for several of the commercially available PM cold-work tool steels as well as the PM M4 high-speed steel discussed previously. Also included are the compositions of conventionally produced A2, D2, and D7 cold-work tool steels. With the exception of PM 9V, all of the tool steels listed in the table are capable of attaining 58 to 62 HRC during heat treatment, which is the typical application hardness range for cold-work tooling. The heat treating procedures used for these materials are similar to those used for the PM high-speed steels. Depending on the alloy composition and desired hardness, the recommended austenitizing temperatures range from about 1024 to 1177 °C (1875 to 2150 °F). Tempering recommendations are also alloy dependent. In some cases, tempering at or below 524 °C (975 °F) is acceptable to maintain high hardness with adequate toughness. In other cases, however, a minimum tempering temperature of 538 °C (1000 °F) is recommended to eliminate retained austenite and to ensure thorough stress relieving for both optimal toughness and size stability. In all cases, multiple tempering is required.

Table 5 Nominal compositions of PM cold-work tool steels

Steel	AISI designation	Commercial equivalent	Composition, wt%				
			C	Cr	Mo	W	V

D7	D7	...	2.35	12.00	1.00	...	4.00

For a given hardness, the relative wear resistance of both the PM and conventional cold-work tool steels is a function of the amount and type (hardness) of primary carbide present in the heat treated microstructure. Carbide size is only a factor under abrasive wear conditions and generally only applies to conventionally produced tool steels that have inherently coarser carbide size compared to the PM tool steels. Table 6 shows the results of SEM and image analysis of the primary carbides observed in heat treated samples of the alloys listed in Table 5. The total volume percent of primary carbides ranges from approximately 5% in PM 3V to 30% in PM 18V. The relative percentages of the primary carbide types present (MC, M₆C, M₇C₃) vary according to the alloying balance, with only PM 3V, PM 9V, PM 10V, PM 15V, and PM 18V having essentially all MC carbides. Although PM M4 and PM 8Cr4V have similar vanadium contents and total carbide volumes (about 12.5%), about two-thirds of the carbides in PM M4 are M₆C and about half the carbides in PM 8Cr4V are M₇C₃-type. These microstructural differences are illustrated in the photomicrographs in Fig. 11, where it can be seen that the various carbide types exhibit characteristically different electronic imaging in the SEM. Figure 12 shows a similar SEM metallographic comparison between PM 12Cr4V and PM 15V both of which contain about 23% total primary carbide volume. Whereas PM 15V contains all vanadium-rich MC-type carbides, PM 12Cr4V has predominantly M₇C₃-type due to the high chromium content. Table 6 also lists the approximate total primary carbide volumes for conventionally produced A2, D2, and D7. With

less than 1% V, A2 and D2 tool steels contain predominantly M_7C_3 -type primary carbides. Conventional D7 has essentially the same alloy composition as PM 12Cr4V and very similar carbide volumes as determined by SEM analysis.

Table 6 SEM image analysis of the primary carbides in PM cold-work tool steels

Steel	Heat treatment	Hardness, HRC	Carbide content, vol%			
			MC	M ₇ C ₃	M ₆ C	Total
PM cold-work tool steels

Fig. 12 Primary carbides in heat treated PM 15V (left) and PM 12Cr4V (right) wear-resistant tool steels containing approximately 23% total carbide volume

Figures 13 and 14 show the results of dry crossed-cylinder (metal-to-metal) and pin-abrasion wear testing, respectively, plotted versus the primary carbide contents of the materials listed in Table 6. In the crossed-cylinder wear test, a tungsten carbide cylinder is pressed and rotated against a perpendicularly oriented and stationary test sample at a specified load. The volume loss of the test sample, which wears preferentially in this test, is determined at regular intervals and used to calculate a wear-resistance parameter based on the load and the sliding distance. In the pin-abrasion wear test, a small cylindrical test sample is rotated and pressed against an abrasive cloth at a fixed load. The abrasive cloth is attached to a movable table, which allows the test sample to be moved back and forth for a fixed distance in a nonoverlapping pattern across fresh abrasive. The weight loss of the sample (or lack thereof) is used as a measure of the wear resistance. The abrasive used for the test was 150 mesh garnet ($\text{Al}_2\text{O}_3\text{-3FeO-3SiO}_2$), which is considered only mildly to moderately abrasive compared to other abrasives, but which generally provides good differentiation in wear test results for hardened tool steels.

Fig. 13 Crossed-cylinder (metal-to-metal) wear test results for PM wear-resistant tool steels

Fig. 14 Pin-abrasion wear test results for PM wear-resistant tool steels

The metal-to-metal wear resistance of the PM cold-work tool steels increases dramatically as the volume percent of vanadium-rich primary MC carbides in the heat treated microstructure increases, as shown in Fig. 13. These results also indicate that simply increasing the total alloy content to achieve larger carbide volumes, or increasing the vanadium content alone, does not guarantee good metal-to-metal wear resistance in this test unless the composition is balanced to obtain significant percentages of the vanadium-rich MC carbide. This can be easily seen by comparing the wear test results for PM 3V, PM 9V, PM 10V, PM 15V, and PM 18V (which contain increasing percentages of only the MC carbide) with the wear test results for A2, D2, D7, and PM 12Cr4V (which contain ≤ 3 to 3.5% MC carbide). Conventional A2 and D2 tool steels contain little or no MC carbide and therefore exhibit very low metal-to-metal wear resistance. The wear test number does increase with an increase in total carbide volume for A2, D2, and D7 tool steels. However, D7 and PM 12Cr4V test only slightly better than PM 3V despite containing 4% V and having substantially greater total carbide volumes.

The influence of MC carbide content rather than total primary carbide volume in the crossed-cylinder wear test can be further illustrated by directly comparing the results for the PM tool steels with either similar vanadium contents or similar total carbide volumes, but very different MC carbide contents. For example, comparing PM 8Cr4V and PM 12Cr4V, which have about 4% V but different chromium contents, PM 8Cr4V exhibits slightly better wear resistance despite having only about half the total carbide volume. These results can be attributed to the 6.5% MC carbide content of PM 8Cr4V compared to about 3% MC carbide in PM 12Cr4V. Although the total carbide volumes of PM 12Cr4V and PM 15V are comparable (about 23%), the metal-to-metal wear resistance of PM 15V is substantially greater due to the fact that all of the primary carbides in PM 15V are vanadium-rich MC. A similar comparison can be made between PM M4 and PM 8Cr4V, which are both 4% V materials with similar total carbide volumes (about 12.5%). The lower wear test number obtained for PM 8Cr4V can be partially explained by the slight difference in test hardness, but the combination of MC and M_6C carbides in PM M4

compared to the combination of MC and M_7C_3 carbides present in PM 8Cr4V is the primary reason for the difference in wear test results. A final comparison can be made between PM 10V and PM 8Cr10V, which have similar vanadium chemical analyses but very different total and MC carbide volumes due to differences in their carbon and chromium analyses. Some of the difference in total carbide volume can also be explained by the heat treatments employed to obtain 60 to 62 HRC; for example, a higher austenitizing temperature would have dissolved more of the M_7C_3 carbide in the PM 8Cr10V material. However, the wear test results correlate directly with the MC carbide content, with PM 10V exhibiting better metal-to-metal wear resistance due to its approximately 17.5% MC carbide content compared to about 13% MC in PM 8Cr10V. The fact that conventionally produced D7 and PM 12Cr4V, with similar alloy compositions and primary carbide contents, test comparably suggests that carbide size is not a major factor in this test.

There is a much better correlation between pin-abrasion weight loss and the total primary carbide volume for all of the materials tested, as shown in Fig. 14. The effects of primary carbide size and MC carbide content, however, are also evident. For example, conventionally produced D7, with an inherently large primary carbide size distribution compared to the PM materials, tests significantly better than PM 12Cr4V. In contrast, PM 15V with relatively small primary carbide size tests as well as D7. This can only be explained by the relative MC carbide content differences between these two materials. Similarly, both PM 12Cr4V and PM 8Cr10V test slightly worse than PM 10V, which has a significantly lower total carbide volume but substantially greater MC carbide content. The good abrasive wear test results for PM M4 relative to PM 8Cr4V can again be explained primarily by the combination of MC and M_6C carbides in PM M4. The fact that PM 9V tests very well at 54 HRC compared to the other PM tool steels at 60 to 62 HRC in both the crossed-cylinder and pin-abrasion wear tests is further testament to the strong influence of MC carbide content on wear resistance in these materials.

The toughness of the PM cold-work tool steels decreases with an increase in total primary carbide volume, relatively independent of the primary carbide type. This can be seen in Fig. 15, which shows the results of longitudinal Charpy C-notch impact testing versus total primary carbide volume for the PM cold-work tool steels as well as for PM M4, A2, D2, and D7. All of the materials were tested at 60 to 62 HRC, except for PM 9V which was tested at 54 HRC. With only 5% total carbide volume, PM 3V exhibits the highest impact toughness properties of the alloys tested, including A2, which has a comparable total primary carbide volume. PM M4 and PM 8Cr4V exhibit lower toughness values due to their increased carbide volumes, but are still considerably tougher than D2 and the higher-alloyed vanadium-rich PM grades. Despite their relatively high total carbide volumes, both PM 12Cr4V and PM 8Cr10V exhibit toughness comparable to the lower carbide volume PM 10V and D2 materials. The relatively low toughness values obtained for PM 15V and PM 18V may restrict their use in metalworking applications where shock loading is anticipated.

Fig. 15 Charpy C-notch impact toughness of PM wear-resistant tool steels

These high-performance PM tool steels are used for a wide range of cold-work punch-and-die applications such as long-run stamping and forming, fineblanking, and can manufacturing. The high-vanadium PM tool steels are particularly well suited for abrasive wear applications such as powder metal compaction, metal-injection molding, and equipment components for the processing of engineering plastics. The latter components include: screw elements, paddles, nozzles, and HIP-clad or solid barrel inserts for compounding; flat and circular pelletizer knives; screws, barrel inserts, nonreturn valves, mold inserts, and trim knives for injection molding; and finally, granulator knives for waste recycling. Examples of the types of tooling or wear parts used in these applications are shown in Fig. 16 and 17.

Wear/Corrosion-Resistant Particle Metallurgy Tool Steels

In many manufacturing operations, tooling and/or wear parts are subjected not only to wear caused by direct contact of the moving parts or by hard abrasive particles in the process media, but also to corrosive attack caused by moisture, acids, or other corrodents. This is particularly true of machinery components used in the high-volume compounding and injection molding of engineering plastics that contain large amounts of fillers that not only cause abrasive wear, but also frequently generate acidic conditions at the ambient or elevated temperatures required to process these materials. Similar operating conditions can also be encountered in the production of synthetics or in the processing and containerization of animal and consumer food products. Thus, the tool steels used in these operations must be both highly wear resistant and corrosion resistant, as well as sufficiently strong and impact resistant to withstand the operating stresses encountered.

To address these operating requirements, a number of high-performance wear/corrosion-resistant PM tool steels have been developed containing the following: (a) significant amounts of vanadium and chromium to form wear-resistant primary carbides, (b) a minimum of 11% matrix Cr after heat treatment to provide increased corrosion resistance compared to the PM tool steels containing 5 to 8% total Cr, and (c) an optimal level of carbon and/or nitrogen to form the wear-resistant carbides and to achieve a minimum of 56 to 58 HRC after heat treatment without forming excessive amounts of retained austenite or

precipitating additional chromium-rich carbides, which would lower the desired matrix chromium. These materials usually also contain a minimum of 1% Mo to improve hardenability and resistance to pitting corrosion.

Table 7 lists the nominal compositions of several commercially available PM wear/corrosion-resistant tool steel grades along with the compositions of conventionally produced T440C stainless steel and D2 tool steel. As shown, the PM wear/corrosion-resistant materials have total chromium contents ranging from about 14 to 24%, vanadium contents ranging from about 3 to 15%, molybdenum contents ranging from about 1 to 3%, and carbon contents ranging from about 1.7 to 3.75%. The relative wear and corrosion resistance of these materials is strongly influenced by the partitioning of the alloying elements between the matrix and the primary carbides during solidification from the melt, by the volume fraction of primary carbides, and by heat treatment.

Table 7 Nominal compositions of wear/corrosion-resistant tool steels

Steel	Commercial equivalent	Composition, wt%				
		C	Cr	V	Mo	Other
PM steels						
PM 14Cr-9V	CPM 420V (9V)	2.30	14	9	1	...

The heat treating procedures recommended for the PM wear/corrosion-resistant tool steels are similar to those recommended for the PM wear-resistant tool steels described in the previous section. All of the materials are designed to be air-hardenable, but may require oil quenching or high-pressure quenching in vacuum systems to minimize intergranular carbide precipitation or to avoid high-temperature transformation products in large cross sections. Austenitizing temperatures typically range from a minimum of about 1080 °C (1975 °F) to a maximum of about 1150 to 1175 °C (2100 to 2150 °F), which permits sufficient solutioning of the alloy carbides for heat treat response without resulting in excessive retained austenite levels during quenching. For optimal corrosion resistance, a maximum tempering range of about 260 to 400 °C (500 to 750 °F) is recommended. However, it may be necessary to employ multiple tempering at higher temperatures, for example, 540 to 550 °C (1000 to 1025 °F), in order to eliminate retained austenite for size stability or to guarantee more thorough stress relieving for wire EDM operations, and so forth. The use of higher tempering temperatures results in less corrosion resistance due to fine chromium carbide precipitation, but the corrosion resistance is still expected to be better than that of other tool steels containing less chromium in the matrix. The use of tempering temperatures in the range of about 425 to 525 °C (800 to 975 °F) should be avoided to prevent a loss in toughness.

When comparing these materials for potential corrosion resistance, it is important to recognize that higher total chromium content does not necessarily guarantee higher matrix chromium for better corrosion resistance, because a significant percentage of the chromium can be present as chromium-rich primary carbides that do not appreciably dissolve at the austenitizing temperatures used for heat treatment. Table 8 shows the results of SEM energy-dispersive x-ray spectrometry analysis of the matrix chromium for T440C and the high-chromium high-vanadium PM tool steels, where it can be seen that the matrix chromiums after heat treatment are comparable (about 12.5 to 13.5%) despite a wide range in total chromium contents (nominally 14 to 24%). Note that the PM 14Cr-9V material with only about 14% total Cr content has about the same matrix chromium as T440C as well as the other PM wear/corrosion-resistant tool steels, which have higher total chromium contents. This is accomplished by carefully "balancing" the carbon/alloy and chromium/vanadium ratios to preferentially form vanadium-rich MC carbides in the microstructure, thereby minimizing the formation of chromium-rich M_7C_3 carbides, and to simultaneously achieve a minimum matrix chromium of about 11 to 12%. In comparison, although D2 tool steel contains a total chromium content of about 11.5%, the matrix chromium of D2 is lower than that required for good corrosion resistance due to the formation of chromium-rich M_7C_3 primary carbides in the microstructure.

Table 8 SEM analysis of heat treated wear/corrosion-resistant tool steels

	T440C	PM 17Cr3V	PM 20Cr4V	PM 17Cr6V	PM 24Cr9V	PM 14Cr9V	PM 14Cr12V	PM 14Cr15V
Approximate matrix chromium versus total chromium content, wt%								
Total	16	17	20	17	24	14	14	14
Matrix	13	11.5	13.5	13.5	13.5	12	12.5	12.5
Primary carbide content determined by image analysis, vol%								
M₇C₃	13.5	18.5	21	20	42	13.5	15.5	14.5
MC	...	2	3.5	4.5	4.5	9.5	12.5	17
Total	13.5	20.5	24.5	24.5	46.5	23	28	31.5

Figure 18 compares the corrosion resistance of the PM wear/corrosion-resistant tool steels to that of T440C and D2 tool steel in two accelerated corrosion tests: (a) the dilute aqua regia test in which samples are immersed for 3 h in a room-temperature aqueous solution containing 5 vol% nitric and 1 vol% hydrochloric acid, and (b) the boiling acetic acid test in which samples are immersed in a boiling aqueous solution of 10 vol% acetic acid for 24 h. The results show that D2 exhibits considerably less corrosion resistance than T440C in both corrosion tests. With the exception of PM 17Cr3V, all of the PM wear/corrosion-resistant tool steels test about the same as T440C in the dilute aqua regia test. Similarly, all of the PM materials except PM 17Cr3V test about the same or slightly better than T440C in the boiling 10% acetic acid test. The somewhat poorer test results observed for the PM 17Cr3V material was determined to be due to an excess carbon balance in this material compared to the other PM materials tested. The fact that the three PM grades containing only about 14% Cr and 9 to 15% V exhibit corrosion resistance comparable to both T440C and the properly balanced 17 to 24% Cr PM grades further illustrates that relative corrosion resistance cannot be absolutely predicted by simply comparing total chromium contents.

Fig. 18 Corrosion testing of PM wear/corrosion-resistant tool steels

As was the case for the PM wear-resistant tool steels, the wear resistance characteristics of the PM wear/corrosion-resistant tool steels are a function of the heat treated hardness, the total primary carbide volume, and the type (hardness) of carbide present. To maintain an optimal composition balance for good corrosion resistance, these materials are typically designed with the minimum carbon level necessary to achieve at least 56 to 58 HRC after heat treatment. Both the total primary carbide volume fraction and the types of carbide present are determined by the relative amounts of total chromium, vanadium, and/or other strong carbide-forming elements in the composition. Very high chromium levels promote the preferential formation of chromium-rich M_7C_3 primary carbides even when significant amounts of vanadium are also present. Conversely, high vanadium levels in the presence of low-to-moderate chromium levels promote the formation of the harder vanadium-rich MC carbides. Table 8 shows the results of SEM image analysis of the primary carbide types present in the PM wear/corrosion-resistant tool steels, where it can be seen that the alloys with nominally 17 to 24% total Cr and 3 to 9% V contain predominantly M_7C_3 carbides and less than about 4.5% by volume of the MC carbides. In contrast, the three PM grades containing only about 14% total Cr and 9 to 15% V by design contain significantly greater volume fractions of the MC carbide in addition to the M_7C_3 carbides that inevitably form at this chromium level. This effect of vanadium content on the total primary carbide volume and relative amount of MC carbide at the 14% Cr level is illustrated in Fig. 19, which shows SEM electronic images of the primary carbides observed in the heat treated microstructures. Carbide size can also affect wear resistance, particularly under abrasive wear conditions, but is generally not a factor for the PM tool steels as discussed in an earlier section.

Fig. 19 Primary carbides in PM wear/corrosion-resistant tool steels containing 14% Cr and 9 to 14.5% V. (a) PM 14Cr9V (9.5% MC-13.5% M_7C_3). (b) PM 14Cr12V (12.5% MC-15.5% M_7C_3). (c) PM 14Cr15V (17% MC-14.5% M_7C_3)

Figure 20 shows the results of crossed-cylinder and pin-abrasion wear testing for several of the wear/corrosion-resistant PM tool steels as well as T440C. All of the materials except PM 24Cr9V were tested at either 56 to 58 or 58 to 60 HRC, which are the typical application hardnesses recommended by the material producers. PM 24Cr9V was tested at its usual application hardness of 63 HRC. As is the case for the PM cold-work tool steels discussed in the previous section of this article, the wear resistance of the PM wear/corrosion-resistant tool steels generally improves with increasing total primary carbide volume and particularly with increasing MC carbide content. Taking into account the slight differences in test hardness, the PM 17Cr6V and PM 20Cr4V materials, with about 24.5% total carbide volume and about 3.5 to 4.5% MC, test about the same in both wear tests and somewhat better than either T440C or PM 17Cr3V, which have lower total carbide volumes and $\leq 2\%$ MC. PM 24Cr9V, with about the same MC carbide content as PM 20Cr4V, tests about the same as PM 20Cr4V in the crossed-cylinder wear test but significantly better than all of the other materials in the pin-abrasion wear test. The latter result is due to the combination of the large total carbide volume and high test hardness of PM 24Cr9V. The significant influence of MC carbide content in both wear tests can be seen by comparing the wear test results for the high-vanadium 14% Cr materials as a group with those of the 17 to 20% Cr materials, which contain predominantly M_7C_3 carbides. Although T440C tests about the same as PM 17Cr-3V in the crossed-cylinder test and somewhat better in the pin-abrasion test (most likely due to the inherently larger primary carbide size of the conventionally produced material), all of the PM wear/corrosion-resistant tool steels are expected to be significantly more wear resistant than T440C in actual service.

Fig. 20 Wear test results for PM wear/corrosion-resistant tool steels

The PM wear/corrosion-resistant tool steels are used in applications where a combination of wear resistance and good corrosion resistance are required. They are particularly well suited for the processing of corrosive engineering plastics and are used for many of the same equipment components where the PM wear-resistant materials are also used. Examples of barrels and screws, nonreturn check ring valves, and granulator and pelletizer knives that make use of these high-performance PM materials are shown in Fig. 17.

Hot Work Particle Metallurgy Tool Steels

The absence of alloy segregation, and the inherently fine carbide and sulfide size distributions typical for PM processing, make PM tool steels attractive for consideration in hot-work applications where standard or premium quality conventional H13 or other hot-work tool steel compositions are currently used. However, unlike the cutting tool and cold-work applications where high hardness and high wear resistance are usually the more critical material property requirements, the most important requirements in hot-work applications are good thermal fatigue resistance and very high toughness. The latter two properties generally restrict the carbon content of the heat treated tool steel matrix to less than 0.40% and also limit the amount of total alloying that may be used to introduce primary carbides to the microstructure for additional wear resistance. Thus, PM alloy development in this application area has been limited.

One of the successful applications of PM processing technology has been the development of a resulfurized (free-machining), preheat treated PM H13 for use in die casting and plastic molding operations. These applications typically require a heat treated hardness of about 44 to 48 HRC for an optimal combination of strength, impact toughness, and heat checking resistance. The potential advantages for using PM H13-S compared with conventionally produced H13-S include the following:

- Fine microstructural control with no alloy segregation, which enables the safe and uniform preheat treatment of large bar cross sections
- Higher transverse impact properties and better thermal fatigue resistance due to the elimination of large sulfide stringers
- Significantly improved machinability and better resulting surface finishes in both the annealed and heat treated conditions

For the die maker, the prospect of being able to machine directly from the heat treated solid represents a significant cost and time savings due to elimination of premachining steps and the avoidance of distortion during heat treatment.

Figure 21 compares typical longitudinal microstructures observed in moderately sized block cross sections of standard quality conventional H13, premium quality H13, and PM H13. As can be seen, the conventionally produced material typically exhibits a banded microstructure due to normal alloy segregation in the cast ingot. Premium quality H13 exhibits a much more uniform but still slightly banded microstructure due to special processing during melting, ingot casting, and subsequent hot working. In comparison, the PM H13 microstructure is completely free of alloy segregation, very uniform, and fine grained. Table 9 shows the nominal composition of resulfurized PM H13 compared to the nominal compositions for premium-quality H13 (low S) produced to the North American Die Casting Association (NADCA) specification as well as conventionally produced H13-S. Table 10 shows the results of transverse impact testing for these same three materials. The detrimental effect of a high sulfur addition in conventional materials can be clearly seen, whereas the high-sulfur PM H13 material has impact properties comparable to the premium quality low-sulfur material. Figure 22 shows laboratory thermal fatigue testing results, where PM H13-S performed somewhat better-than-premium quality H13 and significantly better-than-conventional H13-S. Included in this study was a premium quality H13 test specimen that had been purposely given an EDM surface finish to illustrate the potentially detrimental effect of preexisting surface cracks on thermal fatigue resistance. These results indicate that tool life improvements could be realized in some die casting applications where the cavities can be machined directly from preheat treated PM H13-S, thereby eliminating the need for EDM.

Table 9 Composition of premium quality and resulfurized H13 tool steels

Material	Composition, wt %						
	C	Mn	S	Si	Cr	Mo	V
NADCA PQ H13	0.40	0.35	0.005 max	1.00	5.25	1.35	1.00

Composite Bars, HIP Cladding, and Near-Net Shapes

In some tooling or wear part applications, it may not be practical or economical to produce the component from solid bar stock made entirely from a highly alloyed PM tool steel. In other applications, it may be desirable to produce a composite material to take advantage of the inherent property differences between the materials used to make the composite. In both cases, it is possible to HIP-clad PM tool steel powders to different solid substrate materials, HIP-clad other materials in powder or thin cross-section form to an existing PM tool steel bar product, or produce a composite bar by simultaneously HIP-consolidating two dissimilar prealloyed powders. Successful diffusion bonding during HIP at elevated temperatures and ultimately good bond strength in service generally require that the materials being diffusion bonded have mutual solid-state solubility without intermetallic formation, a wide temperature range for bonding, and compatible thermal expansions and elastic moduli. Consideration must also be given to the effects that the HIP cycle (both the elevated-temperature exposure and the relatively slow cooling rates employed) and/or any required post-HIP heat treatment may have on the basic properties of any nontool steel materials used to form the composite. Where the properties of the substrate or mating material are not critical, it is common to use carbon and low-alloy steels as the substrate materials. Where mechanical strength is a consideration, an air-hardenable tool steel such as H13 might be selected. Where corrosion resistance is required, the substrate or mating material could be an austenitic or martensitic stainless steel.

Many of the advanced wear-resistant and wear/corrosion-resistant PM tool steels have been successfully produced in composite bar form or have been used in powder form for HIP cladding of prefabricated machine components. Figure 23 shows an example of one such application, where a low-alloy steel is HIP-clad to the inside diameter of a highly alloyed wear-resistant PM tool steel (in this case PM 10V) to produce composite bars that are subsequently fabricated into bimetallic extruder screw segments for the plastics industry. The low-alloy steel was specified for the ID to facilitate broaching of the splines and to provide some notch ductility during torque loading in operation. The excellent bond obtained between the PM 10V and the low-alloy steel is shown in Fig. 24.

Fig. 23 Bimetallic plastics extruder component machined from PM composite bar (PM 10V on outside-mild steel core)

Fig. 24 Bond interface for PM 10V/mild steel composite. 500×

Net-shape monolithic products can also be manufactured from the PM tool steels by either direct HIP consolidation of the powders or by warm/hot forging of billet stock. Most of the PM tool steels exhibit excellent hot-working characteristics and can be readily forged from billet into large cylindrical ring sections, simple solid shapes, or closed-die forgings. For large hollow bar applications, where material costs or the outside diameter (OD) or inside diameter (ID) size and length prohibit the use of forged rings or solid bar stock, as-HIP hollow bars can be produced. It is also possible to produce very intricate individual near-net-shape parts by direct HIP of specially designed containers filled with the desired PM tool steel powder. However, unless the desired final shape cannot be physically machined or otherwise fabricated, it is generally more economical to machine directly from the solid or hollow bar form. The composite part shown in Fig. 23 is a good example of where it is actually less expensive to machine the OD and ID profiles directly from the solid composite bar or hollow than it would be to manufacture the same shape as a near-net shape as-HIP part.

Powder Forged Steel

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Introduction

POWDER FORGING is a process in which unsintered, presintered, or sintered powder metal preforms are hot formed in confined dies. The process is sometimes called P/M (powder metallurgy) forging, P/M hot forming, or is simply referred to by the acronym P/F. When the preform has been sintered, the process is often referred to as "sinter forging."

Powder forging is a natural extension of the conventional press and sinter (P/M) process, which has long been recognized as an effective technology for producing a great variety of parts to net or near-net shape. Figure 1 illustrates the powder forging process. In essence, a porous preform is densified by hot forging with a single blow. Forging is carried out in heated, totally enclosed dies, and virtually no flash is generated. This contrasts with the forging of wrought steels, in which multiple blows are often necessary to form a forging from bar stock and considerable material is wasted in the form of flash.

Fig. 1 The powder forging process

The shape, quantity, and distribution of porosity in P/M and P/F parts strongly influence their mechanical performance. The effect of density on the mechanical properties of as-sintered iron and powder forged low-alloy steel is illustrated in Fig. 2. Powder forging, therefore, is a deformation processing technology aimed at increasing the density of P/M parts and thus their performance characteristics.

Fig. 2 Effect of density on mechanical properties. (a) and (b) As-sintered iron. Source: Ref 1. (c) Powder forged low-alloy steel. Source: Ref 2

There are two basic forms of powder forging:

- Hot upsetting, in which the preform experiences a significant amount of lateral material flow
- Hot repressing, in which material flow during densification is mainly in the direction of pressing, is sometimes referred to as hot restriking, or hot coining

These two deformation modes and the stress conditions they impose on pores are illustrated in Fig. 3.

Fig. 3 Forging modes and stress conditions on pores for (a) repressing and (b) upsetting. Source: Ref 3

In hot upset powder forging, the extensive unconstrained lateral flow of material results in a stress state around the pores that is a combination of normal and shear stresses. A spherical pore becomes flattened and elongated in the direction of lateral flow. The sliding motion due to shear stresses breaks up any residual interparticle oxide films and leads to strong metallurgical bonding across collapsed pore interfaces. This enhances dynamic properties such as fracture toughness and fatigue strength.

The stress state during hot repress powder forging consists of a small difference between vertical and horizontal stresses, which results in very little material movement in the horizontal direction and thus limited lateral flow. As densification proceeds, the stress state approaches a pure hydrostatic condition. A typical pore simply flattens, and the opposite sides of the pore are brought together under pressure. Hot repress forging requires higher forging pressures than does hot upset forging for comparable densification. The decreased interparticle movement compared with upsetting reduces the tendency to break up any residual interparticle oxide films and may result in lower ductility and toughness.

While powder forged parts are primarily used in automotive applications where they compete with cast and wrought products, parts have also been developed for military and off-road equipment.

The economics of powder forging have been reviewed by a number of authors (Ref 4, 5, 6, 7, 8, 9). Some of the case histories included in the section "Applications of Powder-Forged Parts" in this article also compare the cost of powder forging with that of alternative forming technologies.

The discussion of powder forging in this article is limited to ferrous alloys. Information on the forging of aluminum, nickel-base, and titanium powders is available in other articles that follow in this Section.

Powder Forged Steel

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Material Considerations

The initial production steps of powder forging (preforming and sintering) are identical to those of the conventional press and sinter P/M process. Certain defined physical characteristics and properties are required in the powders used in these processes. In general, powders are classified by particle shape, particle size, apparent density, flow, chemistry, green strength, and compressibility.

Powder Characteristics. Shape, size distribution, apparent density, flow, and composition are important characteristics for both conventional P/M and powder forging processes. The shape of the particles is important in relation to the ability of the particles to interlock when compacted. Irregular particle shapes such as those produced by water atomization are typically used. In P/M parts, surface finish is related to the particle size distribution of the powder. In powder forging, however, the surface finish is directly related to the finish of the forging tools. This being the case, it might be considered possible to use coarser powders for powder forging (Ref 10). Unfortunately, the potential for deeper surface oxide penetration is greater when the proportion of coarser particles is increased. Typical pressing grades are -80 mesh with a median particle size of about $75\text{ }\mu\text{m}$ (0.003 in.). The apparent density and flow are important to maintain fast and accurate die filling. The chemistry affects the final alloy produced as well as the compressibility.

Green strength and compressibility are more critical in P/M than they are in P/F applications. Although there is a need to maintain edge integrity in P/F preforms, there are rarely thin, delicate sections that require high green strength. Because P/F preforms do not require high densities (typically 6.2 to 6.8 g/cm^3), the compressibility obtainable with prealloyed powders is sufficient. However, carbon is not prealloyed because it has an extremely detrimental effect on compressibility (Fig. 4).

Fig. 4 Effect of alloying elements on the compressibility of iron powder. Source: Ref 10

Alloy Development. Several investigators have shown that forged conventional elemental powder mixes result in poor mechanical properties, such as fatigue resistance, impact resistance, and ductility (Ref 11, 12). This is almost entirely due to the chemical and metallurgical heterogeneity that exists in materials made by this method. To overcome this, very long diffusion times or higher processing temperatures are required to fully homogenize the material, particularly when elements such as nickel are used. Samples forged from prealloyed powder have also been shown to have better hardenability than samples forged from admixed powders (Ref 13). Fully prealloyed powders have therefore been produced by several manufacturers. Each particle in these powders is uniform in composition, thereby alleviating the necessity for extensive alloy diffusion.

Powder purity and the precise nature and form of impurities are also extremely important. In a conventional powder metal part, virtually all properties are considerably lower than those of equivalent wrought materials. The effect of inclusions is overshadowed by the effect of the porosity. For a powder forging at full density, as in a conventional forging, the dominant effect of residual porosity on properties is replaced by the form and nature of impurity inclusions.

The two principal requirements for powder forged materials are an ability to develop an appropriate hardenability to guarantee strength and to control fatigue performance by microstructural features such as inclusions.

Hardenability. Manganese, chromium, and molybdenum are very efficient promoters of hardenability, whereas nickel is not. In terms of their basic cost, nickel and molybdenum are relatively expensive alloying additions compared with chromium and manganese. On this basis, it would appear that chromium/manganese-base alloys would be the most cost-effective materials for powder forging. However, this is not necessarily the case, because these materials are highly susceptible to oxidation during the atomization process. In addition, during subsequent powder processing, high temperatures are required to reduce the oxides of chromium and manganese, and special care must be taken to prevent reoxidation during handling and forging. If the elements become oxidized, they do not contribute to hardenability. Nickel and molybdenum have the advantage that their oxides are reduced at conventional sintering temperatures. Alloy design is therefore a compromise and the majority of atomized prealloyed powders in commercial use are nickel/molybdenum based, with manganese present in limited quantities. The compositions of four commercial prealloyed, low-alloy steel powders are listed below.

Alloy	Typical composition ^(a) , wt%		
	Ni	Mo	Mn
P/F-4600	1.8	0.55	0.20
P/F-4200	0.45	0.60	0.27
P/F-4400	...	0.85	0.15

(a) Fe, balance

The higher cost of nickel and molybdenum along with the higher cost of powder compared with conventional wrought materials is often offset by the higher material utilization inherent in the powder forging process.

Material designations for powder forging are summarized in Table 1. These designations are taken from ASTM Specification B 848 "Standard Specification for Powder Forged (P/F) Ferrous Structural Parts."

Table 1 Material designations for powder forging

(See Table 12 for the chemical composition of the various materials)

Designation	Composition
P/F-10xx	Carbon steel (produced from atomized iron powder and graphite powder)
P/F-10Cxx	Copper-carbon steel (produced from atomized iron powder, copper, and graphite powders)
P/F-11xx	Carbon steel with manganese sulfide for enhanced machinability (produced from atomized iron powder, manganese sulfide, and graphite powders)

P/F-11Cxx	Carbon-carbon steel with manganese sulfide for enhanced machinability (produced from atomized iron powder, copper, manganese sulfide, and graphite powders)
P/F-42xx	Nickel-molybdenum steel (produced from prealloyed atomized iron-nickel-molybdenum powder and graphite powder)
P/F-46xx	Nickel-molybdenum steel (produced from prealloyed atomized iron-nickel-molybdenum powder and graphite powder)
P/F-44xx	Molybdenum steel (produced from prealloyed atomized iron-molybdenum powder and graphite powder)
P/F-49xx	Molybdenum steel (produced from prealloyed atomized iron-molybdenum powder and graphite powder)

More recently, P/F parts have been produced from iron powders (0.10 to 0.25 wt% Mn) with copper and/or graphite additions for parts that do not require the heat-treating response or high strength properties achieved through the use of the low-alloy steels. Detailed descriptions of alloy development for powder forging applications have been published previously (Ref 14, 15).

Inclusion Assessment. Because the properties of material powder forged to near full density are strongly influenced by the composition, size distribution, and location of nonmetallic inclusions (Ref 16, 17, 18), a method has been developed for assessing the inclusion content of powders intended for P/F applications (Ref 19, 20, 21, 22). Samples of powders intended for forging applications are repress powder forged under closely controlled laboratory conditions. The resulting compacts are sectioned and prepared for metallographic examination. The inclusion assessment technique involves the use of automated image analysis equipment. The automated approach is preferred because it is not sensitive to operator subjectivity and can be used routinely to obtain a wider range of data on a reproducible basis.

In essence, an image analyzer consists of a good-quality metallurgical microscope, a video camera, a display console, a keyboard, a microprocessor, and a printer. The video image is assessed in terms of its gray-level characteristics, black and white being extremes on the available scale. The detection level can also be set to differentiate between oxides and sulfides.

Compared with wrought steels, only a limited amount of material flow is present in powder forged components. Inclusion stringers common to wrought steel are therefore not found in powder forged materials. Figure 5(a) illustrates an inclusion type encountered in powder forged low-alloy steels. The fragmented nature of these inclusions makes size determination by image analysis more complex than would be the case with the solid exogenous inclusion shown in Fig. 5(b). Basic image analysis techniques tend to count the inclusion shown in Fig. 5(a) as numerous small particles rather than as a single larger entity. Amendment of the detected video image is required to classify such inclusions; the method used is discussed in Ref 22 and forms the basis for ASTM Test Method B 796, "Standard Test Method for Nonmetallic Inclusion Level of Powder Forged Steel Parts."

Fig. 5 Two types of inclusions. (a) "Spotty particle" oxide inclusion. 800 \times . (b) Exogenous slag inclusion. 590 \times . Source: Ref 21

Iron Powder Contamination. Water-atomized low-alloy steel powders are generally produced and processed in a plant that also manufactures pure iron powders. In the early days of alloy development when alloy powder production was limited, procedures were developed to minimize cross-contamination of powders. Considerable care is still taken to prevent cross-contamination, and iron powder contamination of low-alloy powders is typically <1%. Studies have shown that for "through hardening" applications, $\leq 3\%$ iron powder contamination has little effect on the strength and ductility of powder forged material (Ref 23, 24).

The compact used for inclusion assessment may also be used to measure the amount of iron powder particles present. The sample is lightly pre-etched with 2% nital. Primary etching is with an aqueous solution of sodium thiosulfate and potassium metabisulfite. This procedure darkens the iron particles and leaves the low-alloy matrix very light (Fig. 6) or, in the case of low-alloy contamination, darkens the matrix and leaves the low-alloy particles light.

Fig. 6 Iron powder contamination of water-atomized low-alloy steel powder. Source: Ref 21

The etched samples are viewed on a light microscope at a magnification of 100 \times . The total number of points of a 252 point grid that intersects iron particles for ten discrete fields is divided by the total number of points in the ten fields (2520) to determine the percentage of iron contamination. The approach forms the basis for ASTM B 795.

Powder Forged Steel

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Process Considerations

Development of a viable powder forging system requires consideration of many process parameters. The mechanical, metallurgical, and economic outcomes depend to a large extent on operating conditions, such as temperature, pressure, flow/feed rates, atmospheres, and lubrication systems. Equally important consideration must be given to the types of processing equipment, such as presses, furnaces, dies, and robotics, and to secondary operations, in order to obtain the process conditions that are most efficient. This efficiency is maintained by optimizing the process line layout. Examples of effective equipment layouts for preforming, sintering, reheating, forging, and controlled cooling have been reviewed in the literature (Ref 4, 25). Figure 7 shows a few of the many possible operational layouts. Each of these process stages is reviewed in the following sections.

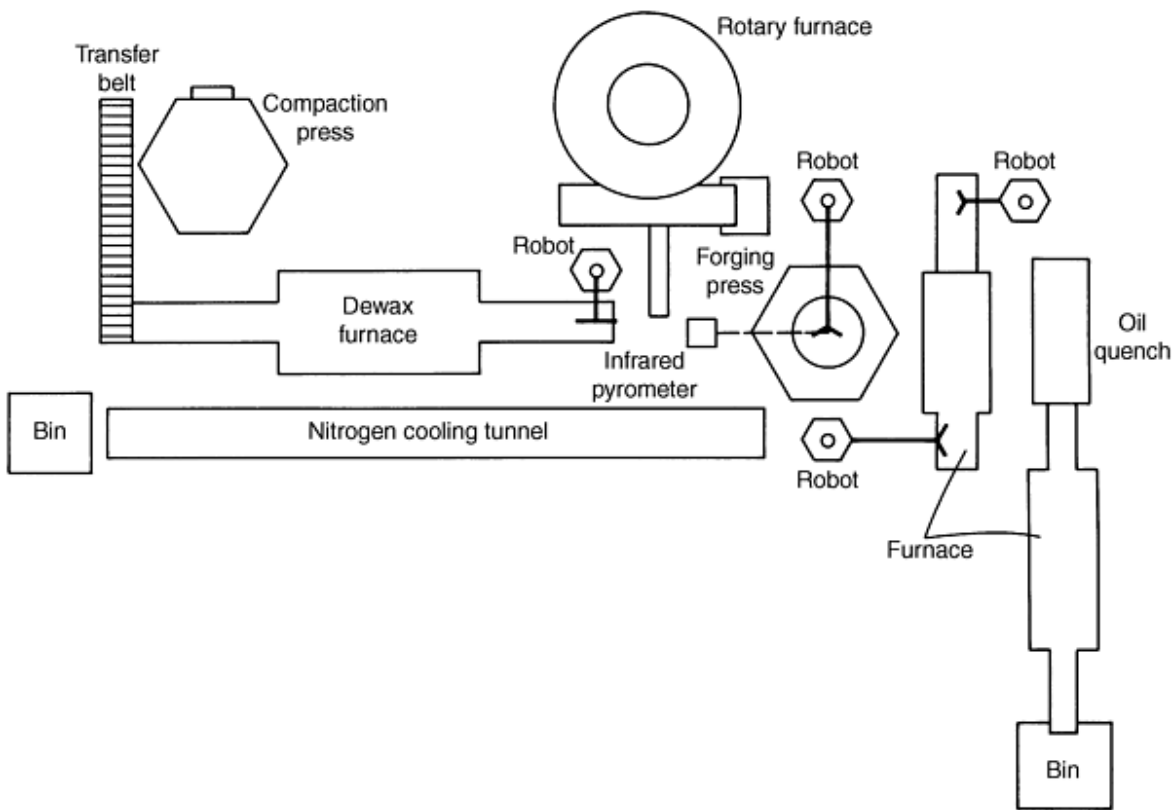

Fig. 7 A powder forging process line. Source: Ref 26

Preforming. Preforms are manufactured from admixtures of metal powders, lubricants, and graphite. Compaction is predominantly accomplished in conventional P/M presses that use closed dies. In order to avoid the necessity of thermally removing the lubricant, preforms can be compacted without admixed lubricants in an isostatic press. However, even though they produce uniform weight and density distributions, the pressure and rate limitations of high-production isostatic presses (414 MPa, or 60 ksi, pressure and 120 cycles per hour) have severely restricted their commercial use for compacting P/F preforms.

Control of weight distribution within preforms is essential to produce full density parts and thus maximize performance in the critical regions of the forged component. Excessive weight in any region of the preform may cause overload stresses that could lead to tool breakage.

Successful preform designs have been developed by an iterative trial and error procedure, using prior experience to determine the initial shape. More recently, computer-aided design (CAD) has been used for preform design (Ref 27, 28, 29). Preform design and workability analysis is covered in detail by Ferguson and Kuhn (Ref 30).

Preform design is intimately related to the design and dimensions of the forging tooling, the type of forging press, and the forging process parameters. Among the variables to be considered for the preforming tools are:

- Temperature, that is, preform temperature, die temperature, and, when applicable, core rod temperature
- Ejection temperature of the forged part
- Lubrication conditions--influence on compaction/ejection forces and tooling temperatures
- Transfer time and handling of the preform from the preheat furnace to the forging die cavity

Correct preform design not only entails having the right amount of material in the various regions of the preform but also is concerned with material flow between the regions and prevention of potential fractures and defects.

An example of the effect of preform geometry on forging behavior can be taken from the work of C.L. Downey and H.A. Kuhn (Ref 31). Figure 8(a) shows four possible preforms that could be forged to produce the axisymmetric part having the cup and hub sections shown in Fig. 8(b).

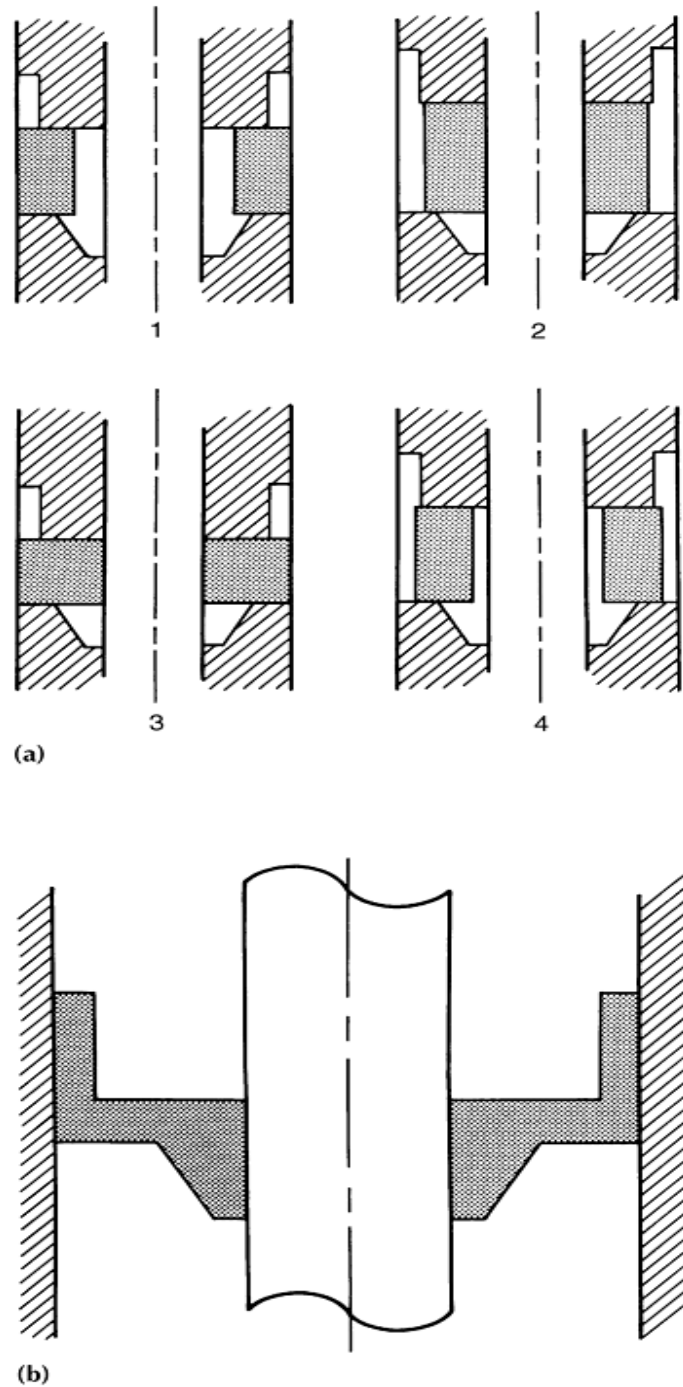

Fig. 8 (a) Possible configurations for the ring preform for forging the part shown in (b). See text for details. (b) Cross section of the part under consideration for powder forging. Source: Ref 31

Preform geometries 2 and 4 in Fig. 8(a) result in defective forgings due to cracking at the outer rim as metal flows around the upper punch radius. This occurs because the deforming preform is expanding in diameter as the metal flows around the corner, even though there is axial compression to help compensate for the circumferential tension. This type of cracking can be avoided by using a preform that fills the die with no clearance at the outside diameter, as in preforms 1 and 3.

Preform 3 can be rejected because it is similar to hub extrusion, and this may lead to cracking at the top surface of the hub. Allowing some clearance between the bore diameter of the preform and the mandrel eliminates this type of crack.

Preform 1 overcomes these problems. Use of this preform has resulted in defect-free parts, while the expected cracking occurred with use of the other preforms (Ref 31).

Sintering and Reheating. Preforms may be forged directly from the sintering furnace; sintered, reheated, and forged; or sintered after the forging process. The basic requirements for sintering in a ferrous powder forging system are lubricant removal, oxide reduction, carbon diffusion, development of particle contacts, and heat for hot densification. Oxide reduction and carbon diffusion are the most important aspects of the sintering operations. For most ferrous powder forging alloys, sintering takes place at $\sim 1120^\circ\text{C}$ (2050°F) in a protective reducing atmosphere with a carbon potential to prevent decarburization. The time required for sintering depends upon the number of sintering stages for delubrication, diffusion of carbon, reduction of oxides, and the type of sintering equipment used. Typical P/M sintering has been commonly performed at 1120°C (2050°F) for 20 to 30 min; these conditions may be required to help diffuse elements such as copper and nickel. In the prealloyed systems used for powder forging, only the diffusion of carbon is usually required. It has been shown that the time required to diffuse carbon and reduce the oxides is ~ 3 min at 1120°C (2050°F) (Ref 32, 33, 34). This is illustrated in Fig. 9. Increases in temperature will reduce the time required for sintering by improving oxide reduction and increasing carbon diffusion. Chromium-manganese steels have been limited in their use because of the higher temperatures required to reduce their oxides and the greater care needed to prevent reoxidation.

Fig. 9 Carbon dissolution as a function of time and temperature. Data are for an iron-graphite alloy at a density of 6.2 to 6.3 g/cm^3 (0.224 to 0.228 lb/in.^3). Source: Ref 34, Ref 8

Any of the furnaces used for sintering P/M parts, such as vacuum, pusher, belt, rotary hearth, walking beam, roller hearth, and batch/box, may be used for sintering or reheating P/F preforms. Delubrication can be accomplished in any of these types of

furnaces or in separate delubrication furnaces before entering the sintering furnace. Typically, belt, rotary hearth, and batch/box furnaces have been used for sintering and reheating preforms. However, the selection of sintering furnace largely depends upon the following conditions:

- Material being forged
- Size and weight of parts
- Forging process route (sinter/reheat versus sinter/forge)
- Forging temperature
- Atmosphere capabilities
- Delubrication capabilities
- Furnace loading capabilities/sintering rate
- Sintering time
- Robotics

The sintered preforms can be forged directly from the sintering furnace, stabilized at lower temperatures and forged, or cooled to room temperature, reheated, and forged. All cooling, temperature stabilization, and reheating must occur under protective atmosphere to prevent oxidation.

Induction furnaces are often used to reheat axisymmetric preforms to the forging temperature because of the short time required to heat the material. Difficulties may be encountered in obtaining uniform heating throughout asymmetric shapes because of the variation in section thickness.

Powder forging involves removing heated preforms from a furnace, usually by robotic manipulators, and locating them in the die cavity for forging at high pressures (690 to 965 MPa, or 100 to 140 ksi). Preforms can be graphite coated to prevent oxidation during reheating and transfer to the forging die. These dies are typically made from hot-work steels such as AISI H13 or H21. Lubrication of the die and punches is usually accomplished by spraying a water-graphite suspension into the cavity (Ref 35, 36, 37).

The forging presses commonly used in conventional forging (Ref 38, 39, 40, 41), including hammers, high-energy-rate forming (HERF) machines, mechanical presses, hydraulic presses, and screw presses, have been evaluated for use in powder forging (Ref 8, 42). The essential characteristics that differentiate presses are contact time, stroke velocity, available energy and load, stiffness, and guide accuracy. Mechanical crank presses are the most widely used because of their short, fast strokes, short contact times, and guide accuracy. Hydraulic presses have also been used for applications in the 7.7 g/cm^3 density range, and screw presses are being used because of their lower cost and short contact times. More information on forging equipment is available in the articles "Hammers and Presses for Forging" and "Selection of Forging Equipment" in *ASM Handbook*, Volume 14, *Forming and Forging*.

Metal Flow in Powder Forging. Some of the problems encountered in powder forging and the probable causes are described in Table 2. These problems are related to the aforementioned sintering and reheating equipment and to the deformation processing described below.

Table 2 Common powder forging problems and their probable causes

Forging problems	Probable causes
Surface oxidation	Extensive transfer time from furnace
Surface decarburization	Overly high forging temperature
	Entrapped liquid/graphite coating during reheat
	Excessive die lubrication (water)
	Oxidation during sintering or reheating
Surface porosity	Excessive contact time
	Low forging temperature
Tool wear	Low preform temperatures
	High or low tool temperature
	Excessive contact time
Poor tolerances	Temperature variations in tools and preforms
Excessive flash/tool jamming	Excessive preform temperature
	High preform weight/incorrect distribution
	Improper tool design
Excessive forging loads	Low preform temperature
	High preform weight
Low densities	Oxidation
	Low forging temperature/pressure
	Low preform weight
	Die chill
Cracks, laps	Improper tool or preform design
Improper die fill	Improper preform weight distribution/material flow

Draft angles, which facilitate forging and ejection in conventional forging, are eliminated in powder forged parts. This means that greater ejection forces (~ 15 to 20% of press capacity as a minimum) are required for the powder forging of simple shapes. However, the elimination of draft angles permits P/F parts to be forged more closely to net shape. Figure 10 illustrates the ejection forces required for a P/F gear as a function of residual porosity (Fig. 10a) and preform temperature (Fig. 10b). To be suitable for powder forging, standard forging presses must be modified to have stronger ejection systems.

(a)

(b)

Fig. 10 (a) Forging pressure and ejection force as functions of density for the P/F-4600 powder forged gear shown in Fig. 12. Preform temperature: 1100 °C (2010 °F). (b) Ejection force after forging as a function of preform temperature for a powder forged gear. Forging pressure ranged from 650 to 1000 MPa (94 to 145 ksi).

The deformation behavior of sintered, porous materials differs from that of wrought materials because porous materials densify during the forming operation. As a consequence, a porous preform will appear to have a higher rate of work hardening than its wrought counterpart. The work-hardening exponent, m , can be defined in terms of the true stress-true strain diagram:

$$\sigma = K\varepsilon^m \quad (\text{Eq 1})$$

where σ is true stress, ϵ is true strain, and K is a proportionality constant. An empirical relationship between m and density ρ for a ferrous preform has been shown (Ref 43):

$$m = 0.31\rho^{1.91} \quad (\text{Eq 2})$$

where ρ is expressed as a fraction of the density of pore-free material. The value of m for pore-free pure iron is 0.31, and any excess over this value for porous iron is due to geometric work hardening.

A further consequence of the densification of porous preforms during deformation is reflected in Poisson's ratio for the porous material. Poisson's ratio is a measure of the lateral flow behavior of a material; for compression of a cylinder, it is expressed as diametral strain ϵ_d divided by height strain $-\epsilon_z$. For a pore-free material, Poisson's ratio for plastic deformation ν is 0.5. This is a direct result of the fact that the volume of the material remains constant during deformation. For example, equating the volume of a cylinder before and after deformation (Ref 44):

$$H_0[(\pi D_0^2)/4] = H_f[(\pi D_f^2)/4] \quad (\text{Eq 3})$$

where H_0 and H_f are initial and final cylinder heights, respectively, and D_0 and D_f are initial and final cylinder diameters, respectively.

Dividing by $H_f D_0^2$ yields:

$$H_0/H_f = (D_f/D_0)^2 \quad (\text{Eq 4})$$

and taking logarithms

$$\ln (H_0/H_f) = \ln (D_f/D_0)^2 = 2 \ln (D_f/D_0) \quad (\text{Eq 5})$$

or

$$-\epsilon_z = 2\epsilon_d \quad (\text{Eq 6})$$

and, from the definition of Poisson's ratio:

$$\nu = \frac{-\epsilon_d}{\epsilon_z} = 0.5 \quad (\text{Eq 7})$$

During compressive deformation of a sintered metal powder preform, some material flows into the pores, and there is a volume decrease. For a given reduction in height, the diameter of a sintered P/M cylinder will expand less than that of an identical cylinder of a pore-free material. Poisson's ratio for a P/M preform will therefore be less than 0.5 and will be a function of the pore volume fraction. H.A. Kuhn (Ref 44) has established an empirical relationship between Poisson's ratio and part density:

$$\nu = 0.5 \rho^a \quad (\text{Eq 8})$$

The best fit to experimental data is obtained with the exponent $a = 1.92$ for room-temperature deformation and $a = 2.0$ for hot deformation. The slight difference in this exponent may be due to work hardening (Ref 44).

In deformation processing of materials, plasticity theory is useful for calculating forming pressures and stress distributions. The above mentioned idiosyncrasies in the deformation behavior of sintered, porous materials have been taken into account in the development of a plasticity theory for porous materials. This has been of benefit in applying workability analysis to porous preforms (Ref 31, 43, 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58).

A typical workability line is shown in Fig. 11, which also indicates the way processing variables affect the location of the line. The line has a slope of -0.5, and workability improves as the plane strain intercept (y-axis intercept) value increases. For a given material, workability can be improved through either temperature adjustment or a change in preform density. Figure 12(b) to (e) show the effects of temperature and pressure on the densification and forming of the powder forged gear shown in Fig. 12(a) (Ref 61). While Fig. 12(b) to (e) indicate that higher temperatures reduce the forging pressures required, Fig. 13 illustrates a region of forging pressure at lower temperatures that is comparable to that for higher-temperature forging. The ability to forge at lower temperatures may be beneficial in extending the life of the forging dies.

Fig. 13 Force required for a 50% reduction in height of water-atomized iron powder preforms as a function of deformation temperature. Source: Ref 62

The data presented in Fig. 13 relate to a pure iron with no added graphite. The dramatic increase in the force required for densification $\sim 900^\circ\text{C}$ (1650°F) is due to the phase transformation from body-centered cubic (bcc) α -iron to face-centered cubic (fcc) austenite. In this temperature range, the flow stress of austenite is higher than that of ferrite. However, although materials are fully austenitic at conventional conditions, in the data reported by Q. Jiazhong, O. Gröner, and Y. Nilsson (Ref 63), the mechanical properties of low temperature forged material are considerably inferior to those of material forged at higher temperatures (Table 3). The low-temperature forging resulted in incomplete densification, and this degraded the mechanical properties. G. Bockstiegel and H. Olsen observed a similar dependence of forged density on preform temperature (Ref 64). They pointed out that the presence of free graphite might impede densification. During subsequent heat treatment, when the graphite goes into solution, it could leave fine porosity, which would degrade the mechanical properties of the material.

(a)

30 kgf load

Metal flow can cause surface fractures. These are generally associated with contact forging temperatures (1000 to 1130 °C, or 1830 to 2065 °F), the flow stress of austenite at 1100 °C (2010 °F) is less than that of ferrite at 850 °C (1560 °F).

A similar low flow stress regime has been observed for prealloyed material (Fig. 14). However, depending on the amount of solution of graphite, the dip in the flow stress versus temperature curve becomes less pronounced and eventually is no longer observed. The presence of carbon in solution alters the phase distribution, and the observed flow stress depends on the relative proportions of ferrite and austenite in the microstructure.

Fig. 14 Influence of hot repressing temperature on flow stress for P/F-4600 at various carbon contents and presintering temperatures. Data are for density of 7.4 g/cm^3 (0.267 lb/in.^3). Source: Ref 65, 66

In order to take any advantage of the low flow stress, the thermomechanical processing of preforms that contain added graphite must therefore be such that the graphite does not go into solution. Even under such conditions, in the data reported by Q. Jiazhong, O. Grinder, and Y. Nilsson (Ref 63), the mechanical properties of low temperature forged material are considerably inferior to those of material forged at higher temperatures (Table 3). The low-temperature forging resulted in incomplete densification, and this degraded the mechanical properties. G. Bockstiegel and H. Olsen observed a similar dependence of forged density on preform temperature (Ref 64). They pointed out that the presence of free graphite might impede densification. During subsequent heat treatment, when the graphite goes into solution, it could leave fine porosity, which would degrade the mechanical properties of the material.

Metal flow can cause surface fractures. These are generally associated with contact between the deforming preform and the forging tooling. Surface fracture problems can be avoided by changing the preform geometry or the lubrication conditions.

Frictional constraint at the interface between the preform and the forging die generates undesirable stress states in the preform that can lead to fracture. The types of fracture encountered in powder forging are free-surface fracture, die contact surface fracture, and internal fracture. Production of metallurgically sound forging requires the prediction and elimination of fracture. An excellent review of the subject is given in Ref 43, 46, 56, and 57.

Tool Design. In order to produce sound forged components, the forging tooling must be designed to take into account:

- Preform temperature
- Die temperature
- Forging pressure
- The elastic strain of the die
- The elastic/plastic strain of the forging
- The temperature of the part upon ejection
- The elastic strain of the forging upon ejection
- The contraction of the forging during cooling
- Tool wear

Specified part dimensional tolerances can only be met when the above parameters have been taken into account. However, there is still some flexibility in the control of forged part dimensions even after die dimensions have been selected. Higher preform ejection temperatures result in greater shrinkage during cooling. Increases in die temperature expand the die cavity and thus increase the size of the forged part. Therefore, if the forgings are undersize for a given set of forging conditions, a lower preform preheat temperature and/or a higher die preheat temperature can be used to produce larger parts. On the other hand, if the forged parts are oversize, the preform preheat temperature could be raised and/or the die temperature lowered to bring the parts to the desired size.

Secondary Operations. In general, the secondary operations applied to conventional components such as plating and peening, may be applied to powder forged components. The most commonly used secondary operations involve deburring, heat treating, and machining.

The powder forged components can require deburring or machining to remove limited amounts of flash formed between the punches and the die. This operation is considerably less extensive than that required for wrought forgings.

The heat treatment of P/M products is the same as that required for conventionally processed materials of similar composition. The most common heat-treating practices involve treatments such as carburizing, quench-and-temper cycles, or continuous-cooling transformations.

The amount of machining required for P/F components is generally less than the amount required for conventional forgings because of the improved dimensional tolerances, shown in Table 4. Standard machining operations can be used to achieve final dimensions and surface finish (Ref 67). One of the main economic benefits of powder forging is the reduced amount of machining required, as illustrated in Fig. 15.

Table 4 Comparison of powder forging with competitive processes

Process	Range of weights		Height-to-diameter ratio	Shape	Material use, %	Surface roughness μm	Quantity required for economical production ^(a)	Cost per unit ^(b)
	kg	lb						
Powder forging	0.1-5	0.22-11	1	No large variations in cross section; openings limited	100	5-15	20,000	200
Precision forging	0.3-5	0.66-11	2	Any; openings limited	80-90	10-20	20,000	200
Cold forging	0.01-35	0.022-77	Not limited	Mostly rotational symmetry	95-100	1-10	5,000	150
Precision casting	0.1-10	0.22-22	Not limited	Any; no limits on openings	70-90	10-30	2,000	100
Sintering	0.01-5	0.022-11	1	No large variation in cross section; openings limited	100	1-30	5,000	100
Drop forging	0.05-	0.11-	Not limited	Any; openings limited	50-70	30-100	1,000	150

(a) For 0.5 kg (1.1 lb) parts.

(b) Sintering = 100%

Fig. 15 Comparison of material used for a conventionally forged reverse idler gear (top) and the equivalent powder forged part (bottom). Material yield in conventional forging is 31%; that for powder forging is 86%. 1 lb = 453.6 g. Source: Ref 61

In general, pore-free P/F materials machine as readily as conventional forgings processed to achieve identical composition, structure, and hardness. Difficulties are encountered, however, if P/F components are machined with the same cutting speeds, feed rates, and tool types as conventional components. These differences in machinability have been related to inclusion types and microporosity (Ref 16, 68). These studies conclude that P/F materials can exhibit equal or greater machinability than wrought steels. Improved machinability can be accomplished by the addition of solid lubricants such as manganese sulfide.

However, the presence of microporosity and low-density noncritical areas in P/F components leads to reduced machinability. The machinability behavior for these areas is similar to that of conventional P/M materials (Ref 69). The overall machinability of a powder forged component may be said to depend on the amount, type, size, shape, and dispersion of inclusions and/or porosity, as well as on the alloy and heat-treated structure.

Powder Forged Steel

W. Brian James, Michael J. McDermott, and Robert A. Powell, Hoeganaes Corporation

Mechanical Properties

Wrought steel bar stock undergoes extensive deformation during cogging and rolling of the original ingot. This creates inclusion stringers and leads to planes of weakness, which affect the ductile failure of the material. The mechanical properties of wrought steels vary considerably according to the direction test pieces are cut from the wrought billet. Powder forged materials, on the other hand, undergo relatively little material deformation, and their mechanical properties have been shown to be relatively isotropic (Ref 70). The directionality of properties in wrought steel is illustrated in Table 5.

Table 5 Comparison of transverse and longitudinal mechanical properties of wrought steels

Material	Specimen orientation	Ultimate tensile strength		Yield strength, 0.2% offset		Impact energy		Fatigue endurance limit		Elongation, %	Reduction of area, %
		MPa	ksi	MPa	ksi	J	ft · lbf	MPa	ksi		
5046	Longitudinal	820	119	585	85	25.5	64

(a) Composition of EN-16: Fe-1.7Mn-0.27Mo.

Mechanical properties of powder forged materials are usually intermediate to the transverse and longitudinal properties of wrought steels. The rotating-bending fatigue properties of powder forged material also have been shown to fall between the longitudinal and transverse properties of wrought steel of the same tensile strength (Ref 74). This is illustrated in Fig. 16.

Fig. 16 Comparison of fatigue resistance of powder forged and wrought materials. Source: Ref 74

While the performance of machined laboratory test pieces follows the intermediate trend described above, in the case of actual components, powder forged parts have been shown to have superior fatigue resistance (Fig. 17). This has generally been attributed not only to the relative mechanical property isotropy of powder forgings but also to their better surface finish and finer grain size.

Fig. 17 Fatigue curves for powder forged and drop forged connecting rods. Source: Ref 75

The present section reviews the mechanical properties of powder forged materials. The data presented represent results obtained on machined standard laboratory test pieces. Data will be reported for four primary materials. The first two material systems are based on prealloyed powders (P/F-4600 and P/F-4200; see the section "Hardenability" in this article). The third material, based on an iron-copper-carbon alloy, was used by Toyota in 1981 to make P/F connecting rods; Ford Motor Company introduced powder forged rods with a similar chemistry in 1986 and powder forged copper-steel connecting rods are also currently used. Mechanical property data are therefore presented for copper and graphite powders mixed with an iron powder base to produce materials that generally contain 2 wt% Cu. Some powder forged components made from plain carbon steel are the fourth and final material for which mechanical property data are presented.

Forging Mode. It is well known that the forging mode has a major effect on the mechanical properties of components. With this in mind, the mechanical property data reported in this section were obtained on specimens that were either hot upset or hot repress forged. The forging modes used to produce billets for mechanical property testing are shown in Fig. 18.

Fig. 18 Forging modes used in production of billets for mechanical testing. Dimensions, given in inches, are average values.

Longitudinal test specimens 10 mm (0.4 in.) in diameter (for tensile and fatigue testing) and 10.8 × 10.8 mm (0.425 × 0.425 in.) square (for impact testing) were then cut from the forged billets. These specimen sizes represent comparable 10 mm (0.4 in.) diam ruling sections used for heat treatment and were the section sizes used unless otherwise noted.

Heat Treatments. There were three heat treatments used in developing the properties of the prealloyed powder forged materials: case carburizing, blank carburizing, and through-hardening (quenching and tempering).

Case carburizing was applied to materials with a nominal core carbon content of 0.20 to 0.25 wt%. Blank carburizing is intended to produce a microstructure similar to that found in the core of case carburized samples. The 0.20 to 0.25 wt% C level results in a core hardness of 45 to 55 HRC.

Quenching and tempering was applied to achieve through-hardened microstructures over a range of forged carbon contents. A low-temperature temper or stress relief at 175 °C (350 °F) resulted in core hardnesses ~55 to 65 HRC for materials with carbon contents of ≥0.4 wt%. In addition, higher-temperature tempers were designed to achieve core hardnesses of 45 to 55 HRC and 25 to 30 HRC in these higher-carbon samples. Details of these heat treatments are given below.

Case Carburizing. Specimens were austenitized for 8 h at 955 °C (1750 °F) in an endothermic gas atmosphere with a dew point of -11 °C (+12 °F). They were then cooled to 830 °C (1525 °F) and stabilized at temperature in an endothermic gas atmosphere with a dew point of +2 °C (+35 °F).

The specimens were quenched in a fast quench rate oil with agitation at a temperature of 65 °C (150 °F). They were then stress relieved at 175 °C (350 °F) for 2 h. This heat treatment resulted in a case depth of ~ 1.52 mm (0.060 in.), with a 1.0 wt% carbon content in the case and a nominal core carbon of 0.25 wt%.

Blank Carburizing. The forged samples were austenitized for 2 h at 955 °C (1750 °F) in a dissociated ammonia and methane atmosphere. They were quenched with agitation in a fast quench rate oil at 65 °C (150 °F). The samples were reaustenitized at 845 °C (1550 °F) for 30 min in a dissociated ammonia and methane atmosphere, followed by oil quenching with agitation in oil held at 65 °C (150 °F). They were then stress relieved at 175 °C (350 °F) for 2 h in a nitrogen atmosphere.

Through-hardening. This quench and temper heat treatment consisted of austenitizing the specimens for 1 h at 955 °C (1750 °F) in a dissociated ammonia and methane atmosphere, followed by quenching with agitation in a fast quench rate oil at 65 °C (150 °F). The specimens were reaustenitized at 845 °C (1550 °F) for 30 min in a dissociated ammonia and methane atmosphere, followed by quenching with agitation in oil at 65 °C (150 °F). They were stress relieved for 1 h at 175 °C (350 °F) in a nitrogen atmosphere or tempered at the various temperatures listed in the tables. This procedure resulted in a uniform microstructure throughout the cross section.

Hardenability. Jominy hardenability curves are presented in Fig. 19 for the P/F-4600, P/F-4200, and iron-copper-carbon alloys. Testing was carried out according to ASTM A 255. Specimens were machined from upset forged billets that had been sintered at 1120 °C (2050 °F) in dissociated ammonia.

Fig. 19 Jominy hardenability curves for (a) P/F-4600, (b) P/F-2000, and (c) iron-copper-carbon materials at various forged-carbon levels. Vickers hardness was determined at a 30 kgf load.

Tempering Response. Tempering curves (core hardness versus carbon content and tempering temperature) are presented in Fig. 20 for P/F-4200 and P/F-4600. The curves for P/F-4600 cover ruling sections of 10 mm (0.40 in.) to 25.4 mm (1.0 in.).

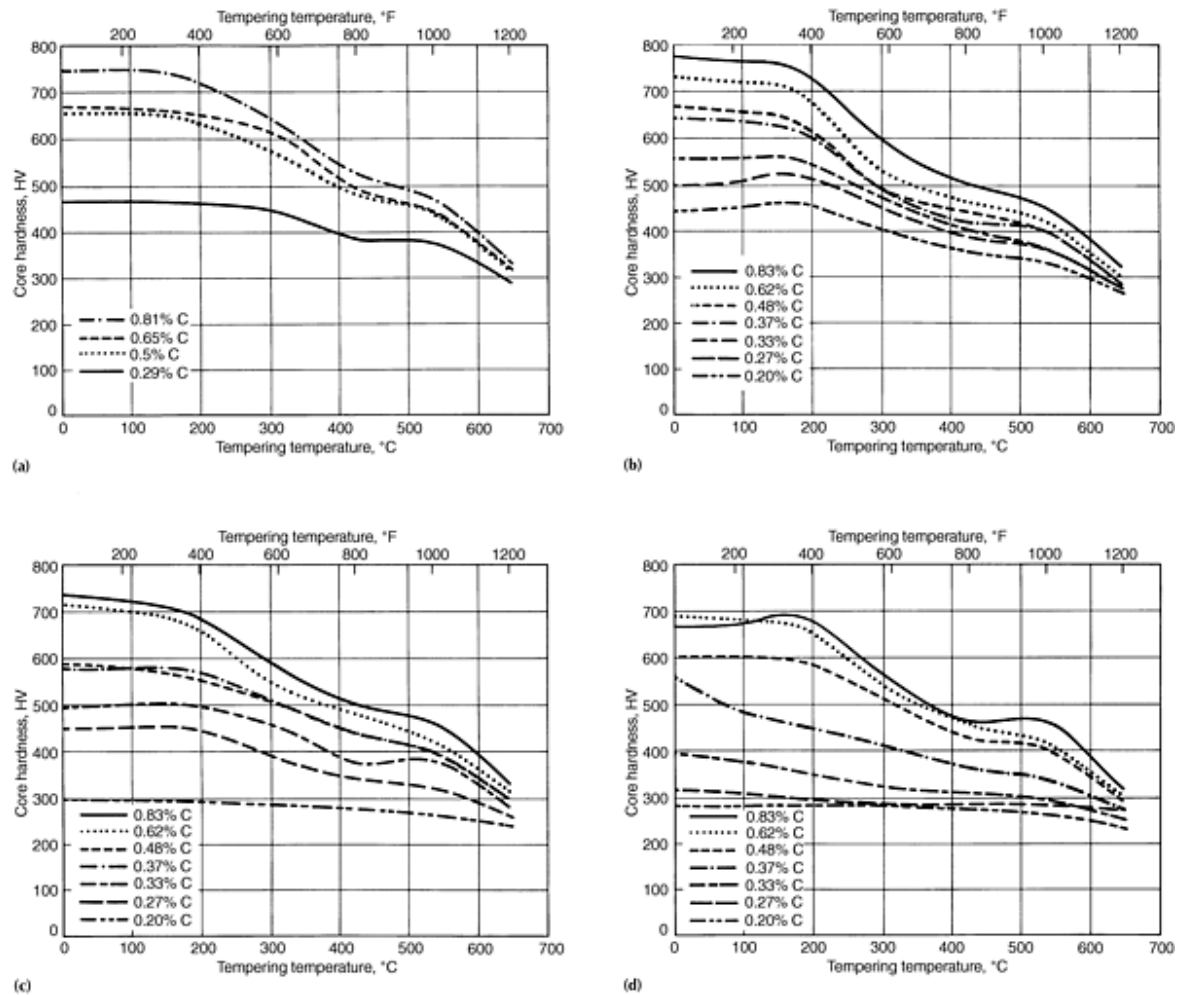

Fig. 20 Effect of tempering temperature and carbon content on the core hardness of (a) P/F-2000 for a ruling section of 10 mm (0.40 in.), and of P/F-4600 materials for ruling sections of (b) 10 mm (0.40 in.), (c) 19 mm (0.75 in.), and (d) 25.4 mm (1.0 in.)

Tensile, Impact, and Fatigue Properties. Tensile properties were determined on test pieces with a gage length of 25.4 mm (1 in.) and a gage diameter of 6.35 mm (0.25 in.). Testing was carried out according to ASTM E 8 using a crosshead speed of 0.5 mm/min (0.02 in./min). Room-temperature impact testing was carried out on standard Charpy V-notch specimens according to ASTM E 23. Rotating-bending fatigue (RBF) testing was performed using single-load, cantilever, rotating fatigue testers. Dimensions of the RBF test specimen are shown in Fig. 21.

Fig. 21 Dimensions (in inches) of rotating-bending fatigue (RBF) test specimens

The tensile, impact, and fatigue data for the various materials are summarized in Tables 6, 7, and 8, and Fig. 22 and 23.

Fig. 22 Mechanical properties versus carbon content for iron-carbon alloys. Source: Ref 76

Fig. 23 Effect of sulfur and carbon on the ultimate tensile strength of iron-copper-carbon alloys. Samples were upset forged and forced-air cooled.

The iron-copper-carbon alloys were either still-air cooled or forced-air cooled from the austenitizing temperature of 845 °C (1550 °F). Cooling rates for these treatments are shown in Fig. 24. The austenitizing temperature influences core hardness. These iron-copper-carbon alloys are often used with manganese sulfide additions for enhanced machinability. The tensile, impact, and fatigue properties for a sample with a 0.35 wt% manganese sulfide addition are compared with a material without sulfide additions in Table 9. The results obtained for a sulfurized powder sample are included for comparison. The tensile properties for iron-copper-carbon alloys with a range of forged carbon content are summarized in Fig. 23. Data from the samples with manganese sulfide and sulfurized powders are included for comparison. The manganese sulfide addition had little influence on tensile strength, whereas the sulfurization process degraded tensile properties.

Table 9 Mechanical property and fatigue data for iron-copper-carbon alloys with sulfur additions

Addition	Carbon, wt%	Oxygen, ppm	Sulfur, wt%	Ultimate tensile strength		0.2% offset yield strength		Elongation in 25 mm (1 in.), %	Reduction of area, %	Room- temperature Charpy V-notch impact energy		Core hardness, HV30	Fatigue endurance limit		Ratio of fatigue endurance to tensile strength

Fig. 24 Cooling rates used for iron-copper-carbon alloys

Powder forged copper steels with tensile strengths ranging from 825 to 950 MPa and fatigue endurance limits from 186 to 292 MPa have been reported in the literature (Ref 77, 78, 79, 80, 81, 82). Marra (Ref 79) conducted fatigue testing of powder forged connecting rods made from an admixed material with 2 wt% Cu, 0.60 wt% C, and 0.35 wt% MnS. The rods were developed for a General Motors V8 engine. The P/F rods showed improved fatigue life compared with that of wrought rods (AISI-SAE 1141) at an elevated test load.

Compressive Yield Strength. The 0.2% offset compressive yield strengths for P/F-4600 at various forged carbon levels and after different heat treatments are summarized in Table 10. A comparison of 0.2% offset tensile yield strength with the compressive yield strength for P/F-4600 with a range of carbon contents is given in Fig. 25 for samples stress relieved at 175 °C (350 °F).

Table 10 Compressive yield strengths of P/F-4600 materials

Forged carbon content, wt %	Forged oxygen content, ppm	Heat treatment	Compressive yield strength (0.2 % offset)	
			MPa	ksi
0.22	460	Stress relieved at 175 °C (350 °F)	1240	180

Rolling-Contact Fatigue. Powder forged materials have been used in bearing applications. Rolling-contact fatigue testing is an accelerated bearing test used to rank materials with respect to potential performance in bearing applications. Rolling-contact fatigue testing of both case carburized and through-hardened P/F-4600 and P/F-2000 materials was carried out using ball/rod testers according to the procedure described in Ref 83. Weibull analysis data are summarized in Table 11.

Effect of Porosity on Mechanical Properties. The mechanical property data summarized in the previous sections are related to either hot repress or hot upset forged pore-free material. The general effect of density on mechanical properties was illustrated in Fig. 2 and the properties of material incompletely densified because of forging at 870 °C (1600 °F) were presented in Table 3. The tensile and impact properties of P/F-4600 with two levels of residual porosity are summarized in Fig. 26 and 27. In one instance, the material was at a density of 7.84 g/cm³ and had a background of very fine porosity (Ref 84). The other series of samples had been purposely forged to a density of 7.7 g/cm³ (Ref 85). The performance of these materials is compared with that for pore-free samples at two levels of core hardness: 25 to 30 HRC (Fig. 26) and 45 to 50 HRC (Fig. 27). At the lower hardness, porosity has no effect on tensile strength, but even fine microporosity significantly reduces tensile ductility and impact energy. Tensile ductility at the higher core hardness is slightly influenced by the fine microporosity, and is significantly reduced for the material with a density of 7.7 g/cm³. The presence of porosity diminishes impact performance.

Fig. 26 Influence of density on the tensile and impact properties of P/F-4600 materials with core hardnesses of 25 to 30 HRC and 28 to 31 HRC. (a) Ultimate tensile strength. (b) Percent reduction of area. (c) Percent elongation. (d) Room-temperature impact energy. See also Fig. 27. • (Ref 78); △ (Ref 79)

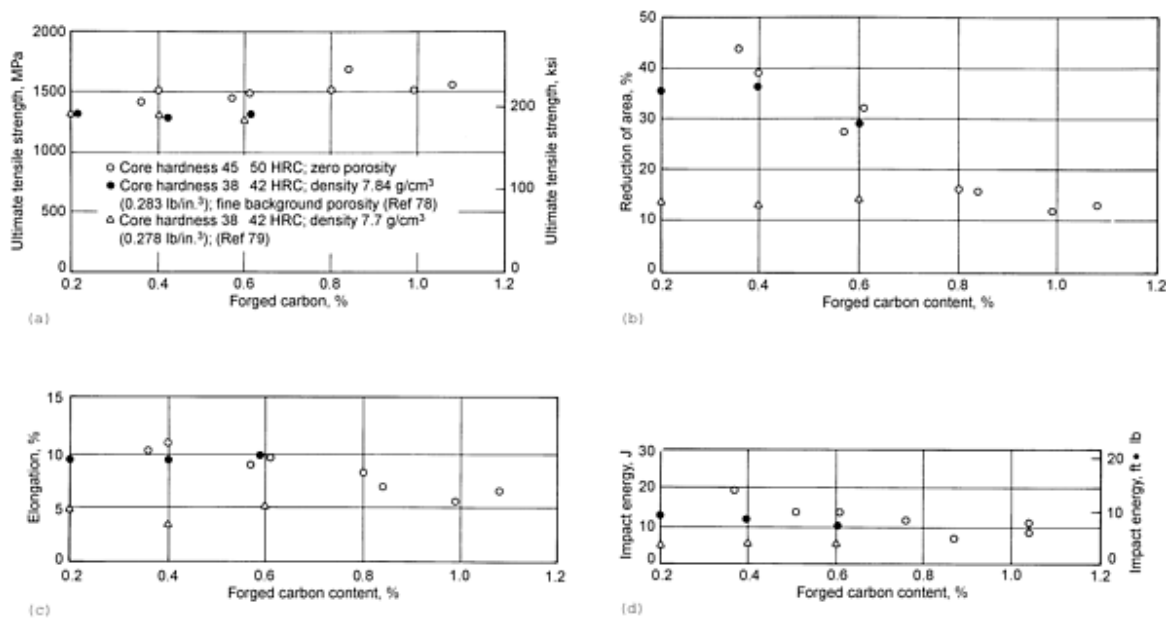

Fig. 27 Influence of density on the tensile and impact properties of P/F-4600 materials with core hardnesses of 38 to 42 HRC and 45 to 50 HRC. (a) Ultimate tensile strength. (b) Percent reduction of area. (c) Percent elongation. (d) Room-temperature impact energy. See also Fig. 26. • (Ref 78); △ (Ref 79)

Recent studies published by Mashl and Smith have shown that, for quench-hardened and tempered impact forged P/F-4650 materials, residual porosity of as little as 0.1% can cause a significant decrease in tensile ductility (Ref 86). High tensile strength and ductility (1800 MPa and 40% reduction of area) have been achieved in P/F-4645 when the forged oxygen and sulfur contents are at very low levels (<100 ppm oxygen, and sulfur \sim 0.005 wt%) (Ref 87). Both tensile ductility and low cycle fatigue life are adversely affected by the presence of sulfide (MnS) and oxide inclusions (Ref 88). In a separate study (Ref 89), manganese sulfide added to P/F-4650 to serve as a machinability enhancer, was found to be detrimental to the ductility and low cycle fatigue life of the material. Strength and ductility levels covered by the study ranged from 2070 MPa with 33% reduction in area for quenched and tempered material, to 690 MPa with 45% reduction in area for a furnace cooled sample.

Quality Assurance for P/F Parts

Many of the quality assurance tests applied to wrought parts are similar to those used for powder forged parts. ASTM specification B 848 covers material designations, chemical composition limits, and appropriate test methods for powder forged parts. Material designations are listed in Table 1 and chemical requirements are summarized in Table 12. Among the parameters specified are part dimensions, surface finish, magnetic particle inspection, composition, density, metallographic analysis, and nondestructive testing. These are discussed below.

Table 12 Chemical composition requirements for powder forged parts (wt%)

Element	P/F-10xx	P/F-10Cxx	P/F-11xx	P/F-11Cxx	P/F-42xx	P/F-46xx	P/F-44xx	P/F-49xx

- (a) Covers manganese sulfide additions of from 0.3 to 0.5 wt%. The manganese content in solution is similar to P/F-10xx or P/F-10Cxx, i.e., 0.10 to 0.25 wt%.
- (b) Carbon content specified by the purchaser.
- (c) When required, maximum oxygen content shall conform to the amount specified by the purchaser.

Part Dimensions and Surface Finish. Typical tolerances for powder forged parts are summarized in Table 13. The as-forged surface finish of a powder forged part is directly related to the surface finish of the forging tool. Surface finish is generally better than 0.8 μm (32 $\mu\text{in.}$), which is better than that obtained on wrought forged parts. This good surface finish is beneficial to the fatigue performance of P/F parts.

Table 13 Typical tolerances for powder forged parts

Dimension or characteristic	Description	Typical tolerance		Minimum tolerance	
		mm/mm	in./in.	mm	in.
<i>a</i>	Linear dimension perpendicular to the press axis	0.0025	0.0025	0.08	0.003
<i>b</i>	Linear dimensions parallel to the press axis	± 0.25	± 0.10	0.20	0.008
<i>c</i>	Concentricity of holes to external dimensions	0.10	0.004
<i>d</i>	Surface finish	Normally better than $0.8 \mu\text{m}$ ($32 \mu\text{in.}$)	

Source: Ref 90

Magnetic particle inspection is used to detect surface blemishes such as cracks and laps.

Composition. Parts are generally designed to a specified composition. The forged carbon and oxygen contents are of particular interest. The specified carbon level is required to achieve the desired heat treatment response, and forged oxygen levels have a significant influence on dynamic properties (Fig. 28).

Fig. 28 Room-temperature impact energy as a function of forged oxygen content for various powder forged alloys. Heat treatments and hardnesses are indicated on the curves. Source: Ref 91

Density. Sectional density measurements are taken to ensure that sufficient densification has been achieved in critical areas. Displacement density checks carried out per ASTM B 311 are generally supplemented by microstructural examination to

assess the residual porosity level. Parts may be specified to have a higher density in particular regions than is necessary in less critical sections of the same component.

For a given level of porosity, the measured density will depend on the chemistry, thermomechanical condition, and microstructure of the sample. The same sample will have a lower density in the quench-hardened and stress-relieved condition than it will after it has been fully annealed. This is extremely important to remember when establishing density levels in connection with part specifications. Empirical attempts to estimate the density of powder forged materials have been proposed by Cundill (Ref 92). More recently, however, methods for calculating the pore-free density of the alpha iron plus iron carbide and the virgin martensitic microstructures of plain-carbon and low-alloy steels have been developed by Smith (Ref 93). The calculations are based primarily on fundamental considerations of the crystal unit cell volume and the mass of each phase in the steel; these account for measured or estimated levels and types of nonmetallic inclusions. The calculation methods do not account for retained austenite or the presence of alloy carbides. The calculations also underestimate the pore-free densities of P/F materials containing admixed copper if significant compositional gradients exist in the material.

Smith and Mashl (Ref 94) compared the measured and calculated values for the density of powder forged steels. Their work showed that a fully virgin martensitic microstructure is difficult to obtain even in small sections that have been very rapidly quenched. They concluded that the alpha iron plus iron carbide ($\alpha + \text{Fe}_3\text{C}$) microstructure, which can be produced by slow cooling from austenite, or by extended spheroidization of a martensitic microstructure, should be used to assess the residual porosity level in P/F materials.

Metallographic Analysis. Powder forged parts are subjected to extensive metallographic evaluation. The primary parameters of interest include those discussed below.

The extent of surface decarburization permitted in a forged part will generally be specified. The depth of decarburization may be estimated by metallographic examination, but it is best quantified using microhardness measurements as described in ASTM E 1077.

Surface finger oxides are defined as oxides that follow prior particle boundaries into the forged part from the surface and cannot be removed by physical means such as rotary tumbling. An example of surface finger oxides is shown in Fig. 29. Metallographic techniques are used to determine the maximum depth of surface finger oxide penetration in accordance with ASTM method B 797.

Fig. 29 Surface finger oxides (arrows at upper right) and interparticle oxide networks (arrow near lower left) in a powder forged material

Interparticle oxides follow prior particle boundaries. They can sometimes form a continuous three-dimensional network but more often will, in a two-dimensional plane of polish, appear to be discontinuous. An example is presented in Fig. 29. Metallographic techniques are used to detect their presence (ASTM B 797).

Most parts have what can be defined as functionally critical areas. The fabricator and end-user decide upon the maximum permissible depth of surface finger oxide penetration and whether oxide networks can be tolerated in critical regions. These decisions are then specified on the part drawing or in the purchase agreement as outlined in ASTM specification B 848.

The microstructure of a powder forged part depends on the thermal treatment applied after the forged part has been ejected from the die cavity. Most parts are carburized, quenched and stress relieved, or quenched and tempered. Other heat treatments used on wrought steels can also be applied to powder forged materials.

Alloyed or unalloyed iron contamination in powder forged parts can be quantified by ASTM method B 795 by using the etching procedure described in the section "Material Considerations" in this article.

The nonmetallic inclusion level in a powder forged part may also be quantified using the image analysis technique described in the section "Material Considerations." However, if the section of a component selected for inclusion assessment is not pore-free, image analysis procedures are not applicable (pores and oxide inclusions have similar gray level characteristics for feature detection). In fact, the presence of porosity makes it difficult for even visual quantitative determination of inclusion size. ASTM method B 796 is not applicable.

Nondestructive Testing. Although metallographic assessment of powder forged parts is common, it is also useful to have a nondestructive method for evaluating the microstructural integrity of components. It has been demonstrated that this can be achieved with a magnetic bridge comparator.

Magnetic bridge sorting can be used to compare the eddy currents developed within a forging placed in a coil that carries an alternating current with the eddy currents produced in a randomly selected reference sample from the same forging batch (Ref 21). Differences are indicated by the displacement of a light spot from its balanced position in the center of the measuring screen of the system. If the part being tested is similar to the reference sample, the light spot returns to the center of the screen. The screen can be arbitrarily divided into a number of zones, as illustrated in Fig. 30. Testing of randomly selected samples can then be used to establish a typical frequency distribution of components within a forged batch relative to the reference sample.

Fig. 30 Sorting grid categories arbitrarily assigned to the measuring screen of the magnetic bridge comparator. See text for details.

Once the frequency distribution has been established for a limited number of components within a forging batch, selected components that are representative of several zones on the screen are subjected to metallographic examination. Limited metallographic testing thus can be used to check the metallurgical integrity of parts from various zones.

Once acceptable zones have been defined, the entire forging batch can be assessed by means of the magnetic bridge. Components in unacceptable categories are automatically rejected. Experience with this technique minimizes the number of parts requiring sectioning for metallographic examination. Core hardness, surface decarburization, surface oxide penetration, and porosity can also be evaluated using this technique.

Magnetic bridge sorting, an adaptation of the technique used to test drop forged parts, enables potentially defective components to be eliminated from a batch of forgings. It also can be used to provide 100% inspection of the metallurgical integrity of a forging batch.

Applications of Powder-Forged Parts

Previous sections in this article compared powder forging and drop forging and illustrated the range of mechanical property performance that can be achieved in powder forged material. The various approaches to the powder forging process were reviewed, as was the influence of process parameters on the metallurgical integrity of the forged parts. The present section concentrates on examples of powder forged components and highlights some of the reasons for selecting powder forged parts over those made by competing forming methods.

Example 1: Converter Clutch Cam.

The automotive industry is the principal user of powder forged parts, and components for automatic transmissions represent the major area of application. One of the earliest powder forgings used in such an application is the converter clutch cam (Fig. 31). The primary reason powder forging was chosen over competitive processes was that it reduced manufacturing costs by 58%, compared with the conventional process of machining a forged gear blank. This cost saving resulted from substantially lower machining cost and lower total energy use.

Fig. 31 Powder forged converter clutch cam used in an automotive automatic transmission. Courtesy of Precision Forged Products Division, Borg Warner Corp.

Powder forged cams are made from a water-atomized steel powder (P/F-4200) containing 0.6 wt% Mo, 0.5 wt% Ni, 0.3 wt% Mn, and 0.3 wt% graphite. Preforms weighing 0.33 kg (0.73 lb) are compacted to a density of 6.8 g/cm³. The preforms are sintered at 1120 °C (2050 °F) in an endothermic gas atmosphere with a +2 °C (+35 °F) dew point. The sintered preforms are graphite coated before being induction heated and forged to near full density (<0.2% porosity) using both axial and lateral flow. After forging, the face of the converter clutch cam is ground, carburized to a depth of 1.78 mm (0.070 in.), and surface hardened by means of induction. The part requires a high density to withstand the high Hertzian stress the inner cam surface experiences in service. Machining requires only one step on the P/F cam; seven machining operations were required for the conventionally processed part. Production of P/F cams began in 1971. Since then, well over 30 million P/F converter clutch cams have been made without a single service failure.

Example 2: Inner Cam/Race.

A part that illustrates the complex shapes that can be formed on both the inner and outer surfaces of a powder forged component is the inner cam/race shown in Fig. 32 (Ref 95). The part is the central member in an automotive automatic transmission torque converter centrifugal lock-up clutch.

Fig. 32 Powder forged inner cam/race for an automotive automatic transmission. Courtesy of Precision Forged Products Division, Borg Warner Corp.

The inner cam/race is forged to a minimum density of 7.82 g/cm^3 from a P/F-4662 material. The part has a minimum quenched and stress-relieved hardness of 58 HRC and a tensile strength of 2070 MPa (300 ksi). The application imposes high stresses on the cams and splines.

Example 3: Internal Ring Gear.

The powder forged internal ring gear shown in Fig. 33 is used in automatic transmissions for trucks with a maximum gross vehicle weight of 22,700 kg (50,000 lb) (Ref 96). The gear transmits $1355 \text{ N} \cdot \text{m}$ ($1000 \text{ ft} \cdot \text{lbf}$) of torque through the gear and spline teeth.

Fig. 33 Powder forged internal ring gear used in automatic transmission for trucks of up to 22,700 kg (50,000 lb) gross vehicle weight. Courtesy of Precision Forged Products Division, Borg Warner Corp.

Originally, the gear was produced by forging an AISI 5140M tubing blank. The conventionally forged blank required rough machining, gear tooth shaping, spline machining, core heat treating, carburizing, and deburring. The only secondary operations required on the powder forged part are surface grinding, hard turning, shot blasting, and vibratory tumbling.

The P/F-4618 ring gear is produced to a minimum density of 7.82 g/cm^3 . The part is selectively carburized using a proprietary process (Ref 97, 98, 99) and quench hardened. Minimum surface hardness is 57 HRC (2070 MPa, or 300 ksi, ultimate tensile strength). The internal gear teeth are produced to AGMA Class 7 tolerances.

Example 4: Powder Forged Tapered Bearing Race.

The use of powder forging for production of tapered roller bearing races has resulted in considerable cost savings. The economy of the P/F process results from material savings, elimination of machining, energy savings from the elimination of subsequent carburizing, and raw material inventory reduction.

In some cases, up to 80% of the material is lost to machining when a bearing race is produced from bar stock. Material savings resulting from powder forging average 50% on bearing cup and cone production. In the example shown in Fig. 34, a material savings of 1.25 kg (2.74 lb) is realized using powder forging; nearly 62% of the feedstock is wasted when this component is machined from hot rolled tube stock.

Fig. 34 Raw material utilization in the production of a tapered roller bearing race. (a) Produced from hot rolled tube stock. (b) Powder forged from preform. Source: Ref 100

In addition to the cost savings, the fatigue life of powder forged cups and cones was found to be greater than that of similar cups produced from wrought bearing steels (Fig. 35).

Fig. 35 Weibull plots of L_{10} life of P/F bearing races compared with L_{10} of wrought and machined races. (a) Cups. (b) Cones. Source: Ref 101

Example 5: Powder Forged Connecting Rods.

Connecting rods were among the components selected for a number of powder forging development programs in the 1960s (Ref 5, 7, 18, 76, 102, 103, 104, 105). However, it was not until 1976 that the first powder forged connecting rod was produced commercially. This was the connecting rod for the Porsche 928 V-8 engine (Fig. 36a).

Fig. 36 Powder forged connecting rods. (a) Rod for Porsche 928 V-8 engine. Note reduced size of balance pads. Courtesy of Powder Forging Division, GKN Forgings. (b) Rod for Toyota 1.9 L engine; balance pads are completely eliminated.

The powder forged connecting rod for the Porsche 928 engine was made from a water-atomized low-alloy steel powder (0.3 to 0.4 wt% Mn, 0.1 to 0.25 wt% Cr, 0.2 to 0.3 wt% Ni, and 0.25 to 0.35 wt% Mo) to which graphite was added to give a forged carbon content of 0.35 to 0.45 wt%. The forgings were oil quenched and tempered to a core hardness of 28 HRC (ultimate tensile strength of 835 to 960 MPa, or 121 to 139 ksi), followed by shot peening to a surface finish of 11 to 13 on the Almen scale.

The preform was designed such that the powder forged component had <0.2% porosity in the critical web region. The powder forged connecting rod had considerably better fatigue properties than did conventional drop forged rods. Its weight control was good enough to allow a reduction in the size of the balance pads (Fig. 36a), resulting in ~10% weight saving (it weighed ~1 kg, or 2 lb). Powder forged connecting rods were subsequently used in both the Porsche 928 and 944 engines.

The first high-volume commercialization of powder forged connecting rods was in the 1.9 L Toyota Camry engine. In this design, the balance pads were completely eliminated (Fig. 36b). Despite the publication of the results of development trials in 1972 (Ref 104), it was not until the summer of 1981 that production rods were introduced (Ref 9, 77).

Toyota selected a copper steel (Fe-0.55 wt% C-2 wt% Cu) based on a water-atomized iron powder to replace conventional forgings, which had been made from a quenched and tempered 10L55 free-machining steel. The preform, which has a preshaped partial I-beam web section, has an average green density of 6.5 g/cm³. The preform shape is such that forging is predominantly in the repressing mode. However, some lateral flow does take place where required in critical regions, such as the web.

Preforms are sintered for 20 min at 1150 °C (2100 °F) in an endothermic gas atmosphere in a specially designed rotary hearth furnace. During sintering, the preforms are supported on flat, ceramic plates. The preforms are allowed to stabilize at ~1010 °C (1850 °F) before closed-die forging.

Exposure of the preform to the atmosphere during transfer to the forging dies is limited to 4 to 5 s. The forging tooling is illustrated in Fig. 37. An ion nitriding treatment is applied to the punches and dies in the regions at which forging deformation occurs (Ref 9). The connecting rods are forged at the rate of 10 per min, and tool lives of over 100,000 pieces have been reported (Ref 106).

Fig. 37 Tooling used for powder forging of the Toyota connecting rod. Source: Ref 77

The forged rods are subjected to a thermal treatment after forging. This results in a ferrite/pearlite microstructure with a core hardness of 240 to 300 HV (30 kgf load). Subsequent operations include burr removal, shot peening, straightening, sizing, magnetic particle inspection, and finish machining.

Savings in material and energy are substantial for the powder forged rods (Ref 9). Billet weight for conventional forging is 1.2 kg (2.65 lb); the powder forging preform weighs 0.7 kg (1.54 lb) and requires little machining. In addition to the benefits in process economics, the variability in fatigue performance for the powder forged rods is reported to be half that of conventionally forged parts (Ref 77).

Good dimensional tolerance and precise control of part mass ($\pm 0.5\%$) require fewer machining operations for powder forged connecting rods compared with their drop forged or cast counterparts. In the case of P/F rods, a recent development involves the fracture splitting of the crank end cap from the rest of the connecting rod (Ref 107, 108, 109, 110, 111, 112). Two approaches are used to accomplish this. In the technique patented by Sintermetallwerke Krebsöge (Fig. 38) (Ref 108), a V-shaped groove is shaped during compaction of the forging preforms and this groove is closed to form a short crack during the forging operation. This controlled defect initiates splitting of the end cap during the fracture splitting process. In an alternative procedure, used by Ford Motor Company, a notch is broached in the powder forged rod to facilitate splitting of the cap (Ref 110, 111, 112). A comparison of the conventional and fracture splitting methods is shown in Table 14.

Table 14 Comparison of connecting rod production methods

Conventional method	Fracture splitting method
Alignment	Obsolete
Machining of outer contours	Obsolete
Deburring of outer contours	Obsolete
Preliminary grinding of side faces	Obsolete
Broaching of small and big end bearings	Obsolete
Machining of cap bolt bores	Machining of cap bolt bores
Drilling of oil bore	Drilling of oil bore
Machining of bolt head and nut seats	Obsolete
Separation of cap from rod	Fracture splitting
Grinding of rod/cap contact surfaces	Obsolete
Insertion of bolt sleeves	Obsolete
Assembly of cap and rod	Assembly of cap and rod
Finish-grinding of side faces	Finish-grinding of side faces

Honing of big end bearing	Honing of big end bearing
Insertion of small end bearing bush	Insertion of small end bearing bush
Insertion of big end bearing shells	Insertion of big end bearing shells
Machining of balance pads	Obsolete
Sorting according to weight	Obsolete

Fig. 38 Fracture splitting process used by GKN (Krebsöge). Source: Ref 108

GKN, Krebsöge of Radevermwald, Germany produces powder forged connecting rods used in the 2-cylinder engine for the new high performance BMW motorcycle-R1100 RS (Ref 107). The rods are made from the same prealloyed, low-alloy steel powder that was used to produce the Porsche connecting rods (Astaloy D). The material used to make the rods has a tensile

strength of 1000 MPa, elongation of 11%, Young's modulus of 200 GPa, and a fatigue endurance limit (RBF) of 340 MPa. Krebsöge is also producing P/F connecting rods for a BMW V8 engine.

Chrysler Corp. is currently using powder forged connecting rods in new 2.0 and 2.4 L four-cylinder engines (Ref 113) while General Motors Corp. is using P/F rods in the 4.6 L V8 Northstar engine (Ref 114) and for 5.0 and 5.7 L V8 engines.

An interesting presentation reviewing the prospects for the production of P/M connecting rods was made during the international P/M conference in Paris (Ref 115). The authors concluded that pressed and sintered rods are a viable manufacturing option.

The results of a joint study by Ford and Krebsöge are summarized in Table 15 (Ref 107). For various connecting rod manufacturing processes, the study compared the mass of the connecting rods produced as well as the relative price of a finished rod. The study indicates that while aluminum or carbon fiber reinforced plastic connecting rods are attractive from the perspective of reduced mass they are currently too expensive compared with cast, drop forged, or powder forged rods. P/M rods appear to offer some promise. However, in order to match fatigue response, the P/M rods may not offer the same potential for reducing mass as that offered by the powder forged rods.

Table 15 Improvements in the relative cost and the mass of connecting rods by various processes

Process/material	1987	1988	1989	1990	1991	1992
Casting						
Cost, %^(a)	100	90
Weight, g	540	540
Drop-forging						
Cost, %^(a)	120	120	...	120
Weight, g	580	550	...	500
Powder forging						
Cost, %^(a)	130	120	100	...	80	...
Weight, g	515	480	460	...	440	...
Conventional sintering						
Cost, %^(a)	130	...	100	...	80	...
Weight, g	650	...	600	...	580	...
Aluminum						
Cost, %^(a)	500	300
Weight, g	300	280
Carbon fiber composite						
Cost, %^(a)	800	400
Weight, g	280	260

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Introduction

HIGH-TEMPERATURE SINTERING of ferrous components continues to be important in the P/M industry. Improvements in both production rates and properties are possible as sintering temperatures increases above 1120 °C (2050 °F). Rounding of the porosity results in increased strengths, especially impact strength. Higher diffusion rates also increase the strength and hardenability of admixed powder compositions. The greater oxide reduction that occurs at higher temperatures proves valuable in powder forging and other applications.

The specific benefits of high-temperature sintering as applied to ferrous P/M products can be categorized as follows:

- Improved mechanical properties
- Improved physical properties
- Development of liquid phase
- Ability to sinter active elements (Cr, Mn) in alloy steels

These four advantages of high-temperature sintering are discussed in this article for various ferrous P/M materials. A brief discussion of sintering stages and effects is also included.

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Sintering Stages and Effects

During the sintering process a wide variety of physical, chemical and metallurgical phenomena occurs within the mass of metal powder particles. These effects are influenced by the sintering conditions (time, temperature, atmosphere), as well as the chemical composition of the powder mass. Because most of these phenomena are directly related to time and temperature, they have been listed in two categories. The first group primarily is associated with the early stages of sintering (conventional sintering practices), and the second group is related to the more advanced stages of sintering, typical of high-temperature methods.

Early stages of sintering (conventional) include the following mechanisms:

- *Homogenization:* The as-cast, dendritic structure of the atomized particles is removed and microsegregation within the particles is eliminated; diffusion between powder particles begins to occur.
- *Alloying:* As the diffusion process continues, admixed additives begin to form alloyed structures with the base ferrous particles. For species such as carbon, this takes place early into the sintering process; for elements such as nickel or molybdenum, diffusion is much slower and takes longer times and higher temperatures to achieve a reasonable level of homogeneity.

- *Removal of gases/oxides:* Chemical reactions between the sintering atmosphere or admixed additives such as graphite and the surface oxides on the metal particles also begins early in the sintering cycle. This breakdown of oxides and removal of adsorbed gases cleanses the metal particle surfaces and promotes the diffusion process.
- *Particle bonding:* The formation of solid bridges or necks between individual or clusters of powder particles is the critical result of the early stages of sintering. These particle bonds give the powder mass integrity and mechanical strength.

Advanced stages of sintering (high temperature) influence several important characteristics, such as:

- *Densification:* As the sintering process continues at higher temperatures, the inherent porosity in the powder mass is reduced as pores are eliminated by bulk diffusion to grain boundaries. This reduction in the amount of porosity results in an increase in the density of the powder compact.
- *Porosity shape:* The remaining pores in the P/M structure lose their angular, irregular nature and become smooth, tending toward perfect spheres, as the sintering temperature increases.
- *Grain growth:* The individual powder particles lose their identity completely as grain boundaries move across prior particle boundaries. Larger grains replace the original fine particle structure.
- *Liquid phase:* Depending on the chemical constituents in the powder mass and the sintering temperature, a transient or permanent liquid phase may be formed. This liquid phase will accelerate particle rearrangement and diffusion, thereby aiding densification and pore elimination. For some additives, such as copper and phosphorus, liquid phase sintering will occur at conventional temperatures, while for silicon iron and the tool steels, high-temperature sintering is required. The phenomena attributed to the early stages of sintering will continue during high-temperature sintering. Thus a greater number and more complete particle bonding, as well as more homogeneous alloying, will occur during the advanced stages of sintering than found during the early stages.

The phenomenological changes that occur during sintering, are shown in Fig. 1 (a-d) for the microstructures of an austenitic stainless steel. Figure 1(a) shows the microstructure of the original compacted powder particles. The dendritic pattern in these particles is clearly seen. After sintering for 5 min at 1066 °C (1950 °F) (Fig. 1b), the cored dendritic structure is still visible, but the particles already show signs of homogenization. The structure after 30 min at 1121 °C (2050 °F) shown in Fig. 1(c), finds homogenization almost complete and particle-to particle bonding beginning to occur. Sintering for 2 h at 1316 °C (2400 °F) (Fig. 1d) produces a completely homogeneous structure, spheroidized porosity, and considerable grain growth. The original particle boundaries have completely disappeared with the formation of a single-phase austenitic structure, peppered with annealing twins.

Effect on Properties. Figure 2 illustrates the effect of sintering temperature on several physical and mechanical properties of the P/M compact (Ref 1). Although somewhat subjective in nature, the general trends are quite evident. As the degree of sintering improves, as indicated by a higher sintering temperature, the properties of the material also improve. The graph also demonstrates that the sensitivity of each of these properties to the sintering temperature can be quite different. The dynamic properties, such as fatigue and impact strength, are more sensitive to the sintering process than conductivity or mechanical strength.

Fig. 2 The variation in compact properties with the degree of sintering as represented by the sintering temperature

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Improved Mechanical Properties

As sintering temperatures are increased, the mechanical properties of ferrous P/M materials will improve due to more complete interparticle bonding, greater diffusion of alloying elements, and, to some extent, increased densification. Unfortunately, the deleterious effects of grain growth can negate the improvements from homogenization and densification if the grain size gets too large. In addition, the higher sintered density has been shown to be a more significant factor for improving dynamic properties than high-temperature sintering alone (Ref 2, 3). A comparison of conventional versus high-temperature sintering for four P/M steels will describe these effects further.

Nickel Steel (FN-0205/FN-0208). The mechanical properties of two standard nickel steel premixes, sintered at 1121 and 1260 °C (2050 and 2300 °F), are provided in Table 1 (Ref 4). Conventional sintering was performed in a nitrogen-base atmosphere belt furnace, while the high-temperature sintering used a nitrogen backfilled vacuum furnace. Tensile and yield strength showed a marked increase from the high-temperature sinter process, with the elongation and impact energy at least doubling for both materials. Because the sintered density of the belt-sintered samples was not reported but can be estimated at nearly equal the green density of 7.2g/cm³, improvements in mechanical properties are due mainly to more homogeneous distribution of the nickel and better particle bonding rather than just density increase alone.

Copper Steels. The data for three copper steels (Ref 5, 6, 7) listed in Table 2 does not show the significant improvements realized with the nickel steels. This improvement can be attributed to the liquid phase that has already formed when the copper melts at conventional sintering conditions; only modest improvements can be expected at the higher sintering temperatures. Note, however, the 70% increase in impact energy for both the Fe-2Cu-2.5Ni and Fe-3Cu materials when high temperature sintered. Fatigue values followed the small increase in tensile strength and remained close to 36% of the ultimate tensile strength, whether sintered conventionally or at higher temperatures.

Partially Prealloyed Steels (Distaloy). High-temperature sintering does not appear to offer much improvement for the Distaloy materials (Ref 2, 3, 5). The data in Table 3, taken from two Hoeganaes investigators, finds only a 10 to 20% increase in strength and no improvement in elongation, impact energy, or fatigue properties. This has been attributed to the greater chemical homogeneity of the nickel in the high-temperature sintered material, leaving fewer nickel-rich areas as sites for the higher strength bainite/martensite microstructural constituents. In this material system, the enhanced diffusion associated with high-temperature sintering helps remove the heterogeneity necessary for improved mechanical properties.

Table 3 Effect of sintering conditions on the mechanical properties of Distaloy

316 Stainless Steel. Prealloyed austenitic stainless steel P/M materials react favorably to high-temperature sintering conditions (Ref 8). The data in Table 4 illustrates the effect of three sintering temperatures on 316 stainless steel samples sintered in vacuum to a final density of 7.0 g/cm³. While the mechanical strength does not change significantly, the ductility more than tripled when the sintering temperature increased from 1121 to 1260 °C (2050 to 2300 °F). In addition, when nitrogen was used as the backfill gas, a small amount of nitrogen was dissolved in the austenitic structure resulting in a marked increase in strength and a lowering of ductility. Thus, high-temperature sintering can affect this alloy not only via the mechanism previously described by also by affecting the solubility of nitrogen in the austenitic steel matrix (Ref 9).

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Improved Physical Properties

High-temperature sintering can improve the physical properties of ferrous P/M materials by means of the same phenomena that improve mechanical properties: more complete particle bonding, increased density, and a cleaner microstructure for similar sintering atmosphere conditions. Three examples will describe these effects.

Soft Magnetic Properties. The effect of high-temperature sintering on the structure sensitive magnetic properties of selected ferrous P/M materials has been described by several authors (Ref 10, 11, 12). Improved magnetization characteristics for high-temperature sintered material have been attributed to easier magnetic domain wall movement across particle boundaries and the decrease in interstitial impurities, such as carbon, nitrogen, and oxygen. Typical results for pure iron and Fe-0.8P have been listed in Table 5. The mass sensitive properties, B₁₅ and Br, do not change at the higher sintering temperatures; in contrast, both coercive force and permeability show significant improvements for both materials even though sintered density remained constant.

Table 5 Effect of sintering conditions on the magnetic properties of iron and iron-phosphorus

	Iron ^(a)		Iron-0.8% Phosphorus ^(b)	
	1121 °C (2050 °F)	1260 °C (2300 °F)	1121 °C (2050 °F)	1260 °C (2300 °F)

- (b) Sintered at 1121 °C (2050 °F) in hydrogen, 1260 °C (2300 °F) in vacuum (Ref 11)

Corrosion Resistance of 316 Stainless Steel. The corrosion resistance of P/M stainless steels has been recognized as inferior to wrought alloys of the same composition due to the presence of porosity (Ref 10). However, recent investigators have clearly established sintering conditions as a main contributor to the corrosion resistance of these alloys (Ref 9, 13).

Optimal sintering requires high sintering temperatures, low dew points, and control of interstitial elements in the alloy structure (nitrogen, oxygen, and carbon). Because many stainless steels are sintered in nitrogen bearing atmospheres, rapid cooling from the sintering temperature is recommended to inhibit absorption of excess nitrogen that would lead to a depletion of chromium from the alloy matrix by the formation of chromium nitrides. This effect is illustrated in Figure 3 for 316 stainless steel (Ref 13), which shows much lower corrosion rates for higher sintering temperatures and lower nitrogen content sintering atmospheres. The higher temperature reduces the nitrogen solubility in the matrix, improves the deoxidizing effect of the hydrogen, and reduces the deleterious effect of tramp iron powder contamination by homogenizing the iron into the stainless steel matrix.

Fig. 3 Corrosion weight loss for 316 stainless steel as a function of sintering atmosphere for three sintering temperatures. Source: Ref 13

Leak Tightness. Because nearly all conventionally sintered ferrous P/M products contain interconnected porosity (unless copper infiltrated), these products must be sealed for those applications requiring leak tightness. Densification during high-temperature sintering can be used to achieve a final density, which eliminates the interconnected porosity and thus provides an impervious structure. A 316 stainless steel alloy, high-temperature vacuum sintered, was used for valve components without requiring any secondary sealing operations (Ref 8). This material successfully passed pressure tests at 250 psi and demonstrated a vacuum leak rate of less than 10^{-10} cm³/s at a vacuum of 10^{-6} torr.

Development of a Liquid Phase

For several types of ferrous P/M alloys liquid phase sintering provides the means for more complete alloying, improved densification, and even attainment of full density. Some of the alloy systems reach liquid phase conditions at conventional sintering temperatures (e.g., iron-copper and iron-phosphorus). However, for the cases presented below, only high-temperature sintering procedures can produce the desired liquid phase conditions.

Iron-Silicon Alloys. The iron-silicon P/M alloys are typically prepared by blending a ferrosilicon master alloy with a pure iron powder. At conventional sintering temperatures little, if any, diffusion of the silicon into the iron matrix is observed, impeded to a large measure by the tenacious oxide film on the ferrosilicon particles. Raising the sintering temperature above 1200 °C will ensure formation of a transient liquid phase, which promotes rapid diffusion and homogeneity of the silicon into the base iron matrix. This effect can be seen in the microstructures shown in Fig. 4(a) and 4(b). The conventional belt sintered product retains the composite structure of soft iron particles and hard ferrosilicon particles (Fig. 4a). The high-temperature sintered product (Fig. 4b) shows a homogeneous microstructure of iron with 3% silicon in solid solution throughout the matrix. Because this material is typically used for soft magnetic applications, it should be evident that without high-temperature sintering the expected magnetic properties cannot be developed.

Fig. 4 Microstructure of Fe-3%Si. (a) Sintered at 1121 °C (2050 °F) for 30 min. (b) Sintered at 1232 °C (2250 °F) for 2 h. ~240×

Tool Steels. The production of fully dense high-speed tool steel P/M structures requires controlled high-temperature sintering at temperatures approaching the solidus temperature for the alloy. Studies by several investigators (Ref 14, 15) have noted the critical role of liquid phase formation for producing accelerated shrinkage and full dense structures. Overheating by as little as 5 °C will result in rapid grain growth and continuous carbide films between adjacent grains, primarily M_6C type carbides. When sintered below the solidus, the carbides dispersed in the structure impede grain growth and densification. On reaching this temperature, the carbides are dissolved, reducing the amount of inhibiting carbide dispersion, and thus grain growth and densification can occur. The desired structure of small grains and finely dispersed carbides can only be obtained if the amount of liquid phase formed during sintering is small and controlled (Ref 14).

The effect of sintering conditions on the densification of both M2 and T15 grade tool steels is listed in Table 6 (Ref 15). Quite clearly, precise control of sintering conditions, temperature as well as time, is critical for obtaining the desired full dense product with the proper microstructure. Due to differences in composition and carbides present, the T15 grade apparently has a wider sintering "window" than the M2 material, because an 8 °C rise in temperature produced an oversintered structure in M2, while the T15 required a 20 °C increment to produce this type of result.

Table 6 Effect of sintering conditions on the densification of high-speed tool steels

Alloy	Sintering conditions	Density, g/cm ³	Microstructure
M2	$\frac{1}{4}$ h 1230 °C	7.45	Under sintered
	5 h 1233 °C	7.69	Under sintered
	$\frac{1}{4}$ h 1240 °C	7.84	Close to optimum
	5 h 1242 °C	8.06	Close to optimum
	$\frac{1}{4}$ h 1250 °C	8.01	Over sintered

	5 h 1245 °C	7.78	Under sintered
	$\frac{1}{4}$ h 1260 °C	8.10	Close to optimum
	5 h 1259 °C	8.18	Close to optimum
	$\frac{1}{4}$ h 1278 °C	8.26	Over sintered
	5 h 1278 °C	8.26	Over sintered
	5 h 1279 °C	8.28	Over sintered

- (a) Theoretical density: 8.23 g/cm³.
- (b) Theoretical density: 8.32 g/cm³.

Structural Alloy. R.M. German and his coworkers (Ref 16) studied the enhanced sintering of ferrous structural products, which led to the development of an alloy system that used both phosphorus and boron as liquid phase formers. A sintering temperature of 1200 °C was required to ensure formation of the iron-boron eutectic. The resultant iron-nickel-molybdenum base alloys developed excellent as-sintered strengths and good ductility with corresponding high sintered densities, as shown in the following table:

Alloy composition	Density, g/cm ³	Tensile strength, MPa (ksi)	Elongation, %
Fe-2.4Ni-3Mo-0.1P-0.25B-0.1C	7.30	720 (104.5)	6
Fe-4Ni-3Mo-0.1P-0.25B-0.1C	7.35	810 (117.5)	2

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Sintering of Active Elements

The ability to sinter P/M steels using chromium and manganese as the principal alloying elements has been stymied by the need for exceptionally low dew points at conventional sintering temperatures. In order to reduce the oxides of these elements, a dew point of -50 °C would be needed, well below the range of commercial atmosphere sintering furnaces. However, if the sintering temperature can be raised to 1250 °C or higher, than a dew point of only -20 °C should be necessary. Work by Sumitomo (Ref 17) has shown effective sintering at 1250 °C in nitrogen-base atmospheres with a dew point of -10 °C for 4100 grade powder. Tensile strengths in excess of 1170 MPa (170 ksi) and an impact energy of 20 J (15 ft · lbf) were measured after heat treatment of this alloy. Therefore, these lower cost alloying elements (as compared with the more popular nickel, copper, and molybdenum) can be employed in prealloyed powders when coupled with high-temperature sintering techniques.

High-Temperature Sintering of Ferrous Powder Metallurgy Components

Howard I. Sanderow, Management & Engineering Technology

Process Control Requirements

With the benefits of high-temperature sintering clearly established for several ferrous alloy systems, the critical processing requirements must also be recognized and controlled in order to ensure this process can produce reliable and consistent P/M products. As with any multi-step manufacturing process, the change from conventional sintering to high-temperature sintering introduces new levels of variation in the final characteristics of the products, whether dimensional accuracy, mechanical properties, or physical conditions. Three sources of process variation requiring tighter control than under conventional sintering practices are the powder blend, green density, and sintering conditions.

Powder Blend. The raw material for any P/M product (i.e., the starting powder blend) is subject to variations from lot to lot. These variations can be seen in particle morphology, compressibility, apparent density, and segregation of admixed constituents. The two most critical to high-temperature sintering response are particle morphology and segregation. Changes in particle size distribution, especially the amount of fine particles, will accelerate the sintering response at higher temperatures more than conventional sintering practices. Higher fines content in the starting powder blend will result in greater densification, larger shrinkages in sintering, and somewhat improved mechanical properties. In order to control these effects, the powder producers must be aware that these powder blends will be used for high-temperature sintering and the level of variation that can be tolerated. The individual data sheets for each powder lot provided by the powder manufacturer must include data pertinent to the high-temperature sintering conditions being used, specifically sintered properties, in order for the parts producer to benefit from the data. In this way both the powder and parts producer will be assured that a specific

powder lot can be used successfully for a high-temperature sintered product. Micro-segregation of admixed additions is another key factor in powder control, especially for compositions that develop a liquid phase. Nonhomogeneous powder blends that cause excessive liquid formation in isolated areas can result in localized porosity, slumped or deformed shapes, and unusual or undesirable microstructures. Care must be taken by the powder supplier to insure control of this type of problem; new bonding techniques for powder mixes can be helpful in reducing this type of segregation (Ref 18).

Green Density. Variation in green density, from part to part and within multi-level parts, is the responsibility of the parts fabricator. Allowances are made during compaction for the effect of power filling, tool motions, press configurations, and the actual powder being used to provide the necessary consistency in the final product. These small variations, which are acceptable at conventional sintering conditions, may no longer be satisfactory for parts sintered at higher temperatures. If excursions in green density are excessive, the result will be out-of-tolerance parts, distortion in part shape, and differences in physical/mechanical properties in different sections of the part.

An example of this effect can be seen by comparing Distaloy AG sintered at 1150 °C with Distaloy 4800A sintered at 1120 °C. Even though the nickel content is higher for the Distaloy AG (8% versus 4%), the dimensional change observed for the AG grade is 0.3% when compacting pressure varies from 30 to 60 tsi, while the 4800A material varies less than 0.1% over the same pressure range (Ref 19, 20). The higher temperature sintering for the Distaloy AG has contributed to this greater variation in size change. Because individual powder blends will react to high-temperature sintering conditions in a unique way, parametric studies by the parts fabricator are required to determine the allowable variation in green density that can be acceptable for the specific product design.

Sintering Conditions. The ability to control variations in sintering parameters (time, temperature, and atmosphere) become even more critical at high temperatures than conventional conditions. Because the physical phenomena discussed earlier are directly related to time and temperature (rate dependent), small variations relative to 1250 °C, for example, will have a greater effect on these rate controlled reactions than the same variation relative to 1120 °C. Such phenomena include diffusion, grain growth, and densification. If a liquid phase is formed, these controls are even more critical, as discussed earlier for high-speed tool steels. Both the parts fabricator and furnace manufacturer must be aware of these effects when specifying and designing the furnace itself, as well as the process control systems. Temperature uniformity within the sintering zone should be monitored frequently with a typical loading of parts in the furnace. It is not unusual to require a maximum temperature variation of ± 5 °C within the hot zone. The time at temperature should also be monitored independent of the furnace control system to insure consistency in the conveyance mechanism. Variations in sintering time of six minutes or less are recommended (Ref 19). The effect of sintering atmosphere control, especially for carbon bearing alloys, is also critical at elevated temperatures. Decarburization reactions will be accelerated if dew point and carbon potential control are not properly maintained. Loss of carbon from the alloy will directly affect size control and final properties.

In order to appreciate the effect of high-temperature sintering on one parameter, size change, the following chart provides a comparison of the relative magnitude of shrinkage that can be expected for the variety of P/M alloys when high temperature sintered.

Material system	Dimensional change, %
Low alloy steels	-0.01 to +0.02 (conventional)
Low alloy steels	-0.30 to -1.00
Stainless steels	-0.50 to -2.50
Tool steels	-5.00 to -8.00

Clearly, small process variations will create a greater effect on the final part size for the stainless steel and tool steel alloys than the low alloy steels.

Conventional Aluminum Powder Metallurgy Alloys

Introduction

ALUMINUM P/M PARTS are used in an increasing number of applications. The business machine market currently uses the greatest variety of aluminum P/M parts. Other markets that indicate growth potential include automotive components, aerospace components, power tools, appliances, and structural parts. Due to their mechanical and physical properties, aluminum P/M alloys provide engineers with flexibility in material selection and design. A variety of pressed and sintered aluminum P/M parts are shown in Fig. 1.

Fig. 1 Typical pressed and sintered aluminum P/M parts made from alloy 601AB. Top: gear rack used on a disc drive. Bottom: link flexure used on a print tip for a typewriter. Right: header/cavity block used on a high-voltage vacuum capacitor. Courtesy of D. Burton, Perry Tool & Research Company

Conventionally pressed and sintered aluminum powder metal parts have been commercially available for many years. Sintered aluminum P/M parts are competitive with many aluminum castings, extrusions, and screw machine products that require expensive and time-consuming finishing operations. In addition, sintered aluminum P/M parts compete with other metal powder parts in applications where some of the attractive physical and mechanical properties of aluminum can be used. The following combination of properties make aluminum attractive for P/M parts:

- Light weight
- Corrosion resistance
- High strength
- Good ductility
- Nonmagnetic properties
- Conductivity
- Machinability
- Variety of finishes

In addition, P/M technology can be used to refine microstructures compared with those made by conventional ingot metallurgy (I/M), which often results in improved mechanical and corrosion properties. Microstructural refinement by P/M is made possible by two broad high-strength P/M technologies--rapid solidification (RS) and mechanical attrition (mechanical alloying/dispersion strengthening). The advantages of P/M stem from the ability of small particles to be processed. This enables:

- The realization of RS rates
- The uniform introduction of strengthening features, that is, barriers to dislocation motion, from the powder surfaces

The powder processes of rapid solidification and mechanical attrition lead to microstructural grain refinement and, in general, better mechanical properties of the alloy. In addition, RS can extend the alloying limits in aluminum by enhancing supersaturation and thereby enabling greater precipitation hardening without the harmful segregation effects from overalloyed I/M alloys. Moreover, elements that are essentially insoluble in the solid state, but have significant solubility in liquid aluminum, can be uniformly dispersed in the powder particles during RS. This can lead to the formation of novel strengthening phases that are not possible by conventional I/M, while also suppressing the formation of equilibrium phases that are deleterious to toughness and corrosion resistance. These topics and the development of dispersion strengthened aluminum-base composites by P/M methods are discussed in the article "Advanced Aluminum Powder Metallurgy Alloys and Composites" in this Volume.

This article focuses on more conventional aluminum P/M alloys and process methods. There are several steps in aluminum P/M technology that can be combined in various ways, but they will be conveniently described in three general steps:

- Powder production
- Powder processing (optional)
- Degassing and consolidation

Powder can be made by various RS processes including atomization, splat quenching to form particulates, and melt spinning to form ribbon. Alternatively, powder can be made by non-RS processes such as by chemical reactions including precipitation, or by machining bulk material. Powder-processing operations are optional and include mechanical attrition (for example, ball milling) to modify powder shape and size or to introduce strengthening features, or comminution such as that used to cut melt-spun ribbon into powder flakes for subsequent handling.

Aluminum has a high affinity for moisture, and aluminum powders readily adsorb water. The elevated temperatures generally required to consolidate aluminum powder cause the water of hydration to react and form hydrogen, which can result in porosity in the final product, or under confined conditions, can cause an explosion. Consequently, aluminum powder must be degassed prior to consolidation. This is often performed immediately prior to consolidation at essentially the same temperature as that for consolidation to reduce fabrication costs. Consolidation may involve forming a billet that can be subsequently rolled, extruded, or forged conventionally, or the powder may be consolidated during hot working directly to finished-product form.

Powder Production

Atomization is the most widely used process to produce aluminum powder. Aluminum is melted, alloyed, and sprayed through a nozzle to form a stream of very fine particles that are rapidly cooled--most often by an expanding gas. Atomization of aluminum is discussed in more detail in the article "Production of Aluminum and Aluminum-Alloy Powders" in this Volume.

Splat cooling is the process that enables cooling rates even greater than those obtained in atomization. Aluminum is melted and alloyed, and liquid droplets are sprayed or dropped against a chilled surface of high thermal conductivity--for example, a copper wheel that is water cooled internally. The resultant splat particulate is removed from the rotating wheel to allow subsequent droplets to contact the bare, chilled surface. Cooling rates of 10⁵ K/s are typical, with rates up to 10⁹ K/s reported.

Melt-spinning techniques are somewhat similar to splat cooling. The molten aluminum alloy rapidly impinges a cooled, rotating wheel, producing rapidly solidified product that is often in ribbon form. The leading commercial melt-spinning process is the planar flow casting (PFC) process (Ref 1). The liquid stream contacts a rotating wheel at a carefully controlled distance to form a thin, rapidly solidified ribbon and also to reduce oxidation. The ribbon could be used for specialty applications in its PFC form but is most often comminuted into flake powder for subsequent degassing and consolidation.

Press and Sintered Aluminum Alloys

Commercially available aluminum powder alloy compositions (Table 1) consist of blends of atomized aluminum powders mixed with powders of various alloying elements such as zinc, copper, magnesium, and silicon. Press and sintered aluminum alloys are based on elemental blends. Prealloyed aluminum powders cannot be processed by conventional P/M press and sinter operations. The non-reducible aluminum oxide coating hinders the development of strong interparticle bonds.

Table 1 Compositions of typical aluminum P/M alloy powders

Grade	Composition, %				
	Cu	Mg	Si	Al	Lubricant
601AB	0.25	1.0	0.6	bal	1.5
201AB	4.4	0.5	0.8	bal	1.5
602AB	...	0.6	0.4	bal	1.5
202AB	4.0	bal	1.5
MD-22	2.0	1.0	0.3	bal	1.5
MD-24	4.4	0.5	0.9	bal	1.5
MD-69	0.25	1.0	0.6	bal	1.5
MD-76	1.6	2.5	...	bal	1.5

The most common heat-treatable grades are comparable to the 2xxx and 6xxx series wrought aluminum alloys. Alloys 201AB and MD-24 are most similar to wrought alloy 2014. They develop high strength and offer moderate corrosion resistance. Alloys 601AB and MD-69 are similar to wrought alloy 6061. These alloys offer high strength, good ductility, corrosion resistance, and can be specified for anodized parts. Alloy 601AC is the same as 601AB, but does not contain an admixed lubricant. It is used for isostatic and die-wall-lubricated compaction. When high conductivity is required, alloy 602AB often is used. Conductivity of 602AB ranges from 24×10^6 to 28×10^6 S/m (42.0 to 49% IACS), depending on the type of heat treatment selected.

Conventional Aluminum Powder Metallurgy Alloys

Aluminum P/M Part Processing

Basic design details for aluminum P/M parts involve the same manufacturing operations, equipment, and tooling that are used for iron, copper, and other metal-powder compositions.

Compacting. Aluminum P/M parts are compacted at low pressures and are adaptable to all types of compacting equipment. The pressure density curve, which compares the compacting characteristics of aluminum with other metal powders, indicates that aluminum is simpler to compact. Figure 2 shows the relative difference in compacting characteristics for aluminum and sponge iron or copper.

Fig. 2 Relationship of green density and compacting pressure

The lower compacting pressures required for aluminum permit wider use of existing presses. Depending on the press, a larger part often can be made by taking advantage of maximum press force. For example, a part with a 130 cm^2 (20 in.^2) surface area and 50 mm (2 in.) depth is formed readily on a 4450 kN (500 ton) press. The same part in iron would require a 5340 kN

(600 ton) press. In addition, because aluminum responds better to compacting and moves more readily in the die, more complex shapes having more precise and finer detail can be produced.

Sintering. Aluminum P/M parts can be sintered in a controlled, inert atmosphere or in vacuum. Sintering temperatures are based on alloy composition and generally range from 595 to 625 °C (1100 to 1160 °F). Sintering time varies from 10 to 30 min. Nitrogen, dissociated ammonia, hydrogen, argon, and vacuum have been used for sintering aluminum; however, nitrogen is preferred because it results in high as-sintered mechanical properties (Table 2). It is also economical in bulk quantities. If a protective atmosphere is used, a dew point of -40 °C (-40 °F) or below is recommended. This is equivalent to a moisture content of 120 mL/m³ (120 ppm) maximum.

Table 2 Typical properties of nitrogen-sintered aluminum P/M alloys

(a) Tensile properties determined using powder metal flat tension bar (MPIF standard 10-63), sintered 15 min at 620 °C (1150 °F) in nitrogen

Aluminum preforms can be sintered in batch furnaces or continuous radiant tube mesh or cast belt furnaces. Optimum dimensional control is best attained by maintaining furnace temperature at ± 2.8 °C (± 5 °F). Typical heating cycles for aluminum parts sintered in various furnaces are illustrated in Fig. 3.

Fig. 3 Typical heating cycles for aluminum P/M parts sintered in (a) a batch furnace. (b) a continuous furnace. (c) a vacuum furnace

Mechanical properties are directly affected by thermal treatment. All compositions respond to solution heat treating, quenching, and aging in the same manner as conventional heat-treatable alloys. More detailed information on sintering of aluminum can be found in the article "Production Sintering Practices" in this Volume.

Repressing. The density of sintered compacts may be increased by repressing. When repressing is performed primarily to improve the dimensional accuracy of a compact, it usually is termed "sizing"; when performed to improve configuration, it is termed "coining." Repressing may be followed by resintering, which relieves stress due to cold work in repressing and may further consolidate the compact. By pressing and sintering only, parts of >80% theoretical density can be produced. By repressing, with or without resintering, parts of $\geq 90\%$ theoretical density can be produced. The density attainable is limited by the size and shape of the compact.

Forging of aluminum is a well-established technology. Aluminum also lends itself to the forging of P/M preforms to produce structural parts.

In forging of aluminum preforms, the sintered aluminum part is coated with a graphite lubricant to permit proper metal flow during forging. The part is either hot or cold forged; hot forging at 300 to 450 °C (575 to 850 °F) is recommended for parts requiring critical die fill. Forging pressure usually does not exceed 345 MPa (50 ksi). Forging normally is performed in a confined die so that no flash is produced and only densification and lateral flow result from the forging step. Scrap loss is <10% compared to conventional forging, which approaches 50%. Forged aluminum P/M parts have densities of >99.5% of

theoretical density. Strengths are higher than nonforged P/M parts, and in many ways, are similar to conventional forging. Fatigue endurance limit is doubled over that of nonforged P/M parts.

Alloys 601AB, 602AB, 201AB, and 202AB are designed for forgings. Alloy 202AB is especially well suited for cold forging. All of the aluminum powder alloys respond to strain hardening and precipitation hardening, providing a wide range of properties. For example, hot forging of alloy 601 AB-T4 at 425 °C (800 °F) followed by heat treatment gives ultimate tensile strengths of 221 to 262 MPa (32 to 38 ksi), and a yield strength of 138 MPa (20 ksi), with 6 to 16% elongation in 25 mm (1 in.).

Alloy 601AB. Heat treated to the T6 condition, 601AB has tensile properties of:

- UTS, 303 to 345 MPa (44 to 50 ksi)
- Yield strength, 303 to 317 MPa (44 to 46 ksi)
- Elongation, up to 8%

Forming pressure and percentage of reduction during forging influence final properties.

Alloy 201AB. In the T4 condition, alloy 201AB has tensile properties of:

- UTS, 358 to 400 MPa (52 to 58 ksi)
- Yield strength, 255 to 262 MPa (37 to 38 ksi)
- Elongation, 8 to 18%

When heat treated to the T6 condition, the tensile strength of 201AB increases from 393 to 434 MPa (57 to 63 ksi). Yield strength for this condition is 386 to 414 MPa (56 to 60 ksi), and elongation ranges from 0.5 to 8%.

Properties of cold-formed aluminum P/M alloys are increased by a combination of strain-hardened densification and improved interparticle bonding. Alloy 601AB achieves 257 MPa (37.3 ksi) tensile strength and 241 MPa (34.9 ksi) yield strength after forming to 28% upset. Properties for the T4 and T6 conditions do not change notably between 3 and 28% upset. Alloy 602AB has moderate properties with good elongation. Strain hardening (28% upset) results in 221 MPa (32 ksi) tensile and 203 MPa (29.4 ksi) yield strength. The T6 temper parts achieve 255 MPa (37 ksi) tensile strength and 227 MPa (33 ksi) yield strength. Highest cold-formed properties are achieved by 201AB. In the as-formed condition, yield strength increases from 209 MPa (30.3 ksi) for 92.5% density to 281 MPa (40.7 ksi) for 96.8% density.

Alloy 202AB is best suited for cold forming. Treating to the T2 condition, or as-cold formed, increases the yield strength significantly. In the T8 condition, 202AB develops 280 MPa (40.6 ksi) tensile strength and 250 MPa (36.2 ksi) yield strength, with 3% elongation at the 19% upset level.

Conventional Aluminum Powder Metallurgy Alloys

Properties of Sintered Parts

Mechanical Properties. Sintered aluminum P/M parts can be produced with strength that equals or exceeds that of iron or copper P/M parts. Tensile strengths range from 110 to 345 MPa (16 to 50 ksi), depending on composition, density, sintering practice, heat treatment, and repressing procedures. Table 2 lists typical properties of four nitrogen-sintered P/M alloys. Properties of heat-treated, pressed, and sintered grades are provided in Table 3.

Table 3 Typical heat-treated properties of nitrogen-sintered aluminum P/M alloys

Heat-treated variables and properties	Grades			
	MD-22	MD-24	MD-69	MD-76
Solution treatment				
Temperature, °C (°F)	520 (970)	500 (930)	520 (970)	475 (890)
Time, min	30	60	30	60
Atmosphere	Air	Air	Air	Air

(a) T6, solution heat treated, quenched, and artificially age hardened

Impact tests are used to provide a measure of toughness of powder metal materials, which are somewhat less ductile than similar wrought compositions. Annealed specimens develop the highest impact strength, whereas fully heat-treated parts have the lowest impact values. Alloy 201AB generally exhibits higher impact resistance than alloy 601AB at the same percent density, and impact strength of 201AB increases with increasing density. A desirable combination of strength and impact resistance is attained in the T4 temper for both alloys. In the T4 temper, 95% density 201AB develops strength and impact properties exceeding those for as-sintered 99Fe-1C alloy, a P/M material frequently employed in applications requiring tensile strengths under 345 MPa (50 ksi).

Fatigue is an important design consideration for P/M parts subject to dynamic stresses. Fatigue strengths of pressed and sintered P/M parts may be expected to be about half those of the wrought alloys of corresponding compositions (see comparisons of two P/M alloys with two wrought alloys in Fig. 4). These fatigue-strength levels are suitable for many applications.

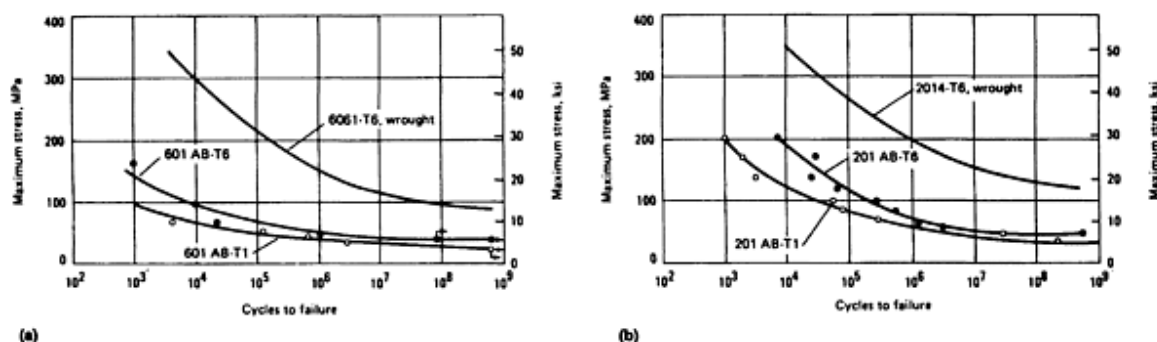

Fig. 4 Fatigue curves for (a) P/M 601AB (b) P/M 201AB

Electrical and Thermal Conductivity. Aluminum has higher electrical and thermal conductivities than most other metals. Table 4 compares the conductivities of sintered aluminum alloys with wrought aluminum, brass, bronze, and iron.

Table 4 Electrical and thermal conductivity of sintered aluminum alloys, wrought aluminum, brass, bronze, and iron

Materials	Temper	Electrical conductivity ^(a) at 20 °C (68 °F), %IACS	Thermal conductivity ^(b) at 20 °C (68 °F), cal/cm·s·°C

Machinability. Secondary finishing operations such as drilling, milling, turning, or grinding can be performed easily on aluminum P/M parts. Aluminum P/M alloys provide excellent chip characteristics; compared to wrought aluminum alloys, P/M chips are much smaller and are broken more easily with little or no stringer buildup. This results in improved tool service life and higher machinability ratings.

Conventional Aluminum Powder Metallurgy Alloys

Powder Degassing and Consolidation

The water of hydration that forms on aluminum powder surfaces must be removed to prevent porosity in the consolidated product. Although solid-state degassing has been used to reduce the hydrogen content of aluminum P/M wrought products, it is far easier and more effective to remove the moisture from the powder. Degassing is often performed in conjunction with consolidation, and the most commonly used techniques are described below. The various aluminum fabrication schemes are summarized in Fig. 5.

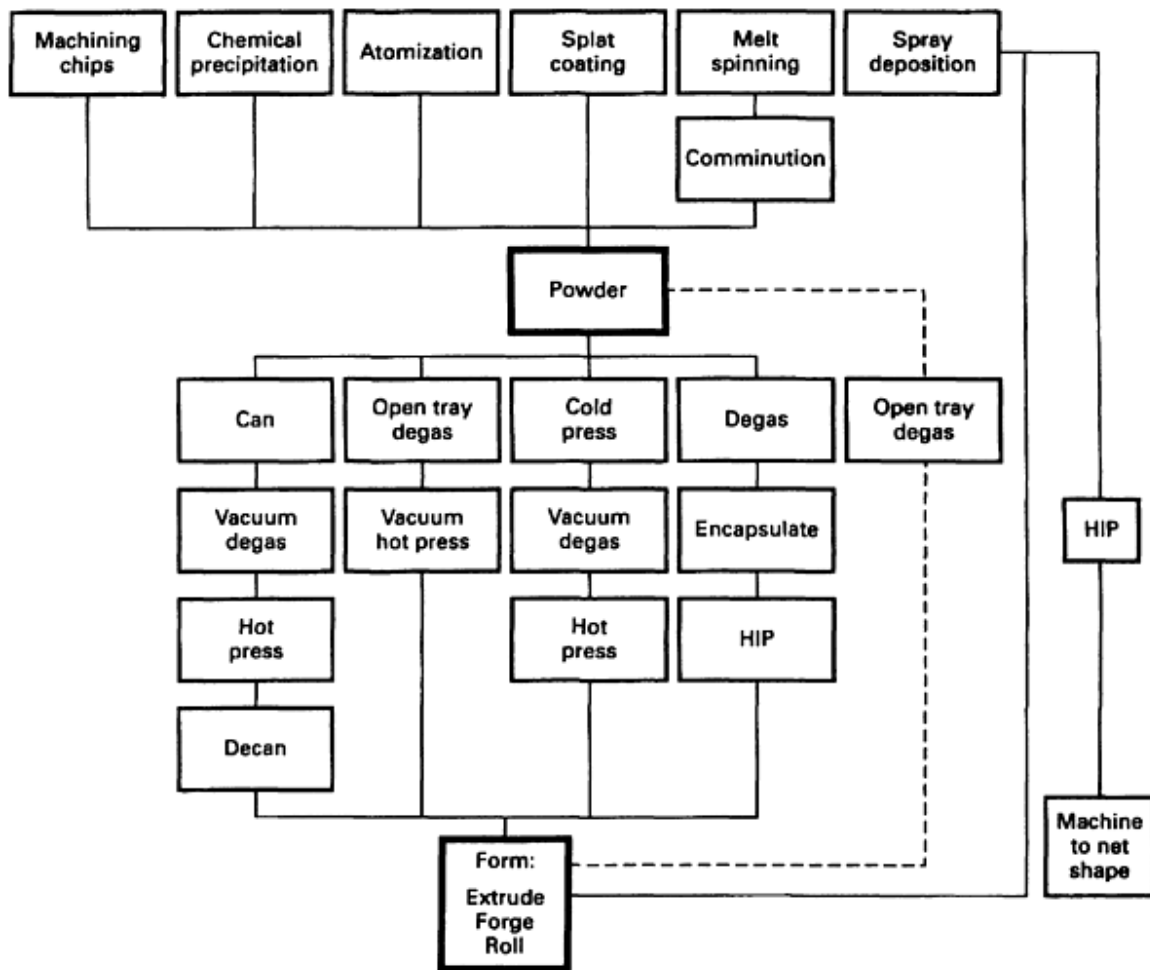

Fig. 5 Aluminum P/M fabrication schemes

Can Vacuum Degassing. This is perhaps the most widely used technique for aluminum degassing because it is relatively non-capital intensive. Powder is encapsulated in a can, usually aluminum alloys 3003 or 6061, as shown schematically in Fig. 6. A spacer is often useful to increase packing and to avoid safety problems when the can is welded shut. It has been found that packing densities are typically 60% of theoretical density when utilizing this method on mechanically alloyed powders. Care must be used to allow a clear path for evolved gases through the spacer to prevent pressure buildup and explosion.

Fig. 6 Degassing can used for aluminum P/M processing

To increase packing density, the powder is often cold isostatically pressed (CIP) in a reusable polymeric container before insertion into the can. Powder densities in the CIPed compact of 75 to 80% theoretical density are preferred because they have increased packing density with respect to loose-packed powder, yet allow sufficient interconnected porosity for gas removal. At packing densities of about 84% and higher, effective degassing is not possible for several atomized aluminum-alloy powders (Ref 2, 3). Furthermore, one must control CIP parameters to avoid inhomogeneous load transfer through the powder, which can lead to excessive density in the outer regions of the cylindrical compact and much lower densities in the center. Such CIP parameters often must be developed for a specific powder and compact diameter.

The canned powder is sealed by welding a cap that contains an evacuation tube as shown in Fig. 6. After ensuring that the can contains no leaks, the powder is vacuum degassed while heating to elevated temperatures. The rate in gas evolution as a function of degassing temperature depends on powder size, distribution, and composition. The ultimate degassing temperature should be selected based on powder composition, considering tradeoffs between resulting hydrogen content and microstructural coarsening. For example, an RS-P/M precipitation-hardenable alloy that is to be welded would likely be degassed at a relatively high temperature to minimize hydrogen content (hotter is not always better). Coarsening would not significantly decrease the strength of the resulting product because solution treatment and aging would be subsequently performed and provide most of the strengthening. On the other hand, a mechanically attrited P/M alloy that relies on substructural strengthening and will serve in a mechanically fastened application might be degassed at a lower temperature to reduce the annealing out of dislocations and coarsening of substructure.

When a suitable vacuum is achieved (for example, <5 millitorr), the evacuation tube is sealed by crimping. The degassed powder compact can then be immediately consolidated to avoid the costs of additional heating. An extrusion press using a blind die (that is, no orifice) is often a cost-effective means of consolidation.

Dipurative Degassing. Roberts and coworkers at Kaiser Aluminum & Chemical Corporation have developed an improved degassing method called "dipurative" degassing (Ref 4). In this technique, the vacuum-degassed powder, which is often canned, is backfilled with a dipurative gas (that is, one that effectively removes water of hydration) such as extra-dry nitrogen, and then re-evacuated. Several backfills and evacuations can be performed resulting in lower hydrogen content. In addition, the degassing can often be performed at lower temperatures to reduce microstructural coarsening.

Vacuum Degassing in a Reusable Chamber. The cost of canning and decanning adversely affects the competitiveness of aluminum P/M alloys. This cost can be alleviated somewhat by using a reusable chamber for vacuum hot pressing. The powder or CIPed compact can be placed in the chamber and vacuum degassed immediately prior to compaction in the same chamber. Alternatively, the powder can be "open tray" degassed, that is, degassed in an unconfined fashion, prior to loading into the chamber. The processing time to achieve degassing in an open tray can be much less than that required in a chamber or can, thereby increasing productivity. Care must be exercised to load the powder into the chamber using suitable protection from ambient air and moisture. The compacted billet can then be formed by conventional hot-working operations.

Direct Powder Forming. One of the most cost-effective means of powder consolidation is direct powder forming. Degassed powder, or powder that has been manufactured with great care to avoid contact with ambient air, can be consolidated directly during the hot-forming operation. Direct powder extrusion and rolling have been successfully demonstrated numerous times over the past two decades (Ref 5, 6). It still remains an attractive means for decreasing the cost of aluminum P/M.

Hot Isostatic Pressing (HIP). In HIP, degassed and encapsulated powder is subjected to hydrostatic pressure in a HIP apparatus. Can vacuum degassing is often used as the precursor step to HIP. Furthermore, net-shape encapsulation of degassed powder can be used to produce certain near net-shape parts. Relatively high HIP pressures (~ 200 MPa, or 30 ksi) are often preferred. Unfortunately, the oxide layer on the powder particle surfaces is not sufficiently broken up for optimum mechanical properties. A subsequent hot-working operation that introduces shear-stress components is often necessary to improve ductility and toughness.

Rapid Omnidirectional Consolidation. Engineers at Kelsey-Hayes Company have developed a technique to use existing commercial forging equipment to consolidate powders in several alloy systems (Ref 7). Called rapid omnidirectional consolidation (ROC), it is a lower-cost alternative to HIP. In ROC processing, degassed powder is loaded into a thick-walled "fluid die" that is made of a material that plastically flows at the consolidation temperature and pressure, and which enables the transfer of hydrostatic stress to the powder. Early fluid dies were made of mild steels or a Cu-10Ni alloy, with subsequent dies made from ceramics, glass, or composites.

The preheated die that contains powder can be consolidated in <1 s in a forging press, thereby reducing thermal exposure that can coarsen RS microstructures. In addition, productivity is greatly increased by minimizing press time. Depending upon the type of fluid die material being used, the die can be machined off, chemically leached off, melted off, or designed to "pop off" the net-shape component while cooling from the consolidation temperature. For aluminum-alloy powders, unconfined degassing is critical to optimize the cost effectiveness of the ROC process. An electrodynamic degasser was developed for this purpose.

Just as in the case of HIP, the stress state during ROC is largely hydrostatic. Consequently, there may not be sufficient shear stresses to break the oxide layer and disperse the oxides, which can lead to prior powder-particle boundary (PPB) failure. Consequently, a subsequent hot-working step of the ROC billet is often necessary for demanding applications. More detailed information on this technique can be found in Ref 8.

Dynamic Compaction. Various ultrahigh strain-rate consolidation techniques, that is, dynamic compaction, have been developed and utilized for aluminum alloys (Ref 9). In dynamic compaction, a high-velocity projectile impacts the degassed powders that are consolidated by propagation of the resultant shock wave through the powder. The bonding between the powder particles is believed to occur by melting of a very thin layer on the powder surfaces, which is caused by the heat resulting from friction between the powder particles that occurs during impact. The melted region is highly localized and self-quenched by the powder interiors shortly after impact. Thus, dynamic compaction has the advantage of minimizing thermal exposure and microstructural coarsening, while breaking up the PPBs.

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Introduction

POWDER METALLURGICAL PROCESSING provides much finer and homogeneous microstructure, better mechanical properties, and near-net shape parts producibility for aluminum alloys in comparison with ingot metallurgy (I/M). In addition to the conventional blending and consolidation of elemental or prealloyed powders into near-net shape parts, emerging processes such as mechanical alloying and rapid solidification (RS) create composite powders that upon subsequent consolidation provide significant improvements in room and elevated-temperature strength, fracture toughness, fatigue life, and corrosion resistance. The real advantage of P/M processing including spray forming is in the production of new alloys and composites with metallurgical structures and compositions that cannot be produced by I/M. Rapid solidification extends the solubility of alloying elements, particularly transition and rare earth elements, and refines the structure of intermetallic phases responsible for improved mechanical properties. Mechanical alloying is a dry, high-energy milling process producing dispersions of insoluble oxides and carbides that stabilize the microstructure leading to high strength at elevated temperatures in the consolidated materials. By blending the alloy powder with a strengthening phase, discontinuously reinforced aluminum-matrix composites containing insoluble dispersoids (oxides and carbides), particulates, whiskers, or fibers are produced for high-performance structural applications (Ref 1, 2, 3, 4, 5, 6). Table 1 includes the chemical composition of aluminum P/M alloys and dispersion-strengthened composites.

Table 1 Chemical composition of aluminum P/M alloys including dispersion-strengthened composites

Alloy designation	Composition
Al-C	Al-3.0C

Al-Mn-Co	Al-(3-8)Mn-(1.5-7)Ni
Al-Mn-Ni	Al-(3-8)Mn-(1.6-6.5)Co
Al-Ni-Co	Al-(2-5)Ni-(2-5)Co

Source: Ref 1, 2, 3

Aluminum-matrix composites with reinforcement of particulates, whiskers, or chopped fibers have been widely studied worldwide. They are generally isotropic and less costly in comparison with continuous-fiber-reinforced aluminum-matrix composites. The discontinuously reinforced aluminum (DRA) composites are attractive for near-term commercial applications. Silicon carbide (SiC) or alumina-particle-reinforced aluminum composites have higher stiffness and, in general, high wear resistance in comparison with the unreinforced aluminum alloys. Silicon carbide whisker, however, is currently the most widely utilized reinforcement for the DRA composites for obtaining high resistance to creep and higher use temperatures. Early work on whisker reinforcement started in the 1960s. Brenner (Ref 7, 8) and Sutton (Ref 9, 10) used α -Al₂O₃ whiskers to fabricate metal-matrix composites (MMCs). These early composites were not attractive because of their relatively low strength and the high cost of the whisker. Later Divecha et al. (Ref 11) used SiC whiskers to fabricate aluminum-matrix composites with good mechanical properties. In 1973, Cutler (Ref 12) introduced his patented process of inexpensively producing SiC whiskers from pyrolyzed rice hulls. This renewed the interest in the development of whisker-reinforced MMCs (Ref 13, 14, 15, 16). There have been concerns in handling fine particulates and whiskers because of health risks. For pathogenic reasons such as mesothelioma induction and fibrogenic and lung cancer potential, it has been found that it is the size and shape of any given particle that causes problems, as well as its chemistry (Ref 17, 18). Hence it is advisable to use particulate with diameters greater than 5 μ m and to avoid contact with fibers or whiskers in the range 0.1 to 3 μ m, with lengths greater than 5 μ m. There has been only a limited interest in whiskers other than SiC for fabricating MMCs. Recently Imai, Nishida, and Tozawa (Ref 19) evaluated the mechanical properties of aluminum-matrix composites with Si₃N₄ whisker. The composites, fabricated by P/M hot pressing and subsequently extruded, showed good mechanical properties. Limited work has been reported on continuous-fiber-reinforced aluminum composites fabricated by P/M processing. Bhagat and coworkers (Ref 20, 21, 22, 23, 24, 25) fabricated stainless steel wire (type 304) reinforced aluminum-matrix composites by hot pressing (800 K, 155 MPa, and 60 s). The composites showed attractive mechanical properties including high fracture toughness and fatigue life. These composites are suitable for structural applications requiring high fracture toughness and high resistance to impact damage.

Selection of suitable composition of the matrix material is important to meet mechanical and physical property requirements of the aluminum-matrix composites. Minor alloying additions in the wrought alloys are generally detrimental to the mechanical properties of the composites because of undesirable interfacial reaction (Ref 26, 27, 28) during the P/M consolidation. The P/M route for producing the discontinuously reinforced composites involves blending elemental or prealloyed powder with the reinforcement, followed by canning, vacuum degassing, and some form of consolidation, such as hot pressing or hot isostatic pressing (HIP), into a billet that is subsequently rolled, forged, or extruded into shapes. During the billet consolidation, however, the matrix alloy may experience incipient melting, creating both large insoluble and excess soluble intermetallics, which form upon resolidification of aluminum alloy matrix. These particles are deleterious to the fracture toughness and ductility of the DRA. This has led to the recent development of the leaner variants of the 2xxx and 6xxx series aluminum alloys (e.g., 2009 and 6090), which contain strengthening elements in concentrations no greater than their mutual solubilities, thereby leading to useful ductility and fracture toughness in the composites (Ref 29, 30, 31). It is important to note, therefore, that the compositional and microstructural requirements are different for dispersion-strengthened alloys and particle or whisker-reinforced aluminum composites.

In addition to fabricating shaped structures, deformation processing (extrusion, forging, or rolling) of the consolidated composites develops the best properties attainable by breaking up any preexisting oxide on the alloyed powder. Extrusion of

whisker-reinforced composites leads to an approximate alignment of the whiskers in the extrusion direction. Production of useful shapes requires, at least to some extent, secondary processing such as machining and joining, which are not well established for the composites. Conventional machining of composites is very difficult because of the high hardness of the ceramic reinforcement. Expensive diamond or cubic boron nitride cutting tools are needed for effective machining. The high-cost conventional machining of MMCs can be eliminated by near-net shape manufacturing or by noncontact machining techniques such as laser processing (Ref 32) and abrasive waterjet cutting (Ref 33). Large-scale commercialization of the aluminum P/M alloys and composites is still small (compared to wrought and cast aluminum alloys), although new applications are emerging (see "Applications Outlook" in this article). Notwithstanding the high cost that remains a major concern for their use, there are other major technological challenges such as reproducibility/reliability, machining, joining, and recycling that need to be addressed.

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Conventional Consolidation

For wrought aluminum P/M alloys such as 601AB and 201AB (see Table 1), prealloyed aluminum powders are cold isostatically pressed into green compacts, degassed, and sintered in nitrogen atmosphere; sintering in dissociated ammonia or vacuum leads to relatively inferior mechanical properties. The cold compaction, degassing and sintering are done typically at 400 MPa, 450 °C, and 600 °C, respectively (Ref 1). The as-sintered products are usually not fully dense and have relatively low strengths. They require heat treatment and deformation processing (rolling, extrusion, or forging) for improved properties (see Table 2).

Table 2 Mechanical properties of nitrogen-sintered wrought aluminum alloys

Alloy	Yield strength, MPa	Ultimate tensile strength, MPa	Elongation, %
201AB-T6 (95% dense)	322	336	2
201AB-T6 (97% dense, rolled)	327	332	2
202AB-T6 (92.4% dense)	147	227	7.3
202AB-T8 (92.4% dense, cold formed, 19% strain)	250	280	3
601AB-T6(96% dense)	230	238	2
601AB-T6 (96% dense, rolled)	241	252	2
602AB-T6 (96% dense)	172	186	3

Source: Ref 1

For full densification, powder particles are compacted isostatically and encapsulated in an aluminum canister. The compact is heated, and gases are evacuated from the canister. The heated canister/compact is pressed into a billet with 100% density. The canister is removed from the billet by machining. The billet is subsequently fabricated into parts by rolling, forging, or extrusion. The conventional P/M processing of the aluminum-matrix composites include the following steps. The reinforcement particulates/whiskers (see Table 3) are deagglomerated prior to mixing or blending in a suitable medium. Ultrasonic agitation of whiskers or fine particulates suspended in alcohol or wet milling in a polar solvent medium such as *n*-butanol is required to eliminate the problem of agglomeration. The deagglomerated mass is mixed with matrix alloy powder and subjected to a dry or wet blending process to obtain a uniform distribution of the reinforcement in the matrix. Improper blending leads to an inhomogeneous distribution of the reinforcement in the final product. The solvent is removed by drying the powder mixture in air. As an example, the powder mixture of 2124 Al and SiC particulates can be heated at 150 °C to remove *n*-butanol from the blend (Ref 34). The mixture is cold compacted in a die using a hydraulic press. Carbowax and stearic acid are suitable lubricants for the die wall to prevent wear. Level of densification is critical to provide some green strength for handling and yet leave behind an open interconnecting pore structure so as not to hinder degassing. Both the physically absorbed and chemically combined water on the matrix alloy powder particles are liberated in the form of water vapor during the degassing. If the degassing is incomplete, the postcompaction thermal exposure can give rise to hydrogen evolution due to reaction between the water vapor and aluminum. This causes blistering in the billet and reduces ductility and fracture toughness of the composite. Degassing temperature and time are critical parameters because lower times and temperatures lead to incomplete degassing, whereas higher times and temperatures lead to a chemical reaction between the matrix and the reinforcement that can result in a weak interface. Jain et al. (Ref 34) experimentally determined the optimal temperature and time of 723 K and 1 h, respectively, for degassing of the 2124/SiC_p green compact. Vacuum hot pressing or HIP is required for final consolidation of the degassed green compact. Full densification is obtained by optimizing the temperature, pressure, and the period of hot pressing. Further details on the conventional P/M processing of particulate or whisker-reinforced metal composites can be found elsewhere (Ref 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44).

Table 3 Typical properties of particulate, whisker, and discontinuous fiber reinforcements

Property	SiC _p	Al ₂ O _{3p}	TiB _{2p}	Si ₃ N _{4p}	Al ₂ O ₃ (Saffil)	SiC _w	Si ₃ N _{4w}	K ₂ O·6TiO _{2w}

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Emerging Technologies

The primary advantage of P/M processing, as mentioned before, is due to the use of emerging technologies such as mechanical alloying, rapid solidification, and spray forming, which provide a greater flexibility in tailoring the composition and microstructure of dispersion-strengthened aluminum alloys and composites with or without particulate/whisker reinforcement.

Mechanical Alloying and Processing (MAP). Mechanical alloying is used for fabricating oxide-dispersion-strengthened alloys and discontinuously reinforced composites. Pure metal powder and alloying ingredients are mechanically alloyed using high-energy ball mills. During this process, a heavy working of powder particles results in the intimate alloying by a process of repeated welding, fracturing, and rewelding (Ref 45, 46, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56). In the case of aluminum alloys, carbon derived from process control agents and incorporated into the processed powder reacts with aluminum to form very fine carbides. These carbides and the fine oxide particles derived from the breakup of surface films on the initial powder particles create a dispersion that stabilizes the fine-grained microstructure. Therefore, a portion or all of the

strengthening may be obtained from the ultrafine grain size stabilized by the oxide and carbide dispersions (see Ref 4). Mechanically alloyed (MA) product (i.e., the composite powder) is subsequently consolidated into suitable shapes. The mechanical alloying is also useful in developing materials with large contents of alloying additions for improving mechanical properties at elevated temperatures. This processing technique alleviates the problems of low solubility according to the phase diagram or possibility of forming low-melting equilibrium or nonequilibrium phases. Thus, an anomalous supersaturation can be achieved in systems such as aluminum-iron, aluminum-nickel, aluminum-chromium, and aluminum-titanium by mechanical alloying with or without particulate additions. Such materials have potential for improved strength at elevated temperatures. A novel use of the mechanical alloying is in the generation of amorphous alloys that, upon subsequent controlled crystallization, can generate nanometer-scale microstructures (Ref 57, 58, 59). The MA aluminum powder 9052 shows improved mechanical properties and corrosion resistance. MA Al-12.5Ti alloy has a stable, ultrafine grain structure containing fine Al_3Ti particles of 20 to 250 nm in size. This alloy has high stiffness, good ductility, and high strength at elevated temperatures. Bhaduri et al. (Ref 60) used mechanical alloying to prepare composite powders of 7010 Al from elemental powder with or without SiC particulates. The addition of SiC particulates appears to inhibit the progress of mechanical alloying. The composites had higher modulus but lower strength values than the matrix at room temperature. However, at temperatures $>200^\circ\text{C}$ the composites exhibited higher tensile strength than the matrix. Other examples of MAP aluminum alloys and composites and their properties are discussed later.

Rapid Solidification and Processing (RSP). Rapid solidification is a "far-from-equilibrium" process that results in a significant undercooling of the molten metals or alloys leading to a refinement of microstructural features and constitutional effects such as extension of solubility limits, synthesis of novel crystalline phases, and formation of metallic glasses (Ref 3, 61, 62, 63, 64, 65, 66). Fabrication of particle-reinforced MMCs by the RSP involves introduction of the particulates into the melt, proper mixing, melt spinning, and canning of the composite particles, followed by extrusion or forging or both into finished shapes. Rapid solidification processing has enabled the development of a new family of high-strength aluminum alloys for elevated-temperature applications. The RSP alloys such as those based on hypereutectic aluminum-iron compositions derive their high strengths from dispersion strengthening; the dispersoids resist dissolution and coarsening when the alloys are exposed to elevated temperatures. Aluminum 7091 and 7090 are Al-Zn-Mg-Cu alloys that are similar in composition to I/M 7175, but contain 0.4 and 1.45% Co, respectively. Cobalt forms Co_2Al_9 or $(\text{Co,Fe})_2\text{Al}_9$ particles that are homogeneously dispersed. These dispersoids refine the grain size for improved high strength and ductility and enhance the resistance to stress-corrosion cracking (Ref 3). Kumpf et al. (Ref 67) produced high-silicon-content (~ 20 wt%) aluminum alloys with high strength at room to elevated temperatures by combining RSP and the mechanical alloying. Courtwright et al. (Ref 68) used RSP for fabricating SiC-particle-reinforced aluminum composites with significantly improved mechanical properties.

A number of aluminum-base amorphous alloys have been fabricated by melt spinning (Ref 69, 70, 71, 72, 73). These aluminum glasses (with or without the presence of aluminum nanocrystals) show very high tensile strength and low density. The rapidly solidified and processed $\text{Al}_{70}\text{Ni}_{20}\text{Zr}_{10}$, $\text{Al}_{90}\text{Fe}_5\text{Ce}_5$, and $\text{Al}_{89}\text{Ni}_7\text{Y}_4$ metallic glasses with 25 vol% of nanocrystals can have yield stresses up to 1550 MPa, good ductility, and high elastic moduli (Ref 3, 74, 75, 76). Generally, these amorphous alloys have poor thermal stability. The problem of poor thermal stability can, however, be alleviated by compositional optimization as reported by Jin et al. (Ref 69). They found that iron in the range of 35 at.% in the rapidly solidified $\text{Al}_{86}\text{Mm}_4\text{Ni}_{1-x}\text{Fe}_x$ (at.%) alloys (Mm represents mischmetal, 49Ce-25La-18Nd-5.4Pr-2.6 other, wt%), provides optimal compositions having good thermal stability combined with high strength for practical structural applications.

Spray forming is a high-deposition-rate metal spraying process for the production of near-net shape parts at a relatively low cost. In this method, molten metal is rapidly atomized to form a fine spray of droplets that are deposited onto a stationary or moving collector. This forming process has proven to be a viable and cost-effective alternative to conventional metalworking technology for the production of metal preforms with properties superior to I/M. Spray forming has been demonstrated to create new materials such as new compositions of aluminum alloys (Ref 77, 78, 79, 80), MMCs (Ref 81, 82, 83, 84, 85, 86, 87), and those suitable for semisolid forming (Ref 88). The spray-formed products are typically free from macrosegregation and prior-particle boundaries that are occasionally present in the conventional P/M products. The spray forming is useful in extending the maximum solute content of alloying elements and achieving a finer distribution of second-phase particles in an equiaxed fine-grain structure. Such homogeneous, low-segregation, fine-scale alloy microstructures are useful for subsequent rolling, forging, extrusion, and superplastic forming operations. The development of low-density aluminum-lithium alloys has a high potential for significant weight savings in aerospace structures. Alloys produced by conventional casting methods are currently limited to lithium levels of approximately 2.5 wt%. Above this level, it is difficult to avoid the formation of coarse second-phase particles and achieve low levels of hydrogen and alkali metal impurities in the

cast ingots. Hydrogen and sodium are known to have an embrittling effect in aluminum-lithium alloys. A high hydrogen level also has detrimental effects on the weldability. These concerns can be eliminated by the spray-forming process that offers a number of significant advantages for producing aluminum-lithium alloys:

- Increasing solute content
- Refining of microstructure
- Elimination of oxide films
- Reduction of hydrogen and sodium levels

Examples of spray-formed aluminum-lithium alloys are UL30 and UL40 having increased levels of lithium and zirconium in comparison with one of the most commonly used aluminum-lithium alloys, 8090 (Al-2.5Li-1.0Cu-0.7Mg-0.12Zr). According to White et al. (Ref 89), UL30 (Al-3.0Li-1.0Cu-0.7Mg-0.3Zr) shows a 4.4% increase in specific modulus over 8090, and the strengthening is primarily by duplex particles of fine Al_3Zr (β') and Al_3Li (δ') and copper and magnesium in solid solution. These duplex particles form without the need of cold working, unlike 8090 in which stretching is required to enhance precipitation of the σ' (Al_2LiMg) phase. Thus, tensile properties of unstretched UL30 can equal those of stretched 8090, with improved isotropy. By obviating the need for cold work, UL30 can be fabricated in near-net shapes by the spray forming process. Palmer et al. (Ref 78) have spray formed UL40 (Al-4Li-0.2Zr) with lithium content reaching the limit of solid solubility at the eutectic temperature. They found the as-sprayed grain structure equiaxed with grain sizes in the range 40 to 50 μm . They also found the presence of some relatively coarse δ phase (AlLi) at the grain boundaries and some needlelike δ phase in the grains. The amount of this fine δ phase was greatest at the spray-form center and decreased toward the surface, indicating that this phase precipitated as a result of slow cooling in the solid state. As expected, no coarse Al_3Zr particles were observed in the microstructure due to a relatively high solidification rate suppressing their formation. A small amount (<1%) of porosity was present in the as-sprayed materials, which disappeared during subsequent extrusion. The extrusion grain structure was very fine and highly elongated. Some of the intergranular δ phase was present in the microstructures. However, most of the intergranular δ phase and all of the intragranular needlelike δ phase were dissolved upon subsequent solution heat treatment.

Based on the transient heat transfer during droplet solidification via finite element analysis (Ref 90), Bhagat (Ref 91) developed a model for solidification and growth kinetics of the primary silicon in spray-formed (Osprey) Al-17Si alloy (Fig. 1). The predicted results were found to agree with the experimental results. Buhrmaster et al. (Ref 92) fabricated SiC-particle- or whisker-reinforced aluminum composites by spray casting. In this process, aluminum wire feedstock is melted and combined with SiC particulates or whiskers entrained in an inert gas. Upon striking a substrate or mold, the mixture of aluminum and SiC solidifies into a composite structure. The fabricated composites lacked uniform distribution of the reinforcement. Discontinuously reinforced MMCs were fabricated by a spray codeposition method wherein the reinforcement particulates or whiskers were introduced into the metal spray leading to their codeposition with the atomized metal onto the substrate (Ref 93, 94). Typical recovery efficiency of the spray codeposition method is 60 to 90%, depending on the product form such as hollow tube, forging stock, extrusion ingot, or plate. Precise control of gas pressures and particulate feed rates are required to ensure that a uniform distribution of particulate is produced within the matrix that may be 95 to 98% dense. The shape of the final product depends on the atomizing conditions and the shape and motion of the collector. Willis (Ref 93) reported uniform distribution of the particulates in a 2014/SiC/15_p composite (15 vol% SiC particulates) fabricated by the spray codeposition method. The average particle diameter was approximately 13 μm ; the starting material was F600 SiC grit. Willis (Ref 93) also reported spray codeposition of aluminum-lithium 8090 reinforced with SiC particulates. The composites were subsequently extruded into shapes. The overall strength of the fabricated 8090/SiC_p composites in the peak aged condition did not show much improvement over the matrix material. However, the improvement in specific modulus for 8090/SiC_p (density = 2.62 g/cm³) over the unreinforced aluminum alloy (density = 2.55 g/cm³) is almost 50%. One of the primary reasons for the attractive properties of the spray-formed MMCs is the integrity of the particle/matrix interface. The interface is free from any precipitate or reaction product in Al/SiC composites according to Warner et al. (Ref 95) as reported in Ref 94. This is attributed to the relatively small (a few seconds) contact time between molten metal and SiC in the spray codeposition. Wu and Lavernia (Ref 96) fabricated 6061Al/SiC_p composites by spray-atomized codeposition technique. A maximum of 16% increase in stiffness of the composite over that of the unreinforced matrix was achieved. Other mechanical properties of the spray-formed composites are discussed later in this article.

Fig. 1 Predicted size of primary silicon in a spray-formed (Osprey) Al-17Si alloy during in-flight cooling and subsequent cooling on the substrate. The prediction is based on a new and validated model for grain growth kinetics developed by the author. ΔT , r_{crit} , and V_i represent undercooling, critical radius of silicon, and instantaneous growth rate, respectively.

In another variation of the spray-forming technology, Siemers et al. (Ref 97) used a low-pressure plasma deposition (LPPD) method for producing MMCs. In this process, a plasma ($\sim 10,000$ to $20,000 \text{ K}$) is formed in the interior of a gun (commonly referred to as plasma gun) by the discharge of a high-intensity dc arc through a flowing gas mixture (argon or N_2 with additions of 2 to 15% H_2 or helium). Powder is injected into the plasma jet through one or more injector ports. The powder is then entrained in the high-velocity (Mach 2 to 3) plasma jet, melted, transported, and impacted on a substrate where the molten droplets solidify at cooling rates of 10^5 to 10^6 K/s . The LPPD process can be used for most metals, metal carbides, or metal oxides excluding those materials that decompose before melting. Siemers et al. (Ref 97) produced composites of metal-metal, metal-carbide, and metal-oxide combinations. They also produced graded layered structures of near-theoretical density to minimize the effects of interfacial stresses developed due to the thermal mismatch between the constituents. Both continuous and discontinuous composite laminates can be fabricated by the LPPD process. Continuous laminates, consisting of alternating layers of metal and reinforcement, are produced by first depositing metal, subsequently depositing the reinforcement, and repeating the sequence to build the desired final thickness. The proportions of the phases and the layer thickness can be varied over considerable ranges to produce tailored composites. For fabricating discontinuous laminates consisting of individual splattered particle lamellae (2 to $4 \text{ }\mu\text{m}$ thick and 50 to $150 \text{ }\mu\text{m}$ diameter), a powder blend of two or more different compositions can be injected into the plasma jet.

Other Technologies. In addition to the aforementioned emerging technologies, there are other P/M processing techniques such as XD process, solid free-form fabrication (SFF), and self-propagating high-temperature synthesis (SHS), which also show potential for developing high-performance aluminum alloys and composites including functionally graded materials. In the proprietary XD process (Martin Marietta, Baltimore, MD), elemental components of the desired reinforcing phase are mixed with or incorporated into the metallic matrix material. The mixture is heated to a high temperature ($>T_m$) where a self-propagating reaction takes place. The elemental constituents react exothermally, forming a dispersion of submicroscopic reinforcing particles in the matrix. Because the particles of the reinforcing phase are formed by an exothermic reaction at an elevated temperature, they tend to be very stable through subsequent processing and use at high temperatures. However, if both elemental constituents of the particulate phase have high diffusivity in the matrix phase, then particle coarsening may occur at high temperatures. In addition, particle shape may change during heat treatment or use at elevated temperatures, if the surface energies are different. Christodoulou et al. (Ref 98) and Larsen et al. (Ref 99) used the XD process to produce a master-alloy material containing TiB_2 particles (TBA-70 sponge: 70 wt% TiB_2 and 30 wt% Al), which was subsequently used for fabricating the discontinuously reinforced aluminum composites.

Solid free-form fabrication facilitates integrated manufacturing, from computer-aided design (CAD) to finished parts, using only additive processing (Ref 100, 101). A solid or surface model is electronically sectioned into layers of predetermined thickness. The sections collectively define the shape of the part. Information about each section is then transmitted layer by layer to the SFF machine. Material is consolidated only at solid areas of the section. Subsequent layers are sequentially processed until the part is complete. It is this sequential, layered, or lithographic approach to parts manufacturing that defines the SFF technology. Selective laser sintering (SLS) and the selective laser reactive sintering (SLRS) are examples of the SFF technology for producing MMCs. Net-shape composite components can be directly produced from the elemental or prealloyed matrix powders mixed with suitable reinforcement by sintering, layer by layer, under a scanning laser beam; the reinforcement phase may be formed in situ.

Self-propagating high-temperature synthesis is a process in which the synthesis reaction proceeds through the reactant mixture in the form of a combustion wave (Ref 102, 103, 104, 105, 106). The progression of the wave is driven by the energetics of the reaction and the characteristics of the reactants. Some of the advantages of the SHS processing may include purity of the product, energy efficiency, formation of metastable phases, and simultaneous synthesis and densification. The SHS process thus has the potential to be a viable method for producing high-performance MMCs.

Functionally graded materials (FGMs) including MMCs create a continuous transition from an essentially ceramic material exposed to high temperatures to a partly or fully metallic material at the lower-temperature side of the structure (Ref 107, 108, 109, 110, 111, 112). Such graded structures have been created in an AlN/Al composite using the conventional P/M technology (Ref 108, 113).

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Mechanical Properties

The discontinuously reinforced aluminum composites, as mentioned earlier, are extruded, forged, or rolled to develop the best properties attainable by breaking up the prior-particle oxide skins. Usually a homogenization annealing is needed to dissolve the intermetallic inclusions in the matrix formed during vacuum hot pressing or HIP. Thomas and King (Ref 114) established an optimal solution treatment (545 °C, 6 h, 33 min) for an extruded P/M 2124/SiC/18_p composite for improved mechanical properties (see Table 4). In the DRA composites, the difference between the coefficients of thermal expansion (CTE) of the matrix aluminum alloys and the reinforcement is very significant. Compare the CTE of pure aluminum, which is $24 \times 10^{-6}/K$ with those in Table 3 for particulate and whisker reinforcements. The CTE mismatch leads to a high dislocation density at interfaces, thereby creating complex residual stresses in the composite, putting matrix in tension and the reinforcement in compression, during the cooling from the processing temperature. The residual stresses adversely affect the mechanical behavior and dimensional stability of the composites. Li et al. (Ref 123) eliminated the residual stresses in P/M 6061/SiC/20_p by low-temperature treatments between -60 °C (ethanol + liquid nitrogen) and -196 °C (liquid nitrogen) and subsequent reheating to room temperature.

Table 4 Properties of P/M aluminum alloys and composites

Reinforcement contents are reported in vol%, if not otherwise specified. The composition of MMCs is described using a nomenclature system developed by the Aluminum Association.

Strain to failure

Fracture

The strengthening mechanisms and fracture of the dispersion-strengthened aluminum alloys are well understood (see Ref 4). However, the same is not true for the particulate- or whisker-reinforced aluminum composites exhibiting a complex fracture behavior. Silicon carbide particle-reinforced aluminum composites are of particular interest for stiffness critical applications. They possess high shear strength in comparison with matrix materials (see Table 5). The tensile properties of these composites, however, cannot be easily predicted. Mechanical properties included in Table 4 suggest that even similar materials have large differences in yield strength and ultimate tensile strength. The ductility, in general, is significantly lower than the matrix alloys. Wang et al. (Ref 118) developed a method to quantify particle cracking behavior as a function of strain in Al/SiC/9_p (23, 63, or 142 μ m SiC particulates) composites fabricated by liquid-phase sintering. The particle crack area and the frequency of cracked particulates were found approximately linear as a function of local strain along the direction of the tensile loading. The particle crack area at a given strain was not significantly affected by reinforcing particle size, but did increase with increasing matrix strength. The frequency of cracked particulates was affected by both reinforcing particle size and matrix strength. The particulates in the composites with high matrix strength are more highly stressed and, therefore, are more likely to fracture. Consider, for example, the mechanical properties of 2124/SiC_p in Fig. 2 reported by Jain et al. (Ref 34) and those in Table 4 by Harrigan (Ref 31). Jain et al. (Ref 34) extruded 2124/SiC_p at 773 K at a ram speed of 33 mm/s for an extrusion ratio of 16 to 1 in the direct extrusion mode. The tensile strength initially increases with increase in the reinforcement volume fraction, peaks at 20 vol%, and then decreases (see Fig. 2). The maximum tensile strength obtained by Jain et al. is only about 50% of that reported by Harrigan for comparable small specimens. Similarly, the yield strength and the ductility are substantially lower for the composites fabricated by Jain et al. in comparison with that of Harrigan. Similar comparisons can be made for other systems. Table 4 includes the mechanical properties of heat treated 7075/SiC/11_p and 7075/SiC/17_p composites (Ref 119). In high-strength aluminum alloys such as 7000 series the reinforcement led to a decrease in yield stress and tensile strength, relative to the matrix alloy, together with reduced ductility. Doel et al. (Ref 119) discuss the fracture micromechanisms to explain the observed high toughness values for low ductility composites (see Table 4). It becomes clear that the choice of matrix compositions, reinforcement particle size, fabrication procedures, and even the test procedures play important roles in reconciling and reproducing desired level of mechanical properties.

Table 5 Shear strength of SiC-particulate-reinforced aluminum composites

Composite	Shear strength, MPa
6061 Al (T-6)	207
25 vol% SiC/6061 Al (T-6)	277.9
30 vol% SiC/6061 Al (T-6)	289.6

25 vol% SiC/7091 Al (T-6)	379.2
30 vol% SiC/7090 Al (T-6)	430.9
2124 Al (T-4, T-6)	283
2124 Al (T-81)	295
25 vol% SiC/2124 Al (T-4)	344.8

Source: Ref 37

Fig. 2 Mechanical properties of SiC particle-reinforced 2124 Al composites (vacuum hot pressed and extruded). Source: Ref 34

Mechanical properties of the whisker-reinforced aluminum-matrix composites are included in Table 6. The whisker-SiC/Al composites (SiC_w/Al) have high specific strength and stiffness (Ref 41, 43, 128, 129, 130, 131) as well as resistance to creep deformation (Ref 131). Komai et al. (Ref 127) found that apart from the elongation at failure, the mechanical properties of the 7075/SiC/20_w-T6 composite were superior to those of an unreinforced 7075-T6 alloy. There has been only a limited interest in whiskers other than SiC for fabricating MMCs. Recently Imai, Nishida, and Tozawa (Ref 19) evaluated the mechanical properties of extruded P/M aluminum-matrix composites with Si₃N₄ or K₂O·6TiO₂ whiskers. The properties of these whiskers are included in Table 3. Elastic modulus of the composites is about 1.6 times that of the matrix. Tensile strength of the 6061/Si₃N₄/25_w composite is 560 MPa, which is comparable to that of the SiC whisker-reinforced aluminum composites (Table 6). The ultimate tensile strength of K₂O·6TiO₂/Al is about 200 MPa at 573 K. Mechanical properties of the MAP and RSP aluminum alloys and composites are presented in Table 7. Table 8 includes the mechanical properties of the spray-formed aluminum alloys and composites.

Strain to failure

Fatigue

A number of crack-tip shielding mechanisms including crack closure via asperity wedging in a coarse-particle-reinforced composite and crack bridging via uncracked ligaments in a composite reinforced with fine particulates have been identified during fatigue crack growth (Ref 141). The fatigue crack growth behavior in an Al/SiC/20_p composite having a strong interface has been examined by Shang and Liu (Ref 142). They suggest that the fatigue crack growth in the composite can be characterized as particle controlled. The interaction of the crack-tip stress field with the particulates results in microcracking, development of uncracked ligaments behind the crack tip, and local trapping of the crack front. Recently, Davidson (Ref 143) reviewed the mechanisms and fracture mechanics of fatigue crack initiation and the growth of small and large fatigue cracks and fracture toughness in aluminum alloys reinforced with SiC and alumina particulates. Fatigue cracks initiate within clumps of and at broken reinforcement particulates, and at intermetallic particles in the matrix. Small fatigue cracks grow faster than would be anticipated from the growth of large cracks and at lower stress-intensity range (ΔK). When ΔK for small and large cracks is adjusted for plasticity-induced fatigue crack closure to give ΔK_{eff} , the growth of all sizes of fatigue cracks are comparable (see Fig. 3). The source of fracture toughness in these composites is homogeneous crack-tip plasticity; fracture occurs at limiting values of strain or work dissipation within the crack-tip deformation zone. This is consistent with the results (see Fig. 4) reported by Doel et al. (Ref 119), who studied the mechanical properties of aluminum-base particulate MMCs fabricated by cospray deposition process (Ref 147). They found that as the particle size is increased from 13 to 60 μm , for a nominally constant volume fraction and for a given aging condition, the uniaxial tensile ductility falls, but the toughness increases.

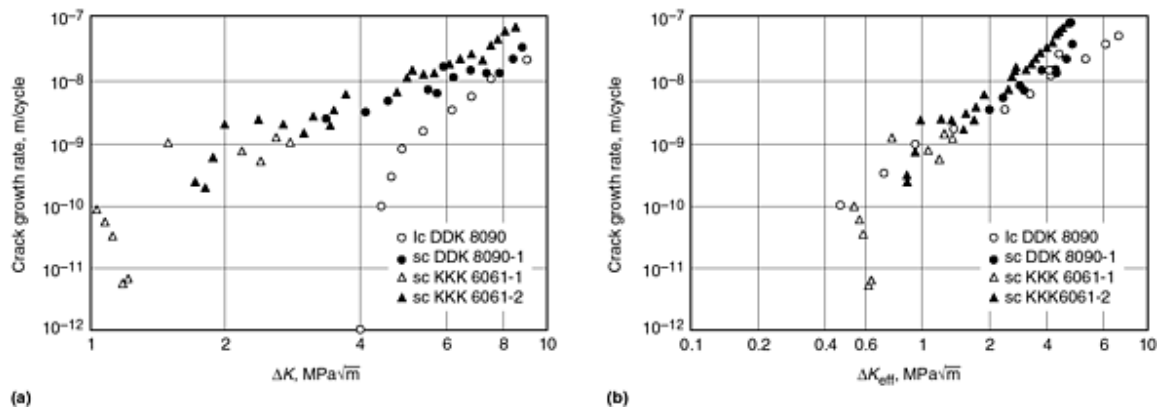

Fig. 3 The growth of large (lc) and small (sc) fatigue cracks compared on the basis of $\Delta K_{\text{applied}}$ (a) and ΔK_{eff} where closure effects have been removed (b). All data are from Ref 144 and 145 as reported in Ref 143.

Fig. 4 Local maximum principal stress distributions in SiC-particle (5 μm) reinforced aluminum composites ahead of the crack tip, just prior to failure. From Ref 19 and 146 as reported in Ref 143

Cernyar et al. (Ref 124) studied the fatigue of SiC whisker-reinforced aluminum composite under load control at 10 Hz, load ratios being 0.1 and 0.5. The composite exhibited a lower plane strain fracture toughness value than the matrix material, but a significantly higher resistance to fatigue crack growth in comparison with the wrought 2124 Al. For the composite, they obtained Paris law exponent n as 5.4, which is higher than that of the matrix (3 to 4), and a threshold stress intensity of 5.5 $\text{MPa}\sqrt{\text{m}}$ under a stress ratio R of 0.1. The complex fatigue damage mechanisms included whisker bridging, whisker pullout, crack deflection along the whisker/matrix interface, whisker tip voids, and whisker fracture. Komai et al. (Ref 127) investigated the fatigue behavior of 7075/SiC/20_w-T6. They found that a fatigue crack initiated at a whisker cluster or a crack at the specimen surface. They also found that the fatigue strength of the composite at a stress ratio of 0.1 was higher than that of an unreinforced 7075-T6 alloy. Narasimhan et al. (Ref 148) evaluated a P/M 6061/SiC/20_w composite for its thermomechanical fatigue performance at temperatures of 150 and 300 °C at a stress ratio of 0.1 under stress-controlled testing. They compared the high-temperature fatigue performance of the composite in terms of a stress-strain product plotted

against cycles to fracture. The use of the stress-strain product term alleviates the problem of often reaching conflicting conclusions based on the conventional S - N type plots for strain-controlled and stress-controlled tests on composites.

Wear

The dispersion-strengthened aluminum alloys and composites generally have the potential for enhanced wear resistance over the matrix alloy (Ref 148, 149, 150, 151, 152). Murakami (Ref 3) has reported improved wear resistance of RSP Al-20Si-2Cu-1Mg 1Mg alloy. Jin et al. (Ref 151) evaluated the wear performance of RSP Al-8.5Fe-1.3V-1.7Si-Ti and Al-16Si-5Fe-3.5Cu-1.2Mg-SiC_p against steel (65 HRC) over a range of sliding speed (0.16 to 1.26 m/s) under a load of 42 N at ambient and 150 °C under dry conditions. For both the materials, the wear rate first decreased with increase in sliding speed, reached a minimum and then increased at higher sliding speed. The transition sliding speed appeared to change the wear mechanism from abrasive wear (at low speed) to wear accompanying plastic deformation (at higher speed). Pin-on-disk wear tests on AA6061 composites containing Saffil, SiC_p, or mixtures of both ceramics against SiC grit and steel counterfaces, showed that composites containing only Saffil had inferior wear resistance to those containing the same volume fraction of SiC_p (Ref 149). Bialo and Duszczek (Ref 152) studied the wear of Al₂O₃/Al composite fabricated by liquid-phase sintering using a pin-on-disk apparatus for pressure (p) and sliding speed (v) range of 0.3 to 3 MPa and 0.1 to 5 m/s, respectively. They observed that the " p v " product is the most significant factor describing the wear process; stable friction and wear behavior of the material occurs only for p v below a threshold value of 3 MPa · m/s. They also observed that the reinforcement particle size has less significant effect on the wear rate than the p v product. Wang and Rack (Ref 153) have reported good wear resistance of SiC_w/Al. Dry sliding wear of DRA composites has been reviewed by Sannino and Rack (Ref 150). In general, DRAs offer substantially better wear resistance than the matrix alloy. However, under particular conditions and wear mechanisms, the wear performance of the overall DRA-metal couple is similar to or lower than the matrix alloy-metal couple. Furthermore, conflicting results regarding the effect of the different tribological parameters on the wear performance of DRAs are observed. This is primarily attributed to interactions of wear parameters; these interactions are currently not well understood.

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

High-Temperature Performance

The dispersion-strengthened aluminum alloys and composites are most attractive for their high-temperature strengths. Particulate or whisker reinforcement enhances their high-temperature capabilities further. Zedalis et al. (Ref 30), for example, developed high-temperature discontinuously reinforced aluminum composites for elevated-temperature applications by incorporating SiC particulate into a rapidly solidified, high-temperature Al-Fe-V-Si (alloy 8009) matrix. On a specific stiffness basis, this composite is competitive with Ti-6Al-4V and 17-4 PH stainless steel to temperatures approaching 753 K (see Fig. 5). In this section, the high-temperature performance of aluminum P/M alloys and composites are discussed in terms of their aging effects on tensile strength and toughness, strength at elevated temperatures, and creep.

Fig. 5 Elevated-temperature specific stiffness of high-temperature discontinuously reinforced aluminum composites compared to that of titanium and stainless steel, reported in Ref 30

Aging Effects

The aging characteristics of spray-atomized and codeposited 6061Al/SiC_p composites are discussed by Wu and Lavernia (Ref 96). There was no evidence of any interfacial reaction products in the composites. They found an enhancement of the interfacial bond strength due to the interdiffusion of the alloying elements into the reinforcing particulates, upon heat treatment. Downes and King (Ref 154) evaluated the fracture behavior and fracture toughness of 8090/SiC/20_p (wt%) as a function of matrix aging condition. The composite was produced by BP Metal Composites (Farnborough, UK) using a P/M route involving HIP, hot forging, and finally hot rolling to a plate thickness of 15 mm. They found the toughness values almost independent of reinforcement size (3, 6, and 23 μ m). Aging at 443 K resulted in a monotonic decrease in toughness with increasing strength up to the peak condition, with no subsequent recovery in toughness on overaging.

Bhagat and coworkers (Ref 155, 156, 157, 158, 159) investigated the aging characteristics of SiC-whisker-reinforced 6061 Al composites ($V_f = 0.20$) received from Advanced Composite Materials Corporation (Greer, SC) in the form of 11.4 by 10.2 by 3.8 cm slabs. The composite was fabricated by a proprietary P/M method followed by extrusion in order to align the whiskers and increase tensile strength in the extrusion direction. The whiskers were found approximately aligned in the direction of extrusion as described in Ref 156. Both tensile dog-bone specimens and hardness samples were heat treated. These samples were placed into steel packets to protect against surface oxidation throughout the entire heat treatment process. The hot-worked condition of the as-received material was removed by first solutionizing the composite. A ramping period of 3 h (2.78 K/min) was used to obtain a stable solutionizing temperature of 803 ± 5 K. This temperature was held for 15 min, and then the samples were immediately water quenched. The solutionized samples were aged for periods of 5 min to 3 h at 473 K and for periods of 5 min to 500 h at 423 K. Following the aging, microhardness was measured at a load of 800 g using the Vickers hardness scale. Twenty values of microhardness were used to obtain the average hardness of the composite under various aging conditions.

Figure 6 includes the measured microhardness of SiC_w/6061 Al aged at 423 and 473 K. The peak microhardness value is 137.7 kg/mm² at 473 K, while at 423 K the peak microhardness value is 147.9 kg/mm². Peak aging times were 60 min and 18 h for aging temperatures of 473 K and 423 K, respectively. As a comparison, the peak microhardness for the resolutionized wrought 6061 Al is 111.7 kg/mm². Figure 6 demonstrates that the composite has significantly higher microhardness than the wrought 6061 Al. The high microhardness of the composite is attributed to the cumulative effect of the matrix material and whisker reinforcement. However, the trend of the aging response of the composite is primarily dependent on the aging response of the matrix. As the matrix hardens, the hardness of the composite increases until the peak is reached, followed by

a drop in hardness due to the overaged matrix. The plots in Fig. 6 demonstrate the accelerated aging response of the composite as compared to the wrought 6061 Al. At the aging temperature of 423 K, peak hardness of the composite is achieved 25 h earlier, and it is 20% higher than the peak hardness of 6061 Al. For the composite, the lower aging temperature of 423 K causes the peak value of hardness to be 7% greater and 17 h later with respect to the higher aging temperature of 473 K. It is well known that the composite has a large dislocation density because of the thermal mismatch between matrix and fiber (Ref 160, 161). The high dislocation density speeds up the nucleation and growth of precipitates leading to the rapid precipitation hardening of the matrix in the composite (Ref 162). Such an accelerated aging for DRAs is also reported by other investigators (Ref 153, 163, 164).

Fig. 6 Aging response of 6061/SiC/20_w and wrought 6061 Al. The composite shows accelerated aging response.

The stiffness of the solutionized and aged composite remains constant around 105.68 GPa (as shown in Fig. 7), which is 28% lower than that of the as-received extruded composite having a stiffness of 147.55 GPa. Stiffness values of the aged composite are of practical significance for high-temperature applications, and they are about 53% higher than that of the wrought 6061-T6 Al. The tensile strength of SiC_w/6061 Al was measured as a function of aging time. Results in Fig. 8 show that the strength of the composite reaches a maximum value in the peak-aged condition. This shows that the dislocation entanglement and the finely dispersed precipitates lend maximum strength at the peak hardness. A 27% decrease in tensile strength is seen from the as-received condition. This is due to the solutionizing step that eliminated the prior hardening or strengthening due to the extrusion of the composite. Plots in Fig. 8 provide further evidence of the accelerated aging of the composite as discussed earlier. Maximum strength in the composite is reached 37 h earlier than 6061 Al with an increase of 40% in strength when measured from peak to peak. Maximum strength in the composite is maintained from 18 to 55 h; whereas 6061 Al peaks in strength at 55 h. Despite the overaging of the matrix (18 to 55 h), the strength of the composite remains almost constant. Aging the composite for 500 h reduces the ultimate tensile strength from 516 to 398 MPa, which still results in an increase of 27% over that of the identically aged wrought aluminum alloy. Ductility of the aged composite was found substantially higher than that of the as-received material which had a maximum elongation of 2%. Strain to failure was obtained by the strain versus load plot up to the fracture load. The composite shows minimum strain to failure in the as-received condition (Fig. 9). The general trend of the elongation--rapid increase in ductility upon solutionization and aging, then decreasing, reaching a low value, and then gradually increasing with the aging time--is as expected. The work of fracture for the composite material is maximized in the overaged condition (500 h at 150 °C) having a value of 8.07 MJ/m³ compared to the as-received condition, which has a work of fracture of 0.35 MJ/m³. Ductile fracture as a result of microvoid coalescence can be seen in the tensile test fracture surface shown in Fig. 10. The fractograph represents a peak-aged composite showing that the whiskers serve as the initiation sites for microvoids. Nutt (Ref 165) has studied and modeled void nucleation at the whisker ends in SiC_w aluminum composites. He found through transmission electron microscopy (TEM) analysis that the voids initially formed at the corners of the whiskers. Figure 11 shows a pulled-out whisker relatively free of interfacial reaction products.

Fig. 7 Young's modulus versus aging time for solutionized 6061/SiC/20_w aged at 423 K. After an initial drop, the Young's modulus is not much affected by the aging time.

Strength at Elevated Temperatures

Bhagat and coworkers (Ref 155, 156, 157, 158) studied the elevated temperature mechanical properties of discontinuously reinforced aluminum-matrix composites. The unsolutionized SiC_w/6061 composite and wrought 6061-T6 Al specimens were subjected to elevated-temperature tensile testing over the range of 423 to 623 K. High-temperature strain gages were mounted to accurately determine Young's modulus and the ultimate tensile strength. Testing temperature was maintained within ± 3 K of the desired set point. A uniform temperature distribution was achieved in the composite specimen by soaking at the testing temperature for 20 min prior to loading. Figures 12 and 13 depict the results of test temperatures on stiffness and ultimate tensile strength, respectively. Stiffness for the composite remains almost constant in the temperature range of 423 to 623 K, while strength decreases gradually. In the as-received condition, the composite exhibits a 111% improvement over 6061 Al in stiffness. At elevated temperatures, the stiffness of the composite exhibits a 56% improvement as compared to wrought 6061 Al. Comparing the ultimate tensile strength of the composite and 6061 Al, the whisker reinforcement at room temperature gives 114% improvement over 6061 Al, decreasing to only a 60% advantage at 623 K. The strength of the composite at elevated temperatures becomes matrix dominated as it is expected for discontinuously reinforced MMCs. An SEM fractograph showing ductile fracture because of microvoid coalescence is given in Fig. 14 for SiC_w/Al tested at 561 K. It can be seen in Fig. 14 that the whiskers form initiation sites for microvoids.

Creep

Several researchers have studied the creep behavior of aluminum-base alloys and composites (Ref 131, 157, 158, 166, 167, 168, 169, 170, 171, 172, 173, 174, 175, 176, 177, 178, 179, 180, 181, 182, 183). The deformation mechanisms for creep of metals and alloys include:

- Dislocation glide due to slip
- Dislocation climb leading to subgrain formation
- Sliding of grain boundaries
- Diffusion of vacancies

These mechanisms may be related to creep deformations of the matrix in the composite, but the influence of the reinforcement is not well understood. The dispersion-strengthened alloys and reinforced composites, generally, show a change of stress exponent from a low to a relatively high value (see Table 9). The creep strength of these high-temperature aluminum alloys is significantly higher than the conventional wrought aluminum alloys. In addition, the creep resistance for the whisker-reinforced aluminum composites has been shown to increase with increasing volume fractions of the reinforcement (Ref 181). Their improved creep resistance can be attributed to the effective load transfer from the matrix to the whiskers and the inhibition of dislocation motion by the whiskers. Bhagat and coworkers (Ref 157, 158) performed the creep testing of 6061/SiC/20_w composite on an 88.96 kN capacity Arcweld creep rupture machine. This machine is equipped with an automatic horizontal leveling arm and a three-zone Arc-weld furnace. The temperature of the furnace was monitored with thermocouples located within the furnace and located next to the gage length. Displacements were measured by an LVDT attached to stainless steel grips. The creep tests were conducted over a temperature range of 505 to 623 K and for applied stresses of 60 to 200 MPa. The steady-state creep rates ($\dot{\epsilon}_{ss}$) for the MMCs as a function of stress (σ) and temperature (T) are represented by the power-law creep equation, which has been historically used for the unreinforced matrix alloys:

$$\dot{\epsilon}_{ss} = A \sigma^n \exp(-Q_a/RT) \quad (\text{Eq 1})$$

The stress exponent (n), activation energy (Q_a) and the constant A of the creep power law (Eq 1) are important parameters in creep studies. The steady-state creep involves steady deformation at high temperatures and stresses. Bhagat et al. (Ref 158) experimentally determined that for an applied stress under 100 MPa, a well-behaved second-stage creep rate existed for the 6061/SiC/20_w composite. The activation energy of the composite was determined by an isostress plot of the natural log of $\dot{\epsilon}_{ss}$ and $1/T$ as shown in Fig. 15. A comparison of the activation energy value obtained by Bhagat et al. (Ref 158) is made in Table 9 with the published results of other investigators. Differences between the values of the activation energy can be attributed to the solution treatment of the samples prior to the creep testing. Bhagat et al. (Ref 158) determined the stress

exponent (n) of 16, representing the slope of the plot shown in Fig. 16. Figure 16 also shows a much smaller value of n in the low-stress regime, which can be ignored considering the high-strength capabilities of the composites. The high-stress regime n of 16 signifies that the composite is more stress sensitive compared to the wrought aluminum. This is true because the stress concentrations are developed at the whisker ends wherein the damage is initiated (see Fig. 17). The fractograph in Fig. 17 represents a creep-rupture surface of the composite tested at 561 K under a load of 100 MPa; the expected dimple morphology is noticeable. The steady-state creep rates for the whisker-reinforced composite, included in Table 10, clearly demonstrate that the composite has improved resistance to creep in comparison to the wrought 6061 Al.

Table 9 Steady-state creep results for P/M aluminum alloys and composites

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Deformation Processing

Secondary processing such as rolling, forging, or extrusion in conjunction with suitable heat treatment is required to develop desired physical and mechanical properties of the aluminum alloys and the DRA composites in addition to producing useful shaped structures (Ref 35, 37, 115, 184). The formability of DRAs, however, is greatly restricted by the incompatible deformation characteristics of the soft matrix and the hard reinforcement. The optimal processing parameters for the matrix materials generally do not apply to the reinforced composites.

Rolling, Forging, and Extrusion

Near-net shape components of DRAs are produced by closed-die forging methods developed for high-strength aluminum alloys. Large components are forged directly from billet using a series of blocker and finish dies. Small parts can often be forged from extruded stock in fewer processing steps. Sheet and plate are hot rolled on conventional rolling mills from extruded bar or extruded-and-forged plate. Most P/M billets are extruded to rods or rectangular bars using lubricated conical or streamline dies. Rods can be reextruded into a variety of shapes using conventional shear-face dies. It has been reported that the forged aluminum parts have strength 40 to 60% higher than nonforged parts (Ref 1). Fatigue endurance limit is double that of nonforged P/M parts. Alloys 601AB, 602AB, 201AB, and 202AB are designed for forging. All of the aluminum P/M alloys respond to strain hardening and precipitation hardening, providing a wide range of properties. Properties of cold-formed P/M alloys are increased by a combination of strain-hardening densification and improved interparticle bonding.

Jokinen and Wiik (Ref 185) studied high temperature formability and mechanical properties of aluminum-matrix composites. They suggested that bulk forming operations applying large compressive forces (extrusion or die forging) are to be preferred when forming the composites. Bhat et al. (Ref 115) studied the constitutive flow behavior of 1100/SiC/10_p under hot-working conditions to generate a processing map. They suggested that the composites be extruded in the dynamic recrystallization regime at a temperature of 500 °C, wherein the dynamic recrystallization reconstitutes the microstructure and redistributes the prior-particle-boundary defects for improved formability. Cernyar et al. (Ref 124) rolled 2124/SiC/20_w into plate for improved properties. Various structural shapes, in addition to round and rectangular tubing, have been produced from composites containing up to 25 vol% SiC_w (Ref 116).

Superplastic Forming

Superplasticity is the ability of polycrystalline material to exhibit, in a generally isotropic manner, very high tensile elongation prior to failure. The high-strain-rate superplasticity (HSRS) is of great interest because it is expected to result in economically viable, near-net shape forming techniques for practical applications. Several P/M aluminum alloys and composites exhibit superplastic behavior at high strain rates over 10⁻² s⁻¹ (Ref 186, 187, 188). Figure 18 shows that the high-strain-rate superplasticity is associated with a very small grain size (<3 μm). It signifies that a fine grain size is a necessary condition for superplasticity, but it is not a sufficient condition for the observed HSRS phenomenon. Tensile elongations of 1250 and 1400% have been achieved in the MAP IN9021 and 6061/SiC/20_w, respectively (see Table 11). Figure 19 shows that the mechanically alloyed IN9021 and IN9021/SiC/15_p exhibit superplastic deformation. Mabuchi and Imai (Ref 189, 190) have reported fabrication of Si₃N₄-reinforced 2124 or 6061 Al composite having superplasticity. The 8090/SiC/17_p

composite in conjunction with superplastic forming has been used for fabricating net-shape components such as a module door for aircraft (Ref 120). Grain-boundary sliding is the principal deformation mechanism during the HSRS flow. The accommodation processes that must take place to allow continued grain boundary sliding include:

- Partial melting at grain boundaries
- Melting at interface
- Adiabatic heating as a result of large strain deformation at high strain rates
- Dynamic recrystallization
- Grain-boundary diffusion
- Lattice diffusion

These accommodation processes, however, are not well understood.

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Technological Challenges

In spite of significant advances in developing high-performance aluminum P/M alloys and composites, there remain major technological challenges that include reproducibility and reliability of performance, machining, joining, and recycling for making these materials attractive and affordable for large-scale commercial applications.

Reproducibility

Process models can be used to simulate the consolidation process, predict stress states and relative density distribution during and after processing, design special tools, and design processing schedules to ensure reproducibility, thus avoiding high cost of trial-and-error-based experiments (Ref 191, 192). For example, the mechanisms that contribute to densification of powder materials during HIP include plastic yielding, power-law creep, and lattice and boundary diffusion. Ashby and coworkers (Ref 193, 194, 195, 196) have developed models for each densification mechanism, in each stage of densification, for the case of pure hydrostatic stress. These mechanisms are greatly influenced by the presence of ceramic particulates or whisker reinforcements. Even in the absence of any reinforcement, nonhydrostatic stress fields arise during consolidation due to the shielding effect of a canister, the geometry of a specimen, and the density and temperature gradients within a specimen. This led to a series of mechanism-based micromechanical modeling efforts (Ref 197, 198, 199, 200, 201, 202). The presence of nonhydrostatic stress states necessitates the inclusion of deviatoric stresses in the constitutive laws governing consolidation leading to the development of PROSIM, a general-purpose finite element program (Ref 191, 203, 204), and other computer programs (Ref 205) capable of analyzing deformation due to time-independent plasticity (plastic yielding) and time-dependent plasticity (power-law creep and diffusion creep). Bhagat and Rajesh (Ref 206) studied the consolidation of aluminum particles using Ashby's HIP map program. Based on the HIP map predictions, they found that the fine aluminum particles can be fully densified at an unrealistic low temperature by hot pressing (Fig. 20). This suggests that the constitutive relationships used in the HIP map program are not appropriate for fine particles (<1 μm).

Fig. 20 Predicted temperatures according to Ashby's HIP map program for fully densifying aluminum powders by hot pressing. The plots represent 24 runs of HIP map considering eight different sizes of powder over three pressures. For each run of HIP map, the powder is assumed to have one fixed particle size.

Machining and Joining

During conventional machining, the ceramic reinforcements dull the cutting tools, thereby reducing the machinability of the composites. The use of expensive diamond or cubic boron nitride cutting tools is not practical from cost consideration. Noncontact machining techniques such as laser processing (Ref 32) and abrasive waterjet cutting (Ref 33) appear attractive for machining these materials. Laser cutting of the SiC-whisker-reinforced aluminum composites is hampered by the formation of aluminum carbide as reported by Meinert and coworkers (Ref 207, 208, 209, 210, 211, 212). They observed an aluminum carbide reaction layer on the cut surface of the composites. In addition, a significant amount of dross containing aluminum carbide remained attached to the bottom of the cut. This may be due to the potential reaction between the molten aluminum and the SiC whiskers, forming a highly viscous mixture of aluminum carbide and silicon. The assist gas moves the mixture toward the bottom of the cut, but is unable to expel it completely, due to its high viscosity. This results in a thin layer of aluminum carbide on the cut surface and a buildup of aluminum carbide dross at the bottom of the cut. The amount of dross attached to the bottom of the cut can be quite significant; the average height of the dross attached to the bottom of a 2 mm thick sample of the 6061/SiC/20_w composite was 1.25 mm. Several different assist gases, power levels, and travel speeds were used in an attempt to minimize the dross formation. Variation of processing parameters had little effect on the cut quality. The formation of aluminum carbide appears to override the ability to obtain laser cuts with a clean surface.

The weldability of the aluminum P/M alloys and composites is limited by the residual hydrogen content and wide freezing range. The hydrogen is associated with the oxides on the surface of the metal powder. Upon melting, the adsorbed hydrogen coalesces and forms pores in the fusion zone and heat-affected zone (HAZ). Minimization of the fusion-zone porosity and retention of the base alloy microstructure in the weld zone are, therefore, the major factors precluding the application of many conventional fusion-welding techniques. These alloys require the use of autogenous electron beam and pulsed Nd:YAG (neodymium:yttrium-aluminum-garnet) laser welding, which show only occasional evidence of fusion-zone porosity (Ref 213). Ellis (Ref 214) summarizes advantages and disadvantages of various joining techniques for aluminum MMCs. Solid-state (both diffusion bonding and friction welding) methods have proved very successful in joining these materials, though geometry of components may preclude these techniques. Fusion-joining techniques are often hampered by interactions between the matrix and the reinforcement material. Laser processing, however, can offer many advantages over conventional techniques. Certain precautions are necessary prior to laser-beam welding of P/M MMCs (Ref 35, 215, 216). The composites should be thoroughly degassed by vacuum annealing to minimize porosity in the weld-fusion zone. In addition, weld energy input should be controlled for preventing formation of Al₄C₃ in the SiC/Al composites.

Similar to the problem encountered during laser cutting, laser welding of SiC-reinforced aluminum composites is hampered due to the following chemical reaction between liquid aluminum and solid SiC:

The formation of brittle aluminum carbide platelets reduces the strength of the weld. Further degradation of the weld takes place due to the dissolution of aluminum carbide in aqueous and moist environments. The formation of aluminum carbide leads to a substantial increase in the viscosity of the melt (Ref 217). The use of aluminum alloys containing relatively high amounts of silicon is one of the most commonly used methods for eliminating the formation of aluminum carbide during molten-metal fabrication techniques. Because the formation of aluminum carbide is inhibited by the high silicon content and a relatively low melt superheat, the fusion joining of these materials is possible if the weld pool temperature is kept below that at which aluminum carbide begins to form (Ref 218). In addition to the chemical reactions, several other factors may affect the quality of the weld. For example, the reinforcement materials generally do not melt or dissolve and may segregate in the weld during the laser processing. Another complication is the increased viscosity of the molten pool due to the presence of the reinforcement. This can lead to a sluggish weld pool and incomplete joining.

Meinert and coworkers (Ref 207, 208, 209, 210, 211, 212) used a commercially available P/M wrought 6061/SiC/20_w composite (Advanced Composite Materials Corporation, Greer, SC) to study the feasibility of laser processing. A Coherent General EFA 51, 1.5 kW, enhanced fast axial flow, CO₂ gas laser, with continuous wave (CW) and pulsed TEM₀₀ mode capability was used during the investigation. A focal arrangement utilizing a 6.35 mm lens produced a focused spot size of 120 μm at an output wavelength of 10.6 μm, in the infrared range. Shielding or assist gas was provided coaxial to the beam, and a computer-controlled micropositioning system was employed to manipulate the test specimens during the laser processing. The assist gas discharges the molten metal from the cut, in the case of laser cutting. In contrast, the molten metal solidifies under an inert shielding gas, in the case of laser-beam welding. The shielding gas prevents the formation of unwanted reactions and gas absorption.

The amount of laser energy absorbed by the material is one factor that determines the effectiveness of the laser processing. In general, a high absorptivity improves the processing efficiency, thereby allowing deeper penetration and faster processing speeds. Aluminum has a relatively high reflectivity, which decreases its ability to effectively absorb, or couple with the laser beam. The reinforcement materials such as aluminum oxide and SiC absorb much more energy at 10.6 μm wavelength. Initial experiments revealed that energy absorbed by the composite materials was greater than the unreinforced aluminum. The improved energy absorption is attributed to the change in reflectivity of the bulk material by the addition of the reinforcement. There appears to be a correlation between the emissivity of the material and the effectiveness of laser processing. As mentioned before, the silicon addition has been successfully used to allow the fusion joining of SiC reinforced aluminum composites (Ref 218). Suppression of the formation of aluminum carbide, however, can be achieved by additions of titanium and zirconium, which are strong carbide formers. Titanium carbide and zirconium carbide are also chemically stable compounds and are not subject to dissolution in water. Meinert and coworkers (Ref 207, 208, 209, 210, 211, 212) laser welded 6061/SiC/20_w composite using commercially pure titanium additions that effectively suppressed the formation of aluminum carbide. Figure 21 shows very fine dendritic structures of TiC (1 to 5 μm) as confirmed by the electron microprobe analysis. The dendrites are evenly dispersed throughout the fusion zone. The analysis of the welds made with zirconium additions showed similar results.

Fig. 21 Micrograph of a laser-welded 6061/SiC/20_w composite using titanium additions. Fine dendritic structures of TiC are evenly dispersed throughout the fusion zone.

Advanced Aluminum Powder Metallurgy Alloys and Composites

Ram B. Bhagat, The Pennsylvania State University

Applications Outlook

In spite of a worldwide interest in developing the high-performance aluminum P/M alloys and composites, these materials have found only limited applications. With a few exceptions such as the spray-formed (Osprey) aluminum-silicon alloys for automotive parts, large-scale commercial use of the aluminum P/M alloys and composites currently does not exist. However, the outlook for potential applications of these materials in aerospace, automotive, business machines, power tools, appliances, and ordnance industries appears very bright. A few examples include:

- *Aerospace components:* Lightweight P/M aluminum alloys are attractive for major airframe primary-load-carrying structural members (Ref 219). The dispersion-strengthened aluminum-iron alloys are expected to replace conventional high-strength alloys and titanium alloys used in the manufacture of selected aerospace components such as fan and compressor cases, stiffeners, vanes and blades in gas turbine engines, fins, winglets, and rocket motor cases in missiles, and helicopter rotors. High-strength P/M 7090 is used for

landing-gear assemblies (link, door actuators) (Ref 1). A high-stiffness SiC_p-reinforced 6092 Al composite has been fabricated into a ventral fin for F-16 jet fighter; the composite provides stiffness 50% higher than monolithic aluminum. The composite is expected to provide more than twice the expected life of the original fins (Ref 220). A module door for aircraft was fabricated by superplastic forming of 8090/SiC/17_p (Ref 120).

- *Automotive parts:* Due to their light weight, high stiffness, and wear resistance, the P/M aluminum-silicon alloys are attractive for automotive parts such as shock absorber, piston, drive shaft, brake rotor disk, engine cylinder block, autobody structures, chassis components, compressor vanes, connecting rod, and sensor housing. Ishijima et al. (Ref 121) developed forged P/M aluminum-silicon alloys for connecting rods for general-purpose engines. The fabricated connecting rods are found to be more than 30% lighter and thinner in comparison with conventional die-cast rods. Near-net shape compressor parts were fabricated by Takeda and Hayashi (Ref 122) using Al-AlN and Al-AlN-SiC composites by reaction sintering of rapidly solidified aluminum alloy/composite powder. The fabricated parts showed improved wear resistance.
- *Business machines:* Drive-belt pulleys, hubs, end caps, connecting collars, and gears
- *Appliances:* Sewing machine parts and thermostat control gears
- *Electrical and electronic applications:* Heatsinks, substrate/housing for microelectronics package, and spacers on structural electric transmission towers
- *Ordnance:* Rifle receiver forging, mortar and artillery projectile fuses, cartridge cases, artillery shells, and rocket warheads

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

Introduction

COPPER-BASE POWDER METALLURGY (P/M) products rank third after iron and steel, and aluminum-base P/M products in terms of volume. The estimated shipments of copper and copper-base alloy powders in 1996 were about 20,500 Mg (23,000 short tons) in North America. The shipments in Europe were estimated to be about 14,000 Mg (15,600 short tons) while the shipments in Japan were estimated at about 6200 Mg (7000 short tons) (Ref 1).

The use of copper in the P/M industry dates back to the 1920s, when commercial porous bronze bearings were developed independently in the research laboratories of General Motors Corporation (Ref 2, 3) and Bound-Brook Oilless Bearing Company (Ref 4). These self-lubricating bearings still account for the major portion of P/M copper and copper alloy applications. Other important applications for copper and copper-base P/M materials summarized in Table 1 include friction materials, brushes, filters, structural parts, electrical parts, additives to iron powders (alloying as well as infiltration), catalysts, paints, and pigments.

Table 1 Applications of copper-base powders

Application	Powder type
Automotive and machinery	
Bearings and bushings	Bronze, copper-lead, and copper-lead-tin
Brake bands and linings	Copper, brass, copper-lead, copper-lead-tin
Bushings	Bronze
Control panels/instruments	Nickel-silver
Counterweights	Copper-tungsten
Chemical and industrial	
Chemical catalyst	Copper
Filters	Bronze
Flame arrestors	Bronze
Fungicide additive	Copper
Soil conditioning	Copper
Valves and pumps	Copper-nickel
Coatings and paints	

Antifouling paints	Copper
Conductive paints and plastics	Copper and brass
Decorative paints	Copper, brass, bronze
Lacquers	Brass, bronze
Mechanical (peen) plating	Copper, brass
Spray coating	Copper, brass
Vacuum metallizing	Copper
Construction hardware	
Conductive and nonsparking floors	Copper
Decorative plastics	Copper, bronze, and brass
Domestic water filters	Brass
Locks and keys	Brass, bronze
Nuts	Brass
Pipe joint compounds	Copper
Electrical and electronic	
Brushes	Copper
Brush holders	Nickel-silver
Contacts	ODS Copper
Heatsinks	Copper
Printed circuits	Copper
Semiconductor stud bases	Copper, dispersion-strengthened copper
Telephone components	Brass, bronze
Switch and contactor components	Copper, brass
Incandescent lamps	ODS Copper
X-ray, microwave tube parts	ODS Copper
Lubricants	
Antigalling pipe joint compounds	Copper
Copper lubricants	Copper
Plastic-filled metal	Copper, bronze
Self-lubricating (oil-filled) parts	Bronze
Manufacturing and machining	
Abrasive wheel bonding	Copper
Brazing compounds	Copper, bronze, brass
Electrodischarge machining	Copper
Electrochemical machining	Copper
Resistance welding electrodes	Copper, dispersion-strengthened copper
Ordnance	
Armor-piercing cores	Copper
Fuse parts	Brass
Projectile rotating bands	Copper, brass
Other equipment or uses	
Business machines	Brass
Coins, metals, medallions	Copper-nickel
Cordless devices	Copper
Fingernail polish	Copper
Lawn and garden equipment	Bronze
Photographic equipment	Bronze, brass, nickel-silver

This article briefly reviews copper-base P/M alloys and composites in terms of the powder types, their processing, and properties. Major applications (such as self-lubricating bearings and filters) are briefly described (Ref 5, 6). For more detailed information on application performance, see the articles "Porous Powder Metallurgy Technology" and "Powder Metallurgy Bearings" in this Volume.

In general, physical and mechanical properties of near-full (theoretical) density copper and copper alloy P/M structural parts are comparable to cast and wrought copper-base materials of similar composition. However, P/M copper parts vary in density from the low density typical of self-lubricating bearings or filters to the near-full density of electrical parts. The physical and mechanical properties depend greatly on the density as a percentage of theoretical density.

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

Copper Powders

Copper powders of 99+% purity are commercially available. The four major methods of producing such copper powders are:

- Atomization
- Oxide reduction
- Hydrometallurgy
- Electrolysis

Of the above methods, atomization and oxide reduction are presently practiced on a large scale globally. Hydrometallurgical and electrolytic copper powders have not been manufactured in the United States since the early 1980s, but they are produced in Europe and Japan.

Table 2 shows a comparison of some of the typical fundamental powder characteristics of commercial copper powders made by the four production processes. Each process produces a unique particle shape and surface area.

Table 2 Characteristics of commercial copper powders

Type of powder	Composition, %			Particle shape	Surface area
	Copper	Oxygen	Acid insolubles		
Electrolytic	99.1-99.8	0.1-0.8	0.03 max	Dendritic	Medium to high
Oxide reduced	99.3-99.6	0.2-0.6	0.03-0.1	Irregular; porous	Medium
Water atomized	99.3-99.7	0.1-0.3	0.01-0.03	Irregular to spherical; solid	Low
Hydrometallurgical	97-99.5	0.2-0.8	0.03-0.8	Irregular agglomerates	Very high

Brief descriptions of each process and relevant powder properties for the four major processes are discussed below. For additional information on these areas, see the article "Production of Copper Powders" in this Volume.

Atomization. In this process, molten copper flows through a refractory nozzle, and the liquid stream is disintegrated into droplets by an impinging jet of water or gas. The droplets solidify into powder particles. The size and shape of these particles is governed by the atomizing medium, pressure, and flow rate. Gas atomization produces spherical particles, while the shape of water-atomized powder particles can be controlled from almost spherical to irregular by controlling the interaction between the water jet and the metal stream. Higher pressures and lower flow rates favor finer powders; average particle sizes less than 325 mesh (45 μm) are feasible.

Water is the preferred atomizing medium for producing copper powder. The atomized powder is often subjected to an elevated temperature reduction (to reduce any oxides formed during atomization) and agglomeration treatment to improve its compacting properties. Table 3 shows the typical properties of commercial water-atomized copper powders.

Table 3 Properties of commercial grades of water-atomized copper powders

Copper, %	Chemical properties, %		Physical properties						
	Hydrogen loss	Acid insolubles	Hall flow rate, s/50 g	Apparent density, g/cm ³	Tyler sieve analysis, %

- (a)Water atomized plus reduced.
- (b)Contains magnesium.

Oxide Reduction. This process involves oxidizing copper (particulate copper scrap, electrolytic copper, atomized copper, etc.) and milling the oxide into powder. The oxide powder is reduced at elevated temperature by solid or gaseous reducing agents, and the resulting sintered cake is milled into powder. The particle size is controlled through milling of the starting oxide and the reduced sinter cake. The milled copper powder particles are irregular and porous. A broad range of pore characteristics can be obtained by controlling the reduction conditions.

The particle size, shape, and pore characteristics determine the compacting properties of the powder and the part produced. Table 4 shows the typical properties of a commercial copper powder produced by the oxide-reduction process.

Table 4 Properties of commercial grades of copper powder produced by the oxide reduction process

Hydrometallurgy. This process produces copper powder from copper ore concentrates or scrap copper. Copper is leached from these materials with sulfuric acid or ammoniacal solutions, and the resulting solution is separated from the residue by filtration. The solution is passed over iron scrap to precipitate copper as powder, generally called cement copper. The wet powder is dried in a reducing atmosphere, then milled, classified, and blended to obtain the desired particle size distribution.

The powder has fine particle size, with relatively low apparent density and high green strength. Low purity in general, and high iron content in particular, restrict the use of cement copper in P/M applications. Its irregular particle shape and high specific surface area, however, impart good green strength and make it useful in friction applications.

Electrolysis. In this process copper is electrodeposited to obtain a spongy powder deposit at the cathode rather than a smooth, adherent deposit. The electrolyte is typically an aqueous solution with a low copper ion concentration and a high sulfuric acid concentration. This, coupled with a high cathode current density, promotes formation of a loose powdery deposit. The anode and the cathode are pure electrolytic copper with the cathode being typically one tenth the size of the anode (Ref 7). After deposition, the powder is washed to remove all traces of the electrolyte and can be annealed in a reducing atmosphere. The reduced copper product is milled, screened, and blended to the desired particle size distribution.

Electrolytic copper powder is generally of high purity; however, impurities more noble than copper are codeposited. Powder morphology is typically dendritic. A wide range of powders with varying apparent densities and high green strengths can be obtained by electrolysis. For applications requiring a powder with a low apparent density and a high surface area, additions to the electrolytic bath can be made that decrease dendrite arm thickness.

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

Copper Alloy Powders

Alloy powders are available in various compositions, including brasses, nickel silvers, tin bronzes, aluminum bronzes, and beryllium bronzes. Alloy powders are produced by either (1) preblending copper powders with other elemental powders such as tin, zinc, or nickel or (2) prealloying during powder production.

Preblending. Preblended powders are mixtures of selected compositions, with or without lubricant, that form the desired alloy during sintering. The most common P/M copper alloy made with preblended powders is tin bronze used in self-lubricating bearings. Typical bronze composition is 90Cu-10Sn, often containing up to 1.5% graphite. Some "dilute" bronze bearings contain various amounts of iron replacing some of the copper and tin. Copper-lead and steel-backed Cu-Pb-Sn materials, used to replace solid bronze bearings, also use preblended powders because lead is virtually insoluble in copper and cannot be prealloyed. Friction materials used in brakes and clutches contain disparate materials such as copper with several other components including lead, tin, iron, graphite, molybdenum disulfide, oxides, and so forth. These can only be made by using preblended powders.

Prealloying. Prealloyed powders are generally produced by melting the constituents to form a homogeneous alloy and atomizing the alloy melt by the methods similar to those used for the production of copper powder. They can also be produced by sintering preblended powders and grinding the materials to attain the desired powder characteristics. Some typical commercial prealloyed powders are discussed below.

Brass and Nickel Silver. Air atomization is generally used for making prealloyed powders of brass and nickel silver for use in high-density ($>7.0 \text{ g/cm}^3$) components. The low surface tension of the molten alloys of these compositions renders the particle shape sufficiently irregular to make the powders compactible. Reduction of oxides is not necessary for the standard P/M grades of brass and nickel silver powders.

Commercial prealloyed brass and nickel silver powders are available in leaded and nonleaded compositions. Commercial brass alloys range from 90Cu-10Zn to 65Cu-35Zn. Leaded versions of 80Cu-20Zn and 70Cu-30Zn are most commonly used for the manufacture of sintered structural parts that may require secondary machining operations. The only commercially available nickel silver powder has a nominal composition of 65Cu-18Ni-17Zn, which is modified by addition of lead when improved machinability is required.

Bronze. Prealloyed bronze powders are not used widely for structural parts fabrication because their nodular particle form and high apparent density result in low green strength. However, blends of such powders with irregular copper powders and phosphorus-copper yield sintered parts with good mechanical properties.

Table 5 shows typical properties of commercial grades of prealloyed brass, bronze, and nickel silver powders.

Table 5 Physical properties of typical brass, bronze, and nickel silver alloy compositions

Powder Pressing

Copper and copper alloy powders are generally cold compacted in closed dies with top and bottom punches used to apply the desired pressure. During cold compaction the powder particles mechanically interlock with each other. Typical compacted densities are 80 to 90% of the theoretical density of the material. When higher densities are required, consolidation methods such as hot pressing, extrusion, hot isostatic pressing (HIP), and hot forging are used. The amount of densification depends on several processing variables such as compaction pressure, powder characteristics, types and amounts of lubricants, and so forth. These basic factors are briefly summarized below for copper-base powders, while more general coverage on consolidation is discussed in the Section "Shaping and Consolidation Technologies" in this Volume.

Compressibility is a measure of the extent to which a mass of powder can be densified by the application of pressure. The pressure required to achieve a given green density depends on the powder particle size distribution, inherent hardness of the material, lubricants, and compaction method (e.g., isostatic or uniaxial). At a given compacting pressure, the density of a green compact generally is:

- Lower for fine particles than for coarse particles (Table 6)
- Lower for hard powders than for soft powders (Fig. 1)
- Higher with lubricants, but there is an optimal lubricant level (Fig. 2)
- Higher for isostatic pressing than for uniaxial pressing (Fig. 1)

Copper powder is relatively soft compared to iron, nickel, and molybdenum powders and thus reaches a higher green density for a given compaction pressure (Fig. 1). Typical compacting pressures and compression ratios (green density of compact/apparent density of powder) for copper and copper alloy powders are summarized in Table 7. The ranges in Table 7 are only typical, as actual pressing requirements depend on the variables noted above.

Table 7 Typical compacting pressure and compression ratios of various copper P/M parts

P/M parts	Compacting pressure		Compression ratio
	MPa	tsi	
Brass parts	414-689	30-50	2.4-2.6 to 1
Bronze bearings	193-275	14-20	2.5-2.7 to 1
Copper-graphite brushes	345-414	25-30	2.0-3.0 to 1

Sintering

The compacted parts are sintered at elevated temperatures under protective conditions to avoid oxidation. During this process the powder particles are metallurgically bonded to each other. Sintering is generally understood as a three-phase process. Initially, neck growth between particles proceeds rapidly, but powder particles retain their identity. In the second phase, when most of the densification takes place, the pores become rounded and grain growth occurs, whereupon powder particles lose their separate identities and diffuse into each other. In the third phase, isolated round pores shrink, and densification proceeds at a slower rate.

The principal driving force for these changes is the decrease in free surface area (decrease in solid/gas interface) when particles grow together and voids shrink under the influence of surface tension or capillary forces. Material transport occurs during sintering by one or more mechanisms from among the following (Ref 12):

- Diffusional flow
- Evaporation/condensation
- Viscous flow
- Plastic flow

In most types of sintering, the most important mechanism is diffusion, which may occur through a lattice volume, along a free surface, or along a grain boundary. All three types of diffusion are governed by Fick's law, which is expressed as:

$$D = D_0 \exp (-Q/RT)$$

where D is the diffusion coefficient, D_0 is a material constant known as the jump frequency, Q is the activation energy for the type of diffusion (volume, surface, or grain boundary), R is the gas constant, and T is the absolute temperature. The activation energy for volume diffusion is the highest, the one for grain-boundary diffusion is lower, and the one for surface diffusion is still lower.

Volume and surface diffusion coefficients for copper, as a function of temperature, are shown in Fig. 3. Values for jump frequencies and activation energies for self-diffusion in copper and for the common alloying elements in copper are given in Table 8. Coefficients for grain-boundary diffusion lie between those for volume and surface diffusion. Generally, diffusion in metals proceeds more rapidly along grain boundaries (i.e., planar defects that are structurally only several atoms thick), and the jump frequency of atoms diffusing along the grain boundaries can be a million times greater than the jump frequency of regular lattice atoms at $2T_m/3$ (where T_m is the melting temperature). Because of the very high atomic mobility at grain boundaries relative to that in the bulk, grain-boundary diffusion plays a crucial role in the kinetics of microstructural changes during metallurgical processing such as sintering and solid-state reactions.

Table 8 Diffusion constants in copper

Diffusing element	Volume diffusion		Surface diffusion	
	D_{v0} , cm ² /s	Q_v , kcal/mol	D_{s0} , cm ² /s	Q_s , kcal/mol
Copper (self-diffusion)	0.6-0.78	50.5-50.9	1000	39
Nickel in copper	6.5×10^{-5}	30
Tin in copper	4.1×10^{-3}	31
Zinc in copper	2.4×10^{-3}	30

Fig. 3 Volume and surface diffusion coefficients of copper. Source: Ref 13

Activated Sintering. This process involves techniques aimed at accelerating the sintering rate by decreasing the activation energy for diffusion. It allows lower sintering temperatures, shorter sintering times, or better properties such as strength, electrical conductivity, and so forth. The rate of sintering can be modified by either physical or chemical treatments of the powder or compact or by adding reactive gases in the sintering atmosphere.

Activated sintering has been observed in copper powders having thin films of copper oxide on the particle surfaces (Ref 14). Oxide layers of 40 to 60 nm show improved properties in sintered compacts as shown in Table 9. The copper oxide is partly soluble in the copper matrix, and the oxygen from the oxide film diffuses into the copper, leaving behind highly active copper surfaces that sinter more efficiently. Thicker layers inhibit sintering as the inferior oxide to oxide contacts overcompensate for the activation effects. Small additions of copper oxide to the copper powders also show a similar activation effect.

Table 9 Effect of copper powder oxide thickness on strength of press-and-sintered compacts

Liquid-Phase Sintering. In this process, a compact made from a mixture of two or more powders is sintered at a temperature below the melting point of the high-melting-point constituent, but above that of the low-melting-point constituent. The sequence of events in heating a mixed phase begins with a mixture of elemental powders, such as copper-tin or copper-iron premixes. When the liquid forms, it flows to wet the solid particles and begins acting on the solid phase. Melt penetration between the solid particles can cause swelling of the compact. Along with melt penetration, there is rearrangement of particles. The combination of wetting, liquid flow, and rearrangement contributes to a rapid change in the volume of the compact.

In the copper-tin system, the tin melts and alloys with copper to form a bronze, with accompanying expansion of the compact. In the iron-copper system, the copper melts, becoming saturated with iron, and the copper-iron alloy diffuses into the iron skeleton, causing expansion of the skeleton. Pores remain at the sites vacated by the copper.

In both the copper-tin and iron-copper systems, growth or shrinkage of compacts can be altered by the addition of carbon in the form of graphite. Thus, graphite can be used to control dimensional changes in these systems. In the Cu-Sn-C system, sintering is inhibited by mechanical separation of the constituents; as a result, expansion increases. In the Fe-Cu-C system, the amount of the liquid phase is increased by the formation of a ternary Fe-Cu-C eutectic that restricts expansion. See the article "Production Sintering Practices" in this Volume for detailed information regarding sintering of copper-base materials.

Homogenization (Interdiffusion). When alloying involves blending of elemental powders, then the sintering step serves not only to increase the contact area between powder particles and promote densification, but also to partially or completely homogenize the alloy ingredients by interdiffusion between powder particles of the constituent elements. As in densification, homogenization is influenced by sintering time, sintering temperature, and particle size. Finer particles can greatly accelerate homogenization by reducing the diffusion distance.

Whether it is economical to produce an alloy by sintering compacts from elemental powders or from homogeneous alloy powders depends primarily on the coefficient for interdiffusion of the alloy ingredients. The difference in diffusion coefficients is a deciding parameter whether solid phase or transient liquid phase sintering can be used successfully. This influence of interdiffusion (homogenization) on densification depends on the difference between the diffusion coefficients of the single elements in a powder mixture. In a nickel-cobalt system ($D_{Co} \approx D_{Ni}$), for example, the interdiffusion exerts only a minor influence on densification. The shrinkage behavior of nickel-cobalt compacts lies between those of nickel and cobalt compacts. There is nearly linear correlation between shrinkage and concentration. Therefore, the densification process of the mixtures is dominated by the same defect-activated material transport mechanisms as in single-component systems.

However, in a copper-nickel system ($D_{Cu} > D_{Ni}$), the effect of interdiffusion is much stronger and depends on whether the component with the higher diffusivity (copper) is the minor or the major component. The faster diffusing species leaves porosity behind (Kirkendall porosity), causing expansion of the compact. An 80%Ni-20%Cu system shows more interdiffusion-induced porosity, while diffusion porosity is less pronounced in a 20%Ni-80%Cu system.

Densification. When compacts from a single metal powder are sintered, they undergo dimensional change as sintering proceeds. Figure 4 shows the dimensional changes that occur during sintering of copper powder compacts. In the initial stage, as the temperature increases, the compacts expand much like solid copper. The entrapped gases in the isolated pores and vaporized lubricant also contribute to this expansion, particularly in compacts pressed to high densities. When sintering begins, the compacts begin to shrink and reach a maximum at the peak sintering temperature. During cooling, the compacts contract like solid copper would. The total result of the three stages is generally a shrinkage and higher density.

Fig. 4 Dimensional change during sintering of compacts from -74+43 mm copper powder. Pressed at 138 MPa (20 ksi) and heated at a rate of 3.9 °C/min (7 °F/min) to 925 °C (1700 °F) and then cooled at the same rate. MPa = 6.8947 ksi. Source: Ref 16

Densification of P/M compacts during sintering depends on several variables, but principal factors are:

- Sintering temperature
- Sintering time
- Powder particle size
- Green density of the compact, which is primarily a function of compacting pressure

Typical sintering temperatures and times for various alloys are given in Table 10; copper alloys are generally sintered at much lower temperatures than iron- and nickel-base alloys. Typical shrinkage of a copper compact is shown in Fig. 5 for various sintering temperatures and times. The rate of shrinkage is initially high, but then decreases with increasing sintering time. Higher sintering temperatures promote a more rapid shrinkage than do longer sintering times.

Table 10 Typical sintering temperature and time of copper alloys and steels

Material	Temperature		Time, min
	°C	°F	
Bronze	760-870	1400-1600	10-20
Copper	840-900	1550-1650	12-45
Brass	840-900	1550-1650	10-45
Iron, iron-graphite, etc.	1010-1150	1850-2100	30-45
Nickel	1010-1150	1850-2100	30-45

Fig. 5 Linear shrinkage of copper powder compacts from -75+44 μm sieve fraction. Source: Ref 17

Another factor affecting densification is the particle size of the powder. In Fig. 6, the sintered density of copper powder compacts pressed at 276 MPa (40 ksi) from two particle size fractions, -105 + 75 and -44 μm , and sintered at 865 °C (1590 °F) is plotted as a function of sintering time. Densification of compacts from the finer powder is faster than that of compacts from the coarser powder and, for sintering times above $\frac{1}{2}$ h, the final density is considerably higher for the compacts from the finer powder.

Fig. 6 Density of compacts from electrolytic copper powder. Source: Ref 18

A final factor affecting the densification of compacts from a single metal powder is the green density of the compact or the pressure at which the compact is pressed, which determines green density. In Fig. 7(a) and (b), dimensional change is plotted versus sintering temperature for various compacting pressures. Higher compacting pressures result in higher green and sintered densities, but the sintering shrinkage, or the change from green to sintered density, is smaller. As previously noted, expansion may also occur when soft metal powders are compacted at higher pressures as shown in Fig. 7(b) for compaction pressures of 550 and 620 MPa (80 and 90 ksi). This effect is associated with expansion of the entrapped gases in the isolated pores.

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

Pure Copper

Pure copper P/M parts are used mainly in electrical and electronic applications because of their high electrical conductivity. It is essential to use very pure copper powders ($\geq 99.95\%$ purity) or to bring about the precipitation of soluble impurities during sintering. As little as 0.023% Fe in solid solution in copper lowers its conductivity to 86% of that of pure copper. Small amounts of iron mechanically mixed with the copper powder lower the conductivity much less, unless the iron dissolves in the copper during sintering. If high-purity copper is used, or if soluble impurities are precipitated during sintering, it is possible to obtain the strength and conductivity values shown in Fig. 8.

Fig. 8 Effect of density on electrical conductivity and tensile strength properties of P/M copper. Source: Ref 5

Conductivity is directly related to porosity; the greater the void content (lower the density), the lower the conductivity. Electrical conductivity of pure copper parts pressed at moderate pressures of 205 to 250 MPa (15 to 18 tsi) and sintered at 800 to 900 °C (1500 to 1650 °F) varies from 80 to 90% IACS on a scale where conductivity of solid annealed copper is 100% IACS. The conductivity of solid copper can be reached or approached in P/M copper parts by sintering the pressed parts at higher temperatures, such as 930 to 1030 °C (1700 to 1900 °F), followed by re-pressing, coining, or forging.

Typical applications of pure copper parts in which high electrical conductivity is required include commutator rings, contacts, shading coils, nose cones, and electrical twist-type plugs. Copper powders also are used in copper-graphite compositions that have low contact resistance, high current-carrying capacity, and high thermal conductivity. Typical applications include brushes for motors and generators and moving parts for rheostats, switches, and current-carrying washers.

Bronze

Powder metallurgy bronzes typically originate as premixes consisting of elemental copper and tin powders plus 0.5 to 0.75% dry organic lubricants such as stearic acid or zinc stearate. Some structural parts, however, requiring densities $>7.0 \text{ g/cm}^3$ are fabricated from prealloyed powders. Prealloyed powders have higher yield strengths and work-hardening rates than premixed powders. Therefore, pressing loads required to achieve given green densities in prealloyed powders are higher than the pressures required for elemental powders. Differences in pressing characteristics of premixed and prealloyed powders are compared in Fig. 9.

Fig. 9 Pressing characteristics of premixed and prealloyed 90Cu-10Sn powders. Source: Ref 20

Typical sintering furnace temperatures for bronze range from 815 to 870 °C (1500 to 1600 °F); total sintering time within the hot zone may range from 15 to 30 min, depending on the furnace temperature selected, required dimensional change, and most importantly, the presence of an optimal α bronze grain structure. Sintering atmospheres should be protective and reducing to facilitate sintering. Reduction of the copper oxides that may surround each copper powder particle and of tin oxide allow for increased diffusion rates. Typical strength/density data for 90Cu-10Sn sintered bronzes with and without graphite additions are shown in Fig. 10. Control of sintered dimensions in premix systems is achieved by manipulating sintering time and/or temperature.

Fig. 10 Effect of density on the strength of copper-tin and copper-tin-graphite compacts. Source: Ref 21

Generally, copper-tin blends composed of relatively coarser powders sinter to higher growth values than a blend composed of finer powders. After powder blends have been tested and adjusted to provide an approximation of target dimensions, final

adjustments are made during production sintering to obtain dimensional precision. Factors affecting the ultimate dimensional values include physical characteristics of the constituents and compacted density.

Bearings. Self-lubricating porous bronze bearings continue to consume the major portion of the copper powder produced each year. These bearings are made by pressing elemental powder blends of copper and tin, followed by sintering. The most widely used bearing material is 90Cu-10Sn bronze, often with the addition of up to 1.5% graphite. So-called dilute bronze bearings contain various amounts of iron. Dilution with iron reduces the cost of a bearing at the expense of some loss in performance.

Compaction pressures for the bronze powders range from about 140 to 415 MPa (20 to 60 ksi). Sintering is typically done in a continuous mesh belt furnace at temperatures between 815 to 870 °C (1500 to 1600 °F) for about 3 to 8 min at temperature. Typical furnace atmospheres are dissociated ammonia or endothermic gas. To obtain reproducible sintering results, it is important to carefully control time and temperature because of their influence upon the kinetics of the homogenization process, which in turn determines the dimensional changes taking place during sintering. Most bearings are sized for improved dimensional accuracy; typical sizing pressures may range from about 200 to 550 MPa (30 to 80 ksi). Bearings are sold either dry or saturated with oil. The pores are filled with oil by a vacuum impregnation process. Most common bearings range in density from 5.8 to 6.6 g/cm³ dry or 6.0 to 6.8 g/cm³ oil impregnated. This range corresponds to about 25 to 35% pore volume.

Figure 11 shows an assortment of bronze bearings. The most common shapes are simple or flanged bushings, but some have spherical external surfaces. Sizes range from about 0.8 to 75 mm ($\frac{1}{32}$ to 3 in.) in diameter. Typical applications of sintered bronze bearings are shown in Table 11.

Fig. 11 Assorted P/M bronze bearings

Filters. Filters constitute one of the major applications for porous P/M parts. The ability to achieve close control of porosity and pore size is the main reason filters are made from metal powders. Most producers of nonferrous filters prefer atomized

spherical powders with closely controlled particle size to allow production of filters within the desired pore size range. The effective pore size of filters generally ranges from 5 to 125 μm .

Tin bronze is the most widely used P/M filter material, but nickel silver, stainless steel, Cu-Sn-Ni alloys, and nickel-base alloys also are used. The major advantage of P/M bronze materials over other porous metals is cost. Porous P/M bronze filters can be obtained with tensile strengths ranging from 20 to 140 MPa (3 to 20 ksi) and appreciable ductility, up to 20% elongation. Powder metallurgy bronze also has the same corrosion resistance as cast bronze of the same composition and thus can be used in a wide range of environments.

Bronze filters usually are made by gravity sintering of spherical bronze powders, which are generally made by atomization of molten prealloyed bronze. These powders typically contain 90 to 92% Cu and 8 to 10% Sn. Filters made from atomized bronze have sintered densities ranging from 5.0 to 5.2 g/cm^3 . To produce filters with the highest permeability for a given maximum pore size, powder particles of a uniform particle size must be used.

Although not widely used, coarser powders for bronze filters can be obtained by chopping copper wire and tumbling the choppings. Filters made from tin-coated cut copper wire with tin contents ranging from 2.5 to 8% are also used to a lesser extent. Filters made from these materials have sintered densities ranging from 4.6 to 5.0 g/cm^3 .

During sintering the filters shrink slightly--as much as 8%. To avoid excessive shrinkage, filters from powders with fine particle size require lower sintering temperatures in the neighborhood of 815 $^{\circ}\text{C}$ (1500 $^{\circ}\text{F}$). Because of the shrinkage during sintering, filters must be designed with a slight draft, so they can be removed from the mold.

Figure 12 shows an assortment of P/M bronze filters. Such filters are commonly used to filter gases, oils, refrigerants, and chemical solutions. They have been used in fluid systems of space vehicles to remove particles as small as 1 μm . Bronze diaphragms can be used to separate air from liquids or mixtures of liquids that are not emulsified. Only liquids capable of wetting the pore surface can pass through the porous metal part.

Fig. 12 Assorted filters made from P/M bronze. Courtesy of Arrow Pneumatics, Inc.

Bronze filter materials can be used as flame arrestors on electrical equipment operating in flammable atmospheres, where the high thermal conductivity of the bronze prevents ignition. They can also be used as vent pipes on tanks containing flammable liquids. In these applications, heat is conducted away rapidly so that the ignition temperature is not reached.

Structural Parts. Powder metallurgy bronze parts for structural applications frequently are selected because of corrosion and wear resistance of bronze. They are generally produced by methods similar to those used for self-lubricating bearings. Typical compositions of bronze structural parts (CT-1000) are included in Table 12, and the typical properties are shown in Table 13.

Brass and Nickel Silver

In contrast to bronze structural parts, parts made from brass, leaded brass, and nickel silver are produced from prealloyed atomized powder. Compositions of some common brass and nickel silver alloys used in structural parts are shown in Table 12. The leaded compositions are used whenever secondary machining operations are required.

The alloy powders are usually blended with lubricants in amounts from 0.5 to 1.0 wt%. Lithium stearate is the preferred lubricant because of its cleansing and scavenging action during sintering. However, bilubricant systems are common, such as lithium stearate and zinc stearate, which minimize the surface staining attributed to excessive lithium stearate. Lubricated powders are typically compacted to 75% of theoretical density at 207 MPa (30 ksi) and to 85% of theoretical density at 415 MPa (60 ksi).

Sintering of brass and nickel silver compacts is normally performed in protective atmospheres. Dissociated ammonia, endothermic gas, and nitrogen-base atmospheres are most common. Temperatures range from 815 to 925 °C (1500 to 1700 °F) depending on alloy composition. To avoid distortion and/or blistering of the compacts, sintering temperatures should not exceed the solidus temperature of the alloy. Through multiple pressing and sintering operations, yield strength and hardness approaching those of the wrought alloy counterparts can be achieved. To minimize zinc losses during sintering, yet allow for adequate lubricant removal, protective-sintering-tray arrangements are used. Table 13 shows the typical properties of common brass and nickel silver P/M parts.

Next to bronze bearings, brasses and nickel silvers are the most widely used materials for structural P/M parts. Typical applications include hardware for latch bolts and cylinders for locks; shutter components for cameras; gears, cams, and actuator bars in timing assemblies and in small generator drive assemblies; and decorative trim and medallions. In many of

these applications, corrosion resistance, wear resistance, and aesthetic appearance play important roles. Figure 14 shows some typical P/M brass components.

Copper-Nickel

Copper-nickel P/M alloys containing 75Cu-25Ni and 90Cu-10Ni have been developed for coinage and corrosion-resistance applications. The 75Cu-25Ni alloy powder pressed at 772 MPa (112 ksi) has a green density 89% of its theoretical density. After sintering at 1090 °C (2000 °F) in disassociated ammonia, elongation is 14%, and apparent hardness is 20 HRB. Re-pressing at 772 MPa (112 ksi) increases density to 95%. This alloy has the color of stainless steel and can be burnished to a high luster. The 90Cu-10Ni alloy has a final density of 99.4% under similar pressing-and-sintering conditions. It has a bright bronze color and also can be burnished to a high luster.

In one method of producing coins, medals, and medallions, a mixture containing 75% Cu and 25% Ni powders is blended with zinc stearate lubricant and compressed, sintered, coined, and resintered to produce blanks suitable for striking. These blanks are softer than rolled blanks because they are produced from high-purity materials. Therefore, they can be coined at relatively low pressures, and it is possible to achieve greater relief depth with reduced die wear.

In another procedure, an organic binder is mixed with copper or copper-nickel powders and rolled into "green" sheets. Individual copper and copper-nickel sheets are pressed together to form a laminate, and blanks are punched from it. Blanks are heated in hydrogen to remove the organic binder and sinter the material. The density of the "green" blanks is low (45% of theoretical), but coining increases density to 97%. After pressing, the blanks are annealed to improve ductility and coinability.

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

Copper-Lead

Copper and lead, which have limited solubilities in each other, are difficult to alloy by conventional ingot metallurgy. Copper-lead powder mixtures have excellent cold pressing properties; they can be compacted at pressures as low as 76 MPa (11 ksi) to densities as high as 80% of theoretical density. After sintering, they can be re-pressed at pressures as low as 152 MPa (22 ksi) to produce essentially nonporous bearings.

Steel-backed copper or Cu-Pb-Sn P/M materials are sometimes used to replace solid bronze bearings. They are produced by spreading the powder in a predetermined thickness on a steel strip, sintering, rolling to theoretical density, re-sintering, and annealing. The end product has a residual porosity of about 0.25%. Blanks of suitable size are cut from the bimetallic strip, formed, and drilled with oil holes or machined to form suitable grooves. These materials include Cu-25Pb-0.5Sn, Cu-25Pb-3.5Sn, Cu-10Pb-10Sn, and Cu-50Pb-1.5Sn alloys.

Copper-Base Friction Materials

Sintered-metal-base friction materials are used in applications involving the transmission of motion through friction (clutches) and for deceleration and stopping (brakes). In these applications mechanical energy is converted into frictional heat, which is absorbed and dissipated by the friction material. Copper-base materials are preferred because of their high thermal conductivity; however, lower cost iron-base materials have been developed for moderate to severe duty dry applications.

Most friction materials contain copper powders blended with other metal powders, solid lubricants, oxides, and other compounds. These constituents are immiscible in each other and therefore can only be made by powder metallurgy. Compositions of some common copper-base friction materials are shown in Table 14.

(a)

W, wet; D, dry.

Mixtures of the appropriate powders are carefully blended to minimize segregation of the constituents. Fine metal powders with high surface area are necessary to provide a strong and thermally conductive matrix. The blended powders are compacted at pressures ranging from 165 to 275 MPa (24 to 40 ksi).

Bell-type sintering furnaces are used where the friction facing is bonded to a supporting steel backing plate such as in clutch disks. The green disks are placed on the copper-plated steel plates and stacked. Pressure is applied on the vertical stack of disks. Sintering temperatures range from 550 to 950 °C (1020 to 1740 °F) in a protective atmosphere. Typical sintering times are 30 to 60 min. The sintered parts are typically machined for dimensional accuracy and surface parallelism.

The friction elements are usually brazed, welded, riveted, or mechanically fastened to the supporting steel members. They may also be pressure bonded directly to the assembly.

The operating conditions encountered by metal-base friction materials can be classified as dry/wet and mild/moderate/severe. Figure 15 shows some typical applications and the corresponding operating conditions. Some examples of copper-base friction elements are shown in Fig. 16.

Copper-Base Contact Materials

Electrical contacts are metal devices that make and break electrical circuits. Arcing, except in applications with low potential or current levels, is a major problem, particularly during opening of the contacts in a live circuit. The arc causes erosion of the contacts by blowing away the molten metal or by vaporizing the material. Welding can occur during closing of the contacts when small areas on the contact surfaces that are molten during arcing fuse together during closure (Ref 25).

Applications involving severe arcing and welding employ contacts made from refractory metals, such as tungsten and molybdenum, which have high melting and boiling points, and excellent resistance to arc erosion. Oxides are often used to prevent welding of the contacts. In both cases, a high conductivity metal such as silver or copper is used in conjunction with the refractory metal or oxide to provide the necessary current-carrying capability. Composites such as these are made by P/M techniques because the individual constituents are immiscible and cannot be made by conventional melt-cast process. Applications where arcing and welding are not severe utilize contacts made of pure metals or alloys. These are generally made by melting and casting followed by suitable metalworking processes.

Copper-base materials are used in electrical contacts because of their high electrical and thermal conductivities, low cost, and ease of fabrication. Their main drawbacks are poor resistance to oxidation and corrosion. Therefore, copper-base contacts are used in applications where the voltage drop resulting from the oxide film is acceptable or where it is possible to protect the contact, such as by immersion in oil or by enclosing the contact in a protective gas or vacuum.

Common copper alloys used in contacts include yellow brass (C27000), phosphor bronze (C51000), and copper beryllium alloys (C17200 and C17500). These are made by the melt-cast process and are limited to lower current applications where arcing and welding are not severe.

Composites of copper with refractory metals or their carbides are used in applications in which limited oxidation of the copper is acceptable or where oxidation is prevented by one of the methods mentioned above. Table 15 presents the compositions, properties, and typical applications for some P/M composite contact materials. The properties of the contacts depend on the manufacturing method used, and therefore the common methods used are also shown in the table. The specific method used depends on the composition of the composite. Generally, materials with 40% or less tungsten or its carbide are manufactured by the conventional pressing, sintering (generally below the melting point of copper), and re-pressing (PSR) technique. Materials containing more than 40% W are generally made by infiltrating (INF) the copper into either loose tungsten powder or pressed-and-sintered tungsten compacts. Their counterparts using tungsten carbide are made by infiltrating the copper into loose powder because the tungsten carbide powder cannot be pressed into compacts.

Copper-Base Brush Materials

Brushes are components that transfer electrical current between the stationary and rotating elements in electric motors and generators. Most common brushes are made from composites of graphite and a conductive metal. The graphite provides the required lubrication, and the metal provides the current-carrying capability; copper and silver are preferred metals because of their high electrical conductivity.

Table 16 shows the compositions of some typical copper-graphite brush materials. The copper content varies from about 20 to 75%, the balance being graphite. Powder metallurgy is the only way to produce these materials because of the immiscibility of the two components. Copper powder used in the brushes could be made by oxide reduction, electrodeposition, atomization, or flaking.

Table 16 Characteristics of typical graphite-metal brush materials

Source: Ref 26

The manufacture of brushes involves blending the copper and graphite powders. These are molded into brushes or large blocks, typically at pressures ranging from 100 to 200 MPa (15 to 30 ksi), providing green densities of 2 to 4 g/cm³. The molded parts are sintered at 500 to 800 °C (950 to 1500 °F) in a protective atmosphere. Machining is performed if necessary to achieve the final dimensional tolerances.

All metal-graphite brush applications must operate at lower voltages than nonmetallic brush materials. Typical voltages range from near 0 to 30 V and can be emanating from a direct current power source such as a battery, a rectifier, or a sensing device such as a thermocouple.

Copper-graphite brushes are widely used in battery-powered tools that require high power outputs in small, lightweight packages. Typically, input voltage influences the metal content required. High voltages require a low metal content, whereas low voltages require a high metal content. Below 9 V, the metal content is usually higher than 80% while above 18 V, the metal content is generally below 50%.

Copper-graphite brushes are also used extensively in automotive applications including starter motors, blower motors, doorlocks, and windshield-wiper motors. The starter motors generally use high copper content grades to enable them to handle extremely high-current densities for short periods of time. Blower motors use lower copper content grades to extend service life to several thousand hours. The doorlocks and windshield-wiper motors use grades that are between the blower and starter motor grades.

Infiltrated Parts

Iron-base P/M parts can be infiltrated with copper or a copper alloy by placing a slug of the infiltrant on the part and then sintering above the melting point of the infiltrant. The molten infiltrant is completely absorbed in the pores by capillary action and a composite structure is created. The amount of infiltrant used is limited by the pore volume in the starting iron part and typically ranges between 15 and 25%.

Infiltration increases the density of the part, resulting in improved mechanical properties, corrosion resistance, electrical and thermal conductivities, machinability, and brazeability. Tensile strengths ranging from 480 to 620 MPa (70 to 90 ksi) can be achieved in iron-base parts infiltrated with 15 to 25% Cu.

Infiltration is used for iron-base structural parts that must have densities greater than 7.4 g/cm³. Typical examples include gears, automatic transmission components, valve seat inserts, automobile door hinges, and so forth. More information is in the article "Infiltration" in this Volume.

Copper Powder Metallurgy Alloys and Composites

A. Nadkarni, OMG Americas, Inc.

ODS Copper Materials

Copper is widely used in industry because of its high electrical and thermal conductivities, but it has low strength, particularly when heated to high temperatures. It can be strengthened by using finely dispersed particles of stable oxides such as alumina, titania, beryllia, thoria, or yttria in the matrix. Because these oxides are immiscible in liquid copper, dispersion-strengthened copper cannot be made by conventional ingot metallurgy; P/M techniques must be used.

Manufacture. Oxide dispersion strengthened (ODS) copper can be made by simple mechanical mixing of the copper and oxide powders (Ref 27), by coprecipitation from salt solutions (Ref 28), by mechanical alloying (Ref 29), or by selective or internal oxidation (Ref 30). Dispersion quality and cost vary substantially among these methods; internal oxidation produces the finest and most uniform dispersion. Aluminum oxide is a common dispersoid used in the manufacture of ODS copper.

In internal oxidation, a copper-aluminum solid-solution alloy is internally oxidized at elevated temperature. This process converts the aluminum into aluminum oxide. For effective internal oxidation, oxygen must diffuse into the matrix (copper) several orders of magnitude faster than the solute element (aluminum). Because internal oxidation depends on diffusion of oxygen into the matrix, the reaction time is proportional to the square of the distance through which the oxygen must diffuse to complete the reaction. To hold reaction times within practical limits, diffusion distance must be small. In wrought form, internal oxidation can only be practical in thin wire or strip, which would severely limit the use of ODS materials. Powder metallurgy offers a unique solution to this problem, because powder particles can be internally oxidized rapidly and then consolidated into almost any shape.

The process involves melting a dilute solid-solution alloy of the aluminum in copper and atomizing the melt by use of a high-pressure gas such as nitrogen. The resulting powder is blended with an oxidant that consists primarily of fine copper oxide powder. The blend is heated to a high temperature; the copper oxide dissociates, and the oxygen produced diffuses into the particles of solid-solution copper-aluminum alloy. Because aluminum forms oxide more readily than copper, the aluminum in

the alloy is preferentially oxidized to aluminum oxide. After complete oxidation of all the aluminum, excess oxygen in the powder is reduced by heating the powder in hydrogen or a dissociated ammonia atmosphere.

Full theoretical density is essential to realize the best potential properties of ODS copper. The powder is fabricated into fully dense shapes by various techniques. Mill forms, such as rod and bar, are made by canning the powder in a suitable metal container (generally copper) and hot extruding it to the desired size. Wire is made by cold drawing coils of rod. Strip is made either by rolling coils of extruded rectangular bar or by directly rolling powder with or without a metal container. Large shapes that cannot be made by hot extrusion are made by HIP of canned powder; alternatively, such shapes can be made by hot forging canned powder or partially dense compacted preforms.

Properties of the consolidated material depend on the amount of deformation introduced into the powder particles. Consequently, low-deformation processes such as HIP and, to a lesser extent, hot forging develop materials with lower strengths and ductilities than those produced by extrusion.

Finished parts can be made from consolidated shapes by machining, brazing, and soldering. Fusion welding is not recommended, because it causes the aluminum oxide to segregate from the liquid copper matrix, resulting in loss of dispersion strengthening. However, flash welding, in which the liquid metal is squeezed out of the weld joint, and electron beam welding, in which a small heat-affected zone is created, have been used successfully. Solid-state welding (with multiple cold upsets in a closed die) has also been used with success to join smaller coils into a large coil for wire drawing.

Properties. Oxide dispersion strengthened copper offers a unique combination of high strength and high electrical and thermal conductivities. More importantly, it retains a larger portion of these properties during and after exposure to elevated temperatures than any other copper alloy.

The properties of ODS copper can be modified to meet a wide range of design requirements by varying its aluminum oxide content and/or the amount of cold work. Figure 17 shows the ranges in tensile strength, elongation, hardness, and electrical conductivity obtained as a function of aluminum/aluminum oxide contents. These properties are typical for rod stock in the hot extruded condition. Cold work can be used to broaden the ranges in tensile strength, elongation, and hardness; its effect on electrical conductivity is minimal.

Fig. 17 Properties of three ODS coppers. Source: Ref 31

Three grades of ODS copper are commercially available. They are designated as C15715, C15725, and C15760 by the Copper Development Association. The nominal compositions of these three grades are:

Grade	Copper		Aluminum oxide	
	wt%	vol%	wt%	vol%
C15715	99.7	99.3	0.3	0.7
C15725	99.5	98.8	0.5	1.2

The free or reducible oxygen content of the three ODS coppers, generally about 0.02 to 0.05 wt%, is present in the form of dissolved oxygen and cuprous oxide. Alloys in this state are prone to hydrogen embrittlement at high temperatures. Low-oxygen (LOX) compositions are available in all of these grades, in which the reducible oxygen is converted to nonreducible oxide by adding up to 0.020 wt% B as the oxygen getter. These grades are then immune to hydrogen embrittlement and must be specified for applications in which the components are likely to be subjected to reducing atmospheres during manufacture or use.

Physical Properties. Because ODS copper contains small amounts of aluminum oxide as discrete particles in an essentially pure copper matrix, its physical properties closely resemble those of pure copper. Table 17 shows physical

properties of the three commercial ODS coppers comparing them with oxygen-free (OF) copper. The melting point is essentially the same as for copper because the matrix melts and the aluminum oxide separates from the melt. Density, modulus of elasticity, and coefficient of thermal expansion are similar to those of pure copper.

Table 17 Physical properties of three ODS coppers and OF copper

Property	Material			
	CC15715	C15725	C15760	OF Copper
Melting point, °C (°F)	1083 (1981)	1083 (1981)	1083 (1981)	1083 (1981)
Density, g/cm³ (lb/in.)	8.90 (0.321)	8.86 (0.320)	8.81 (0.318)	8.94 (0.323)
Electrical resistivity at 20 °C (68 °F), Ω·mm²/m (Ω circular-mil/ft)	0.0186 (11.19)	0.0198 (11.91)	0.0221 (13.29)	0.017 (10.20)
Electrical conductivity at 20 °C (68 °F), M mho/m (%IACS)	54 (92)	50 (87)	45 (78)	58 (101)
Thermal conductivity at 20 °C (68 °F), W/m·K (Btu/ft·h·°F)	365 (211)	344 (199)	322 (186)	391 (226)
Linear coefficient of thermal expansion for 20 to 1000 °C (68 to 1830 °F), ppm/°C (ppm/°F)	16.6 (9.2)	16.6 (9.2)	16.6 (9.2)	17.7 (9.8)
Modulus of elasticity, GPa (10⁶ psi)	130 (19)	130 (19)	130 (19)	115 (17)

High electrical and thermal conductivities are particularly interesting to design engineers in the electrical and electronics industries. At room temperature, these range from 78 to 92% of those for pure copper. Coupled with the high strengths of these materials, they enhance the current-carrying or heat-dissipating capabilities for a given section size and structural strength. Alternatively, they enable reduction of section sizes for component miniaturization without sacrificing structural strength or current and heat-carrying capabilities. At elevated temperatures, the decrease in electrical and thermal conductivities of ODS coppers closely parallel those of pure copper.

Room-Temperature Mechanical Properties. Table 18 shows the room-temperature mechanical properties of the three ODS coppers in available mill forms. These cover a wide range of sizes, typified by various amounts of cold work by drawing and rolling, for example. Oxide dispersion strengthened copper has strength comparable to many steels and conductivity comparable to copper.

Table 18 Typical room-temperature mechanical properties of three ODS coppers

Oxide dispersion strengthened copper has excellent resistance to softening even after exposure to temperatures close to the melting point of copper because the aluminum oxide particles are stable at these temperatures and retain their original size and spacing. These particles block dislocation and grain-boundary motion and thus prevent recrystallization, which is normally associated with softening. Figure 18 compares the softening behavior of C15715 and C15760 strip with OF copper (C10200) and a copper-zirconium (C15000) alloy. At common brazing and glass-to-metal sealing temperatures (above 600 °C) encountered in practice, ODS coppers retain much of their strength while OF copper and copper-zirconium lose most of their strength. Therefore, ODS copper is used in applications in which the component manufacture involves high-temperature operations such as brazing, glass-to-metal sealing, HIP diffusion bonding, and so forth.

Fig. 18 Softening behavior of ODS copper compared to OF copper and copper-zirconium alloy. Source: Ref 34

Elevated-Temperature Mechanical Properties. ODS copper has excellent strength at elevated temperatures. Figure 19 shows the 100 h stress rupture strengths of C15760 and C15715 at temperatures up to 870 °C (1600 °F). Other high-conductivity copper-base materials are shown for comparison. Ranging from pure copper on the low end to precipitation-hardened alloys on the high end, there is a sharp drop in stress rupture strength in the 200 to 450 °C (400 to 850 °F) temperature range. Above 400 °C (750 °F), the ODS coppers are superior to any of the other alloys. Above 600 °C (1100 °F), the ODS coppers have rupture strengths comparable or superior to some stainless steels. Oxide dispersion strengthened copper has excellent thermal stability at high temperatures because the aluminum oxide particles retain their original particle size and spacing even after prolonged heating and do not allow recrystallization of the matrix. Cold work significantly enhances the stress rupture properties of ODS copper; the higher the temperature, the more noticeable the enhancement.

Fig. 19 Elevated-temperature stress-rupture properties of ODS copper compared to several high-conductivity copper alloys. Source: Ref 35

Applications. Oxide dispersion strengthened copper has gained wide market acceptance in several applications, and design engineers are continually developing new applications. The major applications are described below.

Resistance Welding Electrodes. Oxide dispersion strengthened copper electrodes are widely used for resistance welding in automotive, appliance, and other sheet metal industries. Sticking of the electrodes to the workpiece is a major problem when welding galvanized and other coated steels. This usually results in electrodes pulling off their holders and having to stop the assembly line to change the electrodes. Such interruptions are extremely costly. Oxide dispersion strengthened copper electrodes do not stick to galvanized and other coated steels and thus eliminate the costly downtime. Increasing use of coated steels in the automotive industry has prompted wide usage of ODS copper electrodes throughout the world. When used under optimal conditions, including heavy duty welding, these electrodes consistently outperform the conventional copper-chromium electrodes in weld life.

Metal-Inert-Gas Welding Contact Tips. Oxide dispersion strengthened copper is used in metal-inert-gas (MIG) welding contact tips. Its resistance to abrasive wear from the steel wire allows the tips to maintain the bore diameter and minimizes the wandering of the arc. This is very important in automated welding lines. The nonsticking property of ODS copper also minimizes the material buildup on the tip from the weld splatter.

Lead Wires. Oxide dispersion strengthened copper wire is used in leads for incandescent lamps. Its high-temperature strength retention capability enables glass-to-metal seals to be made without undue softening of the leads. This in turn eliminates the need for expensive molybdenum support wires without sacrificing lead stiffness. Superior strength of the leads allows reduction in lead diameter to conserve materials. Thinner lead wires also minimize heat loss from the filament, which enables the lamp to provide higher light output at lower wattage and results in a more energy efficient lamp.

Oxide dispersion strengthened copper wire also can be used in leads for discrete electronic components such as diodes. Advantages of ODS copper wire include its high-temperature strength retention during brazing as well as hermetic sealing. The lead stiffness also enables multiple insertions in circuit boards.

X-Ray and Microwave Tube Components. Oxide dispersion strengthened copper rod and tube are used in x-ray and microwave tube components. An example is the stems for the rotating anodes in x-ray tubes where high strength retention after brazing and glass-to-metal sealing are important. The high thermal conductivity of ODS copper also allows more efficient heat removal, thus lowering the operating temperature and providing longer tube life and quieter tube operation.

Relay Blades and Contact Supports. These are current-carrying arms that move between the fixed contact points to "make" or "break" an electrical circuit. In a limit switch, the force that moves the contact arm (or contact support) to the "make" position is provided by mechanical means, such as a moving object. In a relay, the contact arm (relay blade) is moved by electromagnetic action. In most cases, the spring force of the arm itself moves the contact back to the "break" position.

Generally, the relay blades and contact supports have silver contacts brazed or riveted to them at the point where they touch the fixed contacts. The strength retention capability of ODS copper after exposure to elevated temperatures allows brazing of contacts to the blade without appreciable strength loss. Because of its higher electrical conductivity, ODS copper has replaced conventional copper alloys, such as phosphor bronze and beryllium copper, in some relays. Such relays can carry a higher current than was possible with the prior relays.

Sliding Electrical Contacts. Oxide dispersion strengthened copper bars are used in overhead sliding electrical contacts for high-speed electric trains. Its excellent resistance to abrasive wear against the electrical cable provides up to 10 times longer contact life and reduces the maintenance costs significantly. The higher the train speed, the greater the advantage ODS copper has over other copper-base materials.

Particle Accelerator Components. Particle accelerators are used for physics and materials research, medical diagnostics, and so forth. The high-energy particle beams are shaped and focused by using mirrors, lenses, and prisms in large doughnut-shaped hollow rings. The stray beams are absorbed by special x-ray absorbers. Oxide dispersion strengthened copper plates and bars are used in mirrors and x-ray absorbers because of their high thermal conductivity, high strength, creep resistance, and vacuum integrity.

Hybrid Circuit Package Components. Oxide dispersion strengthened copper strip is used as the base plate for hybrid circuit package cases. Manufacture of these cases involves brazing of the base plates to stainless steel and/or kovar components. The ability of ODS copper to retain its strength after such brazing operation makes it the material of choice when the package is used in high-stress environments. Oxide dispersion strengthened copper wire is also used in the leads for such packages because of its ability to retain its stiffness after the high-temperature ceramic sealing of the leads into the case.

Other Applications. Some other diverse applications of ODS copper include high field magnet coils, anode stems in chlorine cells, electrodischarge machining electrodes, high-speed motor and generator components, commutators, and so forth.

Titanium Powder Metallurgy Alloys and Composites

Daniel Eylon, University of Dayton; F.H. (Sam) Froes, University of Idaho; Stanley Abkowitz, Dynamet Technology

Introduction

THE DRIVE to develop net-shape technologies, such as casting and powder metallurgy (P/M), has been going on for many years. It has been spurred on by the desire to minimize alloy waste and to reduce or eliminate the cost of machining. This article focuses on the properties and applications of titanium P/M compacts.

Because of difficulties encountered with early melting practices, P/M was used in the beginning stages of titanium technology to produce alloy ingots (Ref 1). Titanium P/M has been developed as a net-shape technique only in the last 20 years (Ref 2, 3, 4, 5, 6, and 7). In general, P/M can be divided into two major categories:

- Elemental P/M, in which a blend of elemental powders, along with master alloy or other desired additions, is cold pressed into shape and subsequently sintered to higher density and uniform chemistry
- Prealloyed P/M, which is based on hot consolidation of powder produced from a prealloyed stock

In general, the blended elemental (BE) method produces parts at a low cost, but the parts often are less than fully dense; this technique is typically used for iron (Ref 8), copper (Ref 9), and heavy-metal (Ref 10) alloys. The prealloyed (PA) method is used for making fully dense high-performance components from aerospace alloys, such as nickel (Ref 11, 12), aluminum (Ref 13), and beryllium (Ref 14). Titanium P/M has incorporated both methods: BE is used to produce lower-cost parts that are less than fully-performance, full-density compacts (Ref 15). Recent developments in powder selection, compaction techniques, and postcompaction treatments have made it possible to obtain full density in titanium BE P/M. Properties exceeding those of ingot metallurgy (I/M) products have been achieved in BE and PA products.

This article highlights the properties and applications of both BE and PA titanium P/M compacts. It includes major recent developments that have led to improved performance in BE and PA products, but it does not cover the developments in titanium rapid solidification alloys that have not yet reached the commercialization stage. Detailed discussions of powder production methods and shape-making techniques are available elsewhere in this Volume. These processes are briefly described here in only enough detail to rationalize properties and applications.

Titanium Powder Metallurgy Alloys and Composites

Daniel Eylon, University of Dayton; F.H. (Sam) Froes, University of Idaho; Stanley Abkowitz, Dynamet Technology

Mechanical Properties of Titanium P/M Products

The mechanical properties of titanium P/M products depend on alloy composition and on the density and final microstructure of the compact. The compact density and microstructure depend on the nature of the powder, the specific consolidation technique employed, and postcompaction treatments such as secondary pressing or heat treatment. To date, most components produced by the various P/M methods have been made from Ti-6Al-4V, the most common aerospace titanium alloy. As a result, the majority of the P/M data available in the literature is for this alloy. However, these technologies are also very well suited for other alloys, such as the high-strength β alloys and the high-temperature near- α alloys. This article includes data on a wide variety of alloys to highlight the range of potential applications available for titanium P/M.

Blended Elemental Compacts

The blended elemental method, which is basically a pressing and sintering P/M technique, involves cold pressing or cold isostatic pressing (CIP) a blend of fine elemental titanium and master alloy powders that have been sintered. Titanium sponge fines (-100 mesh) are the most common elemental powder used in this process; these particles are obtained as by-products of the Hunter or Kroll reduction processes (Ref 4). The metallic titanium sponge produced by these processes is vacuum arc melted into ingots. The titanium sponge fines that are too small to be used in the melting process are available at a relatively low cost. This powder has an irregular shape (Fig. 1a), which makes it easy to cold press into green shapes. The powder is sintered at temperatures in the range of 1150 to 1315 °C (2100 to 2400 °F) in a vacuum to prevent gas contamination that can

severely degrade compact properties. The high sintering temperature is needed to provide particle bonding and to homogenize the chemistry. It is well above the β transus (that is, the lowest equilibrium temperature at which the material is 100% β) of all common titanium alloys, and as a result, the compact microstructure in $\alpha + \beta$ alloys consists of colonies of similarly aligned coarse α plates (Fig. 1b). The plates are about 8 μm (320 $\mu\text{in.}$) wide and 25 μm (1000 $\mu\text{in.}$) long. The colonies are about 50 μm (0.002 in.) in diameter. The prior β grains are about 80 μm (0.0032 in.) in diameter. This microstructure is much finer than ingot material treated at the same temperature because of the inherent porosity of the powder compact (Ref 16). The porosity is the result of sodium chloride residues (Kroll process) in the sponge from the reduction process (Ref 4). The sponge fines contain from 0.12 to 0.15% Cl, and, as can be seen in Fig. 1(a), the resulting porosity cannot be entirely closed, even after secondary operations such as hot pressing or hot isostatic pressing (HIP) (Ref 17).

Fig. 1 Photomicrographs of titanium BE materials. (a) -100 mesh titanium sponge fines. (b) Microstructure of a pressed and sintered 99% dense Ti-6Al-4V compact. (c) Crushed hydrogenated-dehydrogenated titanium ingot or machine turnings. (d) Microstructure of a fully dense, pressed and sintered, and hot isostatically pressed Ti-6Al-4V compact. (e) Microstructure of a Ti-6Al-4V compact treated to produce a broken-up structure. (f) Microstructure of a Ti-6Al-4V compact treated with thermochemical processing

BE compacts have a green density of 85 to 90% after 415 MPa (60 ksi) cold pressing. After vacuum sintering, they have a density of 95 to 99%. Control of particle size and size distribution can produce compacts that are 99% dense. In ferrous, copper, and heavy-metal P/M alloys, 99% is considered to be full density; however, in titanium alloy compacts, such a level of residual porosity (Fig. 1a) will degrade both fatigue and fracture properties. A substantial effort has been made to entirely eliminate the porosity so that BE P/M parts can be used for fatigue-critical aerospace applications. Postsintering HIP densification can lead to 99.8% density and improved properties (Ref 4, 5). However, it is impossible to entirely eliminate the porosity with postsintering hot-pressing operations. During hot pressing, the chlorides present in the compact become volatile and create pockets of insoluble gas. Under the HIP pressure, these relatively large pressurized cavities (Fig. 2a) will break up into a multitude of submicron voids (Fig. 2b) (Ref 16, 17, 18) with sodium chloride in the center of the cavity (Fig. 2c). Both macrovoids and microvoids have an approximate hexagonal shape that is associated with basal-plane facets, which are the most energetically stable planes of the hexagonal close-packed structure (Ref 19). During cooling to room temperature, the

gas in the voids transforms into cubic chloride crystals, as can be seen in the transmission electron microscopy image in Fig. 2(b).

Fig. 2 Chlorine-induced porosity in a titanium BE compact. (a) Scanning electron microscopy photomicrograph of large-size residual porosity in a sectioned Ti-6Al-4V BE compact. (b) Transmission electron microscopy photomicrograph of a Ti-6Al-4V BE compact after postsintering HIP at 925 °C (1700 °F). (c) Chemical analysis showing sodium chloride contaminant at the center of a micropore

To obtain pore-free 100% density material such as that produced by ingot metallurgy, the BE method must use chloride-free titanium powder (Ref 20). One source for such powder is commercially pure titanium ingot material or machine turnings embrittled by hydrogenation that are subsequently crushed and dehydrogenated. This powder is angular (Fig. 1c), and the sintered microstructure is much coarser (Fig. 1d) because of the lack of porosity during sintering.

Tensile Properties and Fracture Toughness. As with data for other titanium technologies, most of the published BE data are on Ti-6Al-4V. Table 1 is a comprehensive listing of tensile properties of Ti-6Al-4V BE compacts processed under a variety of conditions. Table 2 provides the more limited available information on the properties of additional titanium BE alloys.

- (a) HIP, hot isostatic pressing; STA, solution treatment and aging.
- (b) High modulus (Young's modulus of 20×10^6 psi, or 140 GPa).

Blended Elemental Ti-6Al-4V. As indicated in Table 1, most Ti-6Al-4V BE compact conditions exceed minimum MIL-T-9047 specifications. The process details for each condition are in the corresponding references listed in the table. The final shape of the compact can be achieved through a number of process sequences:

- Pressing and sintering
- Pressing and sintering plus HIP
- Pressing and sintering plus rolling
- CIP and sintering
- CIP, sintering, and HIP (collectively designated as cold and hot isostatic pressing, or CHIP)
- CIP, sintering, and rolling
- CIP, sintering, and forging

By controlling the process parameters, it is possible to obtain compacts with densities between 92 and 100% of the theoretical density. The yield and tensile strength of the compacts are proportional to the density (Fig. 3). The fracture toughness also increases with density (Fig. 4). Above 98% density, BE compacts have K_{Ic} values at the level of mill-annealed I/M materials. However, I/M materials with coarse lenticular microstructures similar to those of BE compacts (Fig. 1d) will have much higher K_{Ic} values (70 to 100 $\text{MPa}\sqrt{\text{m}}$, or 65 to 90 $\text{ksi}\sqrt{\text{in.}}$). The relatively lower K_{Ic} level of the BE compacts is probably the result of higher oxygen levels (Ref 26) and residual porosity.

Fig. 4 Effect of density on the fracture toughness of press and sintered Ti-6Al-4V BE compacts. The values are not valid K_{Ic} and thus are labeled as K_Q . Source: Ref 21

Blended elemental compacts can be used as forging preforms (Ref 17). The strong effect of forging deformation on tensile strength and elongation is shown in Fig. 5.

Additional BE Alloys. The limited available mechanical test data for other BE alloys, such as Ti-6Al-2Sn-4Zr-6Mo, Ti-5Al-2Cr-1Fe, and Ti-4.5Al-5Mo-1.5Cr, are listed in Table 2. The most detailed work has been done on the Ti-10V-2Fe-3Al alloy, with some results reported at levels close to those for I/M materials (Ref 33). However, more data are needed for these alloys before reliable parameters for property levels and optimum processes can be established. In the case of Ti-10V-2Fe-3Al, a tensile strength of 1268 MPa (184 ksi) with 10% elongation can be achieved with BE methods.

Fatigue Strength and Crack Propagation. The fatigue life scatterband of chloride-containing Ti-6Al-4V BE compacts is compared in Fig. 6 to a mill-annealed I/M alloy. The effect of low chloride levels and postsintering treatments on fatigue strength is shown in Fig. 7. The effect of compact density on fatigue strength is shown in Fig. 8. The fatigue strength of BE compacts is inherently low when compared to that of mill-annealed I/M products because of the inherent chloride and related porosity of BE materials. Low fatigue strength limits the use of the lower-cost pressing and sintering or CIP and sintering processes to applications that are not fatigue critical, such as missile components. By increasing density through secondary pressing operations and through the use of chloride-free titanium powder, it is possible to further improve fatigue strength (Fig. 8). However, this method increases the cost of these products, thereby negating one of their primary advantages (Ref 15, 35).

Fig. 6 Comparison of the room-temperature fatigue life scatterbands of BE and PA Ti-6Al-4V compacts to that of a mill-annealed I/M alloy

Fig. 7 Comparison of the fatigue strengths of fully dense extra-low chloride Ti-6Al-4V BE compacts with the scatterband for an I/M alloy. The BE compacts were tested in the as-HIP, broken-up structure (BUS), and

thermochemically processed (TCP) conditions. Smooth axial fatigue data were obtained at room temperature. Stress ratio (R), 0.1; frequency (f), 5 Hz with triangular waveform. Source: Ref 27

Fig. 8 Effect of compact density on fatigue strength of CIP and sintered Ti-6Al-4V BE compacts. Note that the higher densities are only possible in the low-chloride material. BUS, broken-up structure; TCP, thermochemical processing. Source: Ref 15

Very limited data are available on the fatigue crack growth rate of Ti-6Al-4V BE compacts. Figure 9 shows that the fatigue crack growth rate of this material is between that of a β -annealed material and that of a mill-annealed I/M material (Ref 26). The BE material tested had a porosity of 1 to 2 vol%, which at this level seems not to adversely influence the fatigue crack growth rate.

Fig. 9 Comparison of fatigue crack propagation rates of BE and I/M Ti-6Al-4V as a function of the stress intensity factor range at room temperature in air. Stress ratio (R), + 0.1 ($R = \sigma_{\min}/\sigma_{\max}$, where σ_{\min} is the minimum stress and σ_{\max} is the maximum stress); frequency (f), 5 Hz. Source: Ref 26

Prealloyed Compacts

While BE compacts are produced and used in a wide range of densities, PA P/M parts are acceptable only at 100% density (Ref 2, 3, 4, 5, 15, and 35). The titanium PA powders are commercially available as spherical particles that have high tap density (65%) and good powder flow and mold fill characteristics. Two main production methods are used for making clean PA powder:

- Gas atomization (Ref 36)
- Plasma rotating-electrode process (PREP) (Ref 37), a modification of the older rotating-electrode process (REP) (Ref 38)

It is also possible to produce PA powders by comminution (Ref 39) and coreduction (Ref 40, 41) methods. However, because of insufficient mechanical property data, these techniques are not discussed in this article.

Hot isostatic pressing is the primary compaction method for PA powders (Ref 2, 3, 4, 5, 15, and 35), but vacuum hot pressing (VHP) (Ref 42, 43), extrusion (Ref 44), and rapid omnidirectional compaction (ROC) (Ref 45, 46, 47, and 48) have also been successfully used. The shape-making step is achieved by containing the powder in a shaped, evacuated, mild-steel can. The compaction is typically carried out at a temperature below the β transus to minimize reaction with the can. Processing in the $\alpha + \beta$ phase field results in a coarse low-aspect-ratio α structure (Fig. 10a). This material is most commonly compared to mill-annealed I/M material because of its microstructure and full density.

Fig. 10 Microstructure of Ti-6Al-4V PA compacts. (a) As-HIP. (b) Treated to produce a broken-up structure. (c) Thermochemically treated

Powder cleanliness is one of the main factors governing the quality of PA compacts. Because of the full compact density, even a low level of contamination with foreign particles will lead to a substantial loss of inherent properties such as fatigue strength (Ref 49). As a result, only data obtained from clean powders are considered in this article. Also, because fully dense PA compacts are considered for more demanding applications than are the less-dense BE compacts, more mechanical test data have been developed within the aerospace industry on PA P/M than on BE P/M compacts. Only data considered to be typical are reviewed in this article. The majority of PA work has been done on Ti-6Al-4V.

Tensile Properties and Fracture Toughness. Table 3 is a comprehensive listing of the tensile properties of Ti-6Al-4V PA compacts processed under various conditions. Table 4 provides limited information on the properties of additional alloys. When the alloy compacts are produced using HIP (Ref 55), VHP (Ref 42), or ROC (Ref 48) at higher pressures but at lower temperatures, higher strength levels without losses in ductility are achieved. This result is due to the substantial microstructure refinement developed during high-pressure low-temperature powder processing. Similarly, post-compaction hot work, such as rolling (Ref 57) or forging (Ref 58), results in microstructural refinement that improves tensile strength and ductility. Property improvement after postcompaction treatments are discussed in the section "Postcompaction Treatments" in this article.

Additional PA Alloys. Table 4 shows the extent to which other PA titanium alloys have been studied. Almost all major I/M alloys have been evaluated in the PA P/M form. These include the high-strength metastable β alloys (Ref 33, 52, 65, 66, 67, and 68), the versatile $\alpha + \beta$ alloys (Ref 63, 64, 66), the high-temperature near- α alloys (Ref 59, 60), and the ordered titanium aluminide alloys (Ref 70, 71, 72). Of special interest is the alloy Ti-1.3Al-8V-5Fe (Ref 67, 68, 69). This alloy has a remarkable tensile strength of 1516 MPa (220 ksi) with 8% elongation. With conventional I/M methods, the high iron content of this alloy results in segregation problems. Powder metallurgy, on the other hand, produces fine-grain, homogeneous, and segregation-free products. Such alloys have the potential of expanding the market for titanium P/M technology.

Fatigue Strength and Crack Propagation. The smooth-bar fatigue life scatterband of Ti-6Al-4V PA compacts is compared to that of a mill-annealed I/M alloy in Fig. 6 (Ref 4). The P/M data were obtained by testing high-cleanliness REP and PREP compacts that had undergone hot isostatic pressing; some of the compacts received a postcompaction heat treatment. The data for the PA compacts are at equivalent levels to the best I/M results. Powder contamination must be avoided to maintain a high fatigue strength in these materials. The effect of 50, 150, and 350 μm (0.002, 0.006, and 0.014 in.) diameter contaminants on the fatigue strength of Ti-6Al-4V PA compacts is shown in Fig. 11 (Ref 49). Even 50 μm (0.002 in.) contaminant particles are sufficient to noticeably reduce fatigue strength. Figure 12 compares the fatigue characteristics of an actual P/M component to those of an I/M material. Figure 12(a) shows results for smooth-bar high-cycle fatigue; Fig. 12(b) covers notched-specimen high-cycle fatigue; and Fig. 12(c) shows data for strain-controlled low-cycle fatigue. In general, high-cycle fatigue results are in the range of 10^6 to 10^8 cycles to failure, and low-cycle fatigue results fall below 10^5 cycles to failure. For all three tests, the P/M alloy performance was comparable to or exceeded that of the I/M material. The component tested is an actual Ti-6Al-4V P/M part used in military airframes (Ref 61).

Fig. 11 Effect of contaminant particles on the room-temperature fatigue strength of Ti-6Al-4V PA compacts. Unseeded compacts are compared with SiO₂-seeded PREP compacts. Stress ratio (R), +0.1; frequency (f), triangular waveform load/time cycle at 5 Hz. Source: Ref 49

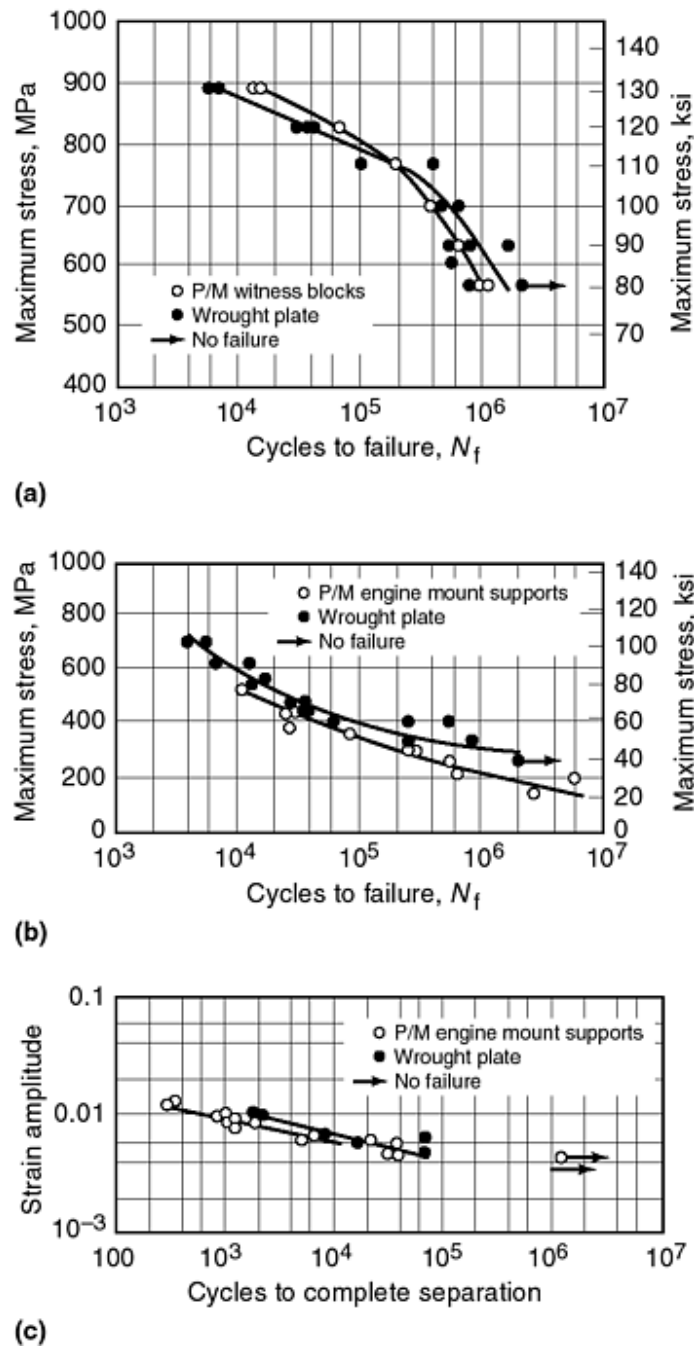

Fig. 12 Comparison of the fatigue strengths at room temperature in air of PREP HIP Ti-6-Al-4V P/M components to those of I/M products. (a) Load-controlled smooth-specimen high-cycle fatigue for large bars (13 mm, or $\frac{1}{2}$ in., in diameter). Stress ratio (R), 0.1. (b) Load-controlled notched-specimen high-cycle fatigue. Stress concentration factor (K_t), 3; stress ratio (R), 0.1. (c) Strain-controlled low-cycle fatigue for small specimens (6.4 mm, or $\frac{1}{4}$ in., in diameter). Stress ratio (R), -1. Source: Ref 73

Figure 13 compares the fatigue crack growth rate of Ti-6Al-4V PA compacts to that of an I/M material with a similar composition and microstructure. Rates are at equivalent levels for both materials, even in PA material with a low level of contamination (Ref 74).

Fig. 13 Comparison of the fatigue crack growth rate at room temperature in air of Ti-6Al-4V PA compacts with that of an I/M alloy material. Stress ratio (R), 0.1; frequency (f), 5 to 30 Hz (5 Hz for a PA compact). Source: Ref 74

Postcompaction Treatments

Most P/M alloys that are subjected to postcompaction working or to lower-temperature consolidation display improved tensile and fatigue strengths as a result of microstructure refinement. However, in most cases, process economics do not allow subsequent working because it nullifies the objectives of a true net-shape technology. Therefore, only those postcompaction methods leading to microstructure refinement without the use of working will be considered in this article. Two approaches that meet this requirement are heat treatment and thermochemical processing (TCP).

Heat Treatment. In the case of BE Ti-6Al-4V, the only successfully used heat treatment has been the broken-up structure (BUS) treatment in which a β quench is followed by 850 °C (1560 °F) long-term annealing (Ref 27). After such treatment, the microstructure of the alloy is showing broken-up α phase in a matrix of β (Fig. 1e). This microstructure provides a significant improvement in both tensile and fatigue strengths (Fig. 7).

The BUS method is an improvement over standard heat treatments, which typically provide higher tensile properties but no increase in fatigue strength properties.

In the case of Ti-10V-2Fe-3Al BE compacts, β solution treatment and subsequent aging resulted in materials with good combinations of tensile strength and ductility (Ref 33). However, the K_{Ic} was found to be too low (Table 2), possibly because

of the high chloride levels and the associated porosity. The Ti-6Al-4V PA compacts responded well to the BUS treatment (Fig. 10b) (Ref 51), as well as to solution treatment and aging (Ref 52). Figure 6 shows the improvement in fatigue strength of both BE and PA Ti-6Al-4V compacts as a result of a microstructure refinement brought about by heat treatment.

Thermochemical Processing. The TCP method (Ref 75) involves the use of hydrogen as a temporary alloying element to refine the microstructure of titanium alloys. This method is very suitable for net-shape products because no hot or cold work is needed to refine the microstructure. An example of the refinement obtained in Ti-6Al-4V P/M products can be seen by comparing Fig. 1(d) with Fig. 1(f) and Fig. 10(a) with Fig. 10(c). This microstructural refinement provides slightly higher strength levels than those typically obtained in I/M or conventional P/M materials (Table 3); more significantly, it substantially enhances the fatigue behavior of the P/M products (Fig. 6, 7, 8).

Applications of Titanium P/M Products

The two distinctively different titanium P/M technologies, the blended element and the prealloyed methods, not only produce compacts with different sets of properties, but also with two different price ranges. The relative low cost of titanium sponge fines and the volume production capability of the pressing and sintering technology allow the production of BE complex-shape aerospace alloy parts at a cost of under \$100/kg (\$45/lb). Prealloyed powders, on the other hand, require an expensive melt stock, ultraclean handling, and expensive compaction tools. As a result, the higher-performance fully dense PA parts are currently priced above \$200/kg (\$90/lb), although it is projected that volume production will bring this price down substantially. The differences in density, property, and price target these two technologies to different application markets. Because of their lower cost, more BE components than PA parts are currently in use. The introduction of gas-atomized powder (Ref 36) is expected to lower powder costs and make PA products more cost competitive.

Blended Elemental Products

On the low end of the density scale (20 to 80%), commercially pure (CP) titanium filters are produced for electrochemical and other corrosion-resistant applications. Higher-density pressed and sintered CP titanium parts are made commercially for the chemical-processing industry.

For more demanding applications, Ti-6Al-4V BE components with densities from 98% to close to 100% are produced by CIP and sintering and by pressing and sintering methods. Very complex shapes, such as impellers or pivot fittings, can be produced by CIP using elastomeric molds (Ref 7). Part size is currently limited to a maximum length of 610 mm (24 in.) by the availability of CIP equipment. The possible dimensional tolerances for small parts are ± 0.5 mm (± 0.02 in.). The pressing and sintering method is more volume oriented.

Prealloyed Products

The relatively high product cost of PA parts has thus far limited the consideration of potential applications of PA technology for the most part to the manufacture of critical aerospace components. As previously discussed, property levels have been attained in properly processed PA compacts that match those of high-quality I/M parts. The decision-making process for using PA P/M is based primarily on economic considerations.

Future Trends in Titanium P/M Technology

Clearly, sufficient data are now available to allow both prealloyed and blended elemental Ti-6Al-4V P/M compacts to be used with confidence. However, cost remains a major concern. Use of the PA P/M approach is difficult to justify for parts with approximately the same, or perhaps even slightly higher, mechanical property levels. Only a significantly lower cost for PA compacts would enable them to replace reliable I/M materials. The production of a low-cost powder either by a scaled-up gas atomization process or by a direct chemical method would be a significant breakthrough. The BE P/M technique can be cost effective for less critical parts, and its increased use in this area is likely. However, as with the PA material, the production of fully dense chloride-free BE products is likely to be stymied by cost unless a breakthrough occurs.

The trend with other conventional titanium P/M alloys is likely to follow that previously described for the Ti-6Al-4V alloy. An exception is the high-strength Ti-1.3Al-8V-5Fe (Ti-185) alloy (Ref 67, 68, 69), which cannot be satisfactorily made by the I/M approach because of the segregation of the iron. This alloy should be strictly classified with rapid solidification alloys (discussed below) that require rapid transformation from the liquid to solid states.

The ordered intermetallic titanium aluminides are much more difficult to process and machine than the conventional titanium alloys. In fact, their production characteristics approach those of the superalloys. Thus, the cost benefits to be gained by a net-shape P/M approach are great (particularly for the equiatomic titanium aluminide, TiAl), and these benefits could accelerate the acceptance of titanium P/M methods, particularly with the development of a lower-cost powder.

Research is being conducted to expand the boundaries of conventional titanium P/M technology. Efforts are in progress to evaluate the possibility of using advanced techniques, such as rapid solidification (Ref 76, 77), mechanical alloying (Ref 78), and nanostructures (Ref 79), to enhance the behavior of titanium-base materials.

Work on rapid solidification has focused on increasing the temperature capability of both terminal alloys and intermetallic compositions by dispersion strengthening. However, while some improvements have been made, they are not considered to be significant enough to warrant the extra cost and concern over product quality assurance associated with a P/M method. The rapid solidification technique has two major drawbacks. The first is that it has been unable to produce more than about 6 vol% of second-phase particles. Second, rapid solidification results in a smaller than desirable β grain size and a lack of elongated α phase formed on cooling into the α - β phase field after a β anneal. Unfortunately, a β anneal, which corrects the second drawback, results in unacceptable coarsening of the dispersoids.

Mechanical alloying of titanium alloys is at a very early stage, but it does exhibit the potential to increase the volume percentage of dispersoids for elevated-temperature applications. In addition, there are indications that the normally immiscible titanium and magnesium can be combined by mechanical alloying to produce a low-density titanium alloy.

Very preliminary results on the mechanical alloying of titanium-magnesium and titanium-eutectoid formers such as nickel and copper suggest that a very fine nanoscale microstructure ($\sim 10^{-9}$ m scale) can be obtained; such a microstructure could have novel physical and mechanical properties. Further information on powder production and P/M applications of titanium alloys is in the article "Production of Titanium Powder" in this Volume.

Titanium Powder Metallurgy Alloys and Composites

Daniel Eylon, University of Dayton; F.H. (Sam) Froes, University of Idaho; Stanley Abkowitz, Dynamet Technology

Particulate Reinforced Titanium

S. Abkowitz, Dynamet Technology Inc.

Since the late 1980's, the unique benefits of the solid-phase processing of P/M titanium alloys have been used in the development of discontinuously reinforced titanium matrix composites. For example, titanium carbide and titanium diboride powders have been added to both commercially pure titanium and the common titanium alloys utilizing the BE technique (Ref 34, 80, 81, 82, and 83). The resultant family of particulate-reinforced metal matrix composites (PR-MMCs) provide improved wear-resistance, elastic modulus, creep, fatigue, and corrosion properties with less than a 3% change in alloy density. Elongation and, to a lesser extent, fracture toughness decrease in the tradeoff. The following examples typify several titanium PR-MMCs, both in current production and under development.

Among the first titanium-base PR-MMC materials introduced to the commercial market was CermeTi-C (Dynamet Technology Inc., Burlington, MA). These composites are created by the BE technique with the addition of titanium carbide (TiC) to prominent titanium alloys, such as Ti-6Al-4V and Ti-6Al-6V-2Sn. The titanium alloy matrix is formed during sintering by diffusion-driven solid state alloying, typically at temperatures less than 250 °C (450 °F) above the β transus, or 1230 °C (2245 °F) for Ti-6Al-4V. As opposed to melt processing, the thermal decomposition of the TiC reinforcing particulate (melting point 3065 °C) can be limited to a practical extent during the sintering cycle. The resultant PR-MMC displays improved strength and elastic modulus, reflecting the load-sharing contribution of the tightly-bonded TiC particulate (density of 4.92 g/cm³, elastic modulus of 448 GPa, and hardness of 3200 HV (Ref 84).

From 5 to 20 wt% TiC is added to commonly used titanium alloys. Typical properties are summarized in Table 5. As an alternative to HIP or in addition to HIP operation, hot working (including forging, rolling, and extrusion) further increases the density and mechanical properties of the titanium alloy PR-MMC. The mechanically homogenized particulate distribution and the refined acicular α - β microstructure are retained by air cooling from the forging or extrusion temperature with a commensurate increase in tensile strength and ductility, as shown in Table 5. High-temperature rigidity and yield strength are shown in Fig. 14 and 15.

Table 5 Comparison of mechanical properties of BE P/M titanium alloys reinforced with TiC or TiB₂ particulate

Be titanium alloy matrix	Yield strength		Ultimate tensile strength		Elongation, %	Reduction in area, %	Modulus, GPa	K_Q or K_{Ic} , MPa \sqrt{m}	Oxygen, ppm
	MPa	ksi	MPa	ksi

Fig. 14 Modulus of elasticity for Ti-6Al-4V and particulate reinforced composites of Ti-6Al-4V

Fig. 15 Yield strength of Ti-C reinforced Ti-6Al-4V after forging. RT, room temperature

The addition of TiB_2 particulate by the BE technique is also done (Ref 85, 86). During normal sintering at 1200 °C (2190 °F), the TiB_2 particulate, in contact with the elemental titanium powder, reacts extensively or completely to form TiB. Upon cooling, the resultant TiB phase platelets extend beyond the boundaries of the prior titanium particles and bridge multiple α - β colonies. Figure 14 shows the effect of elevated temperature on the modulus of TiB_2 -Ti-6Al-4V composite.

In an effort to increase high-cycle fatigue properties over those of the BE matrix alloy, two BE titanium alloy matrix materials, Ti-6Al-2Sn-4Zr-2Mo and Ti-6Al-1.7Fe-0.1Si, have been evaluated with a 5 wt% TiB_2 particulate reinforcement (Ref 87, 88). Starting with low residual chloride, hydride-dehydride Ti powder, and master alloy powders, the blend was mixed with 5 wt% TiB_2 and processed as follows:

- CIP at 400 MPa
- Sintered at 1200 °C (2190 °F) for 3 h
- HIP at 930 °C and 200 MPa

The in situ formation of TiB platelets, with an average measured length of 30 μm and width of 2 μm , regardless of matrix, appeared to decrease the aspect ratio of the α platelets as well. After water-quenching from 1050 °C and a 930 °C anneal, the 10% TiB reinforced Ti-6Al-2Sn-4Zr-2Mo matrix achieved high cycle (10^7) fatigue strength of 590 MPa, a 35% increase in tensile strength, and a modulus of 140 GPa (Table 4).

At the Toyota Central Research and Development Laboratories, Inc., Saito et al. have continued efforts to reduce the cost of BE TiB_2 -based PR-MMCs of titanium alloys (Ref 89, 90, 91, 92, and 93). When 5 wt% TiB is added to BE-derived, metastable β matrix, composed of Ti-4.3Fe-7.0Mo-1.4Al-1.4V, a derivative of Timetal LCB (TIMET, Denver, CO), the resultant 10% TiB reinforcement forms a stable, crystallographically-oriented, coherent interface boundary, increasing the strength, stiffness, hardness, fatigue properties, and heat resistance of the matrix (Table 4). Deformation flow stress of this material at 700 °C approximates that of medium carbon steel, aiding producibility. The authors claim that production cost estimates for automotive engine parts (such as connecting rods or gears), produced from this PR-MMC material, almost compete with steel, but require a stable supply of low-cost titanium powder.

Wear resistance, specific (density-normalized) stiffness, and specific strength are primary considerations in the selection of titanium PR-MMC material for typical applications. The combination of near-net sizing, the absence of an alpha case in the CHIP condition, and machinability similar to the matrix alloy enhance the producibility of BE titanium PR-MMCs.

Prospective performance-driven applications of these BE titanium PR-MMC materials include automotive valves, connecting rods, sporting goods, aerospace and defense missile structures, and industrial tooling.

Future Trends. The practical utilization of titanium PR-MMC materials is growing on three fronts: design, matrix and particulate composition, and producibility. The potential to design and build BE structures with controlled gradients in physical (thermal expansion, density) and mechanical (wear, toughness, fatigue) properties requires close technical interaction between product designer and producer. Because the BE CHIP process allows multiple layers of different titanium alloys and composites to be built up in specific areas before cold isostatic pressing, the concept holds promise as a means of optimizing structural and environmental performance. As examples of increasing design awareness, particulate reinforced composites are under evaluation for clad missile fins and engine valves.

The optimization of BE alloy and particulate compositions will continue under increasing market pressure to reduce production cost without diminishing specific mechanical properties. The ongoing differentiation between automotive and aerospace PR-MMCs continues as the tradeoffs between mechanical property requirements and production economics becomes more focused. Efforts to reduce the cost of the BE titanium matrix constituents, to limit impurities (oxygen and chlorine), and to refine P/M process parameters for consistent production densities above 99% are technical goals of both markets.

Producibility and shape-making technology considerations are driving research in superplastic forming and investment casting of titanium-base PR-MMCs. Elongations of more than 200% have been achieved in TiC reinforced materials in ongoing research in transformation mismatch superplasticity (Ref 94, 95, 96). Recent investment casting trials of TiC composite of Ti-6Al-4V showed improved fluidity, castability, and weldability versus Ti-6Al-4V in thin-walled components.

Titanium Aluminides

D. Eylon, University of Dayton

Interest in titanium aluminide alloys based on the α_2 Ti₃Al and γ TiAl phases began in the 1970s, and powder metallurgy was one of the first alloy processing solutions due to the difficulty in processing alloy cast ingots. Plasma rotating electrode process (PREP) powder and gas atomized (GA) powders were good solutions to achieve uniform chemistry and microstructure materials (Ref 98, 99) for both α_2 (Ref 100, 101) and γ based (Ref 102, 103) alloys. An earlier work on rapidly solidified titanium alloy particulate material (Ref 104) showed that lower temperature HIP compaction can be achieved by increasing the pressure from 100 to 300 MPa, thus retaining the ultrafine particulate structure, which leads to higher strength and ductility. Similar practice resulted in α_2 (Ti-25Al-10Nb-3V-1Mo) and γ (Ti-48Al-2Cr-2Nb) powder compacts with tensile properties better than wrought (Ref 100, 103) due to the retention of fine equiaxed grain structure. The fine equiaxed structure PM compacts were also suitable preforms for forging (Ref 105, 106, 107, and 108) and sheet rolling (Ref 109, 110, 111). The γ alloy P/M rolled sheets are of a very high quality and are now marketed by Plansee in Austria (Ref 110).

Powder Metallurgy Superalloys

John H. Moll and Brian J. McTiernan, Crucible Research, Crucible Materials Corporation

Introduction

THE TERM SUPERALLOY is used to describe those materials with high strength at high temperatures that are used primarily in turbine engines for aircraft and power generation. Superalloys are predominantly nickel-base alloys that are strengthened by solid-solution elements including molybdenum, tungsten, cobalt, and precipitation of a Ni_3Al -type compound designated γ' . There are several iron-, iron-nickel, and cobalt-base compositions that also meet the general description of superalloys.

The development of superalloys has been driven by the need for increasingly higher strength at higher temperatures for advanced aircraft engines. As the strength of these materials increased, hot workability decreased. Additional problems were encountered as the result of increased segregation associated with more complex alloying and the need for larger ingots for larger turbine disks. A solution to these problems was to minimize segregation through rapid solidification of the metal by atomization to powder and consolidation by methods that do not melt the powder particles but still attain full density. A further benefit of the P/M process is that the consolidated products were superplastic and amenable to isothermal forging. Thus, force requirements were greatly reduced and near-net forgings could be made. Near-net shapes are also made by hot isostatic pressing (HIP). Whereas P/M alloys cost more than conventional wrought alloys, they have allowed designers to design to higher creep strength and tensile capability while maintaining the expected cyclic life of components. The value added to the system in terms of the performance benefit gained by the system operating temperature and weight reduction more than balances the increased cost of P/M application.

Initial P/M superalloy compositions were modifications of existing alloys such as IN-100, Astroloy, and René 95. These alloys have been used in aircraft engines for more than 20 years and are still the most widely used P/M superalloys. With segregation essentially eliminated, alloy designers were able to develop a number of new P/M alloys, such as AF115 and AF2-1DA, with exceptionally high strength. Unfortunately the defect tolerance of these alloys was generally not acceptable. Defect tolerance is the ability of a material to resist the growth of a crack initiated by a defect in the microstructure. Current P/M superalloy development centers on somewhat lower strength but highly defect-tolerant compositions such as N18, René 88DT, and Udimet 720.

Powder Metallurgy Superalloys

John H. Moll and Brian J. McTiernan, Crucible Research, Crucible Materials Corporation

Current Use of P/M Superalloys

The first power plant to employ widespread use of extruded and isothermally forged nickel-base superalloy turbine was the Pratt & Whitney F100. It began operational service on the F-15 Eagle fighter in 1974. Currently, most rotating aircraft turbine components are produced via extrusion and isothermal forging. A typical aircraft engine will utilize anywhere from 680 to 2040 kg (1500 to 4500 lb) of nickel-base superalloy powder isothermal forgings. Table 1 lists engines utilizing P/M superalloy forgings (Ref 1).

Table 1 Engine systems utilizing forged P/M superalloys

Engine	Number produced through 1996
GE T-700	9674
GE F-404/414	3077
GE-F110	2259
GE 90	38
PW F100	6496
PW 2000	951
PW 4000	1819

In addition to the widespread use of extruded and isothermally forged components, more than 100,000 as-hot isostatically pressed P/M superalloy components are flying daily in a variety of military and commercial engines worldwide. Table 2 lists engine power plants and airframes utilizing as-hot isostatically pressed P/M superalloy components.

Table 2 Engines and airframe systems utilizing as-HIP P/M superalloys

GE Aircraft Engines		CFM International		AlliedSignal	
Turbine	Airframe	Turbine	Airframe	Turbine	Airframe

T-700-GE-401	Bell AH 1W	CFM56-8	B 737-600/800	RE-220	Gulfstream V Global Express CRJ-700
T-700-GE-401	Sikorsky SH-60B/F				
T-700-GE-700	Sikorsky UH-60A/L				

One of the most interesting and current developments utilizing nickel-base superalloys is the AlliedSignal dual-alloy turbine wheel concept for aircraft auxiliary power units (Ref 2, 3, 4). This design, which began development in 1979, HIP bonds a cast MAR-M-247 blade ring to an as-HIP low-carbon Astroloy hub. This provides an assembly with a fine-grained, fatigue-resistant hub and an investment-cast, creep-resistant blade ring. Since the introduction into commercial service, more than 1000 assemblies on the GTCP 331 APU engine alone have accumulated more than 12 million cycles without failure. Based upon this experience, nine other turbine applications have either been introduced or are in the process of being designed and certified by AlliedSignal. Nearly 10,000 as-HIP turbine disks with integral or inserted blades are also in use in other APU applications, and this usage continues to increase.

Powder Metallurgy Superalloys

John H. Moll and Brian J. McTiernan, Crucible Research, Crucible Materials Corporation

Powder Metallurgy Superalloy Processing

Conventional processing of P/M superalloys involves production of spherical prealloyed powder, screening to a suitable maximum particle size, blending the powder to homogenize the powder size distribution, loading the powder into containers, vacuum outgassing and sealing the containers, and then consolidating the powder to full density. For most applications, the consolidated powder is consolidated by extrusion and subsequently forged to enhance mechanical properties, particularly high-temperature strength and ductility. For some applications, powder consolidated by HIP is utilized without further thermomechanical processing. In either case, the resulting product is fully dense and has properties that are generally superior to cast and wrought material.

Powder Production and Processing. Virtually all powder used to produce P/M superalloys is prealloyed, meaning that the powder is made from the molten state and each powder particle is essentially a mini-ingot with the same composition as the molten alloy. The principal commercial powder-making processes are gas atomization and vacuum atomization. In gas atomization, high-purity raw materials are vacuum induction melted and subsequently atomized using gas. Typically, the equipment consists of a top-melt chamber where high-purity raw materials are vacuum induction melted. The metal is delivered to a nozzle to form a small metal stream that is atomized by high-pressure gas using either a continuous annular-type nozzle or discrete individual nozzles. The resulting powder, which is highly spherical, is collected in a bottom chamber and/or cyclone collector. Argon gas is normally used to atomize superalloys. Nitrogen gas atomization can also be used to reduce cost and to eliminate entrapped argon. The use of nitrogen usually requires slight modifications in composition such as lower carbon content, to accommodate the nitrogen increase associated with the atomization process.

Vacuum atomization is a commercial practice based on the principle that, when a molten metal is supersaturated with gas under pressure and is then suddenly exposed to a lower pressure, the gas expands, comes out of solution, and causes the liquid metal to be atomized. The equipment consists of two vertical chambers connected by a transfer tube. The metal is vacuum induction melted in the lower chamber. When the lower chamber is pressurized with gas, the molten metal is forced upward through the transfer tube. As the metal rises into the upper chamber, it is atomized by escaping gases. The resulting powder falls to the bottom of the upper chamber and then through a powder drain into a collection container. See the article "Atomization" in this Volume.

Superalloy powder can also be produced using the plasma rotating electrode process (PREP) and the centrifugal atomization process. In the PREP process, a plasma arc is used to melt the end of a rapidly rotating prealloyed bar. The high-speed rotation of the bar causes liquid droplets to spin from the end of the bar and solidify in flight through a helium atmosphere. In centrifugal atomization, a molten stream of prealloyed metal is poured onto a spinning disk and atomized by centrifugal force. The emitted liquid particles are further broken up and subsequently cooled by high-pressure helium gas.

Following powder production, the powders are screened to remove oversized particles and then blended to obtain a uniform size distribution. All powder handling is performed to minimize the possibility of introducing foreign material into the powder. This involves the use of specially designed stainless steel containers, valves, and inert handling or air handling of powder in clean rooms. Powder is normally screened to minimize the inclusion size in the final part. Depending on the application, powder sizes ranging from -60 mesh (-250 μm) to -325 mesh (-45 μm) are typically used. Prior to being loaded into containers for consolidation, superalloy powders are evaluated for cleanliness by techniques such as water elutriation, which separates nonmetallic inclusions from the powder for counting, sizing, and identification. A consolidated sample of the

powder can also be evaluated by conducting large bar (e.g., 1.27 mm, or 0.500 in., diameter \times 5.08 mm, or 2.0 in., gage section) fatigue tests. Cleanliness is evaluated on the basis of fatigue life and fracture origin.

Containers for consolidation are made from stainless steel or mild steel. Exhaustive procedures are used to ensure that the containers are clean before powder loading. A "final filter" is commonly used to rescreen the powder as it enters the container as a final in-process control to ensure that no oversized particles are in the consolidated part. At some point in the processing, the powder is subjected to a vacuum and heated to remove air and adsorbed moisture. This can be accomplished during loading or after loading the powder into a container. In the former case, powder is loaded from an evacuated container into an evacuated consolidation container and then the container is sealed. In the latter case, powder is loaded in air into a consolidation container which is subsequently cold and hot outgassed and then sealed. Various combinations or modifications of these two outgassing techniques are used by different manufacturers.

Powder Consolidation. Superalloy powders are consolidated to full density using a combination of high temperature and high pressure. The primary consolidation methods for superalloys are HIP, extrusion, or a combination of the two. For HIP, the powder containers can be simple geometric shapes or complex near-net shapes. The product can be a billet suitable for subsequent extrusion and/or forging. The HIP product can also be a near-net forging preform or a near-net machining preform to be used without additional hot working. The HIP parameters generally used are 1040 to 1205 °C (1900 to 2200 °F) at 105 to 205 MPa (15 to 30 ksi) for 3 to 5 h. An example of a HIP near-net sonic shape and the resulting turbine disk is shown in Fig. 1.

Fig. 1 As-HIP René 95 turbine disks. As-HIP shape (upper left), sonic shape (upper right), finished machined disks (bottom). Courtesy Crucible Compaction Metals

Extrusion of superalloy powders can be done either as the extrusion of loose powder or extrusion of a preconsolidated billet. The extrusion of loose powder requires a specialized container with a nose plug designed to protect the evacuation stem on the container from rupturing prior to entering the extrusion die. Extrusion ratios used for direct extrusion of powder are at least 7 to 1. With extrusion of preconsolidated billet, the powder may be preconsolidated by HIP, a separate forging press, or in the extrusion press against a blank die. Extrusion ratios for solid billet are normally at least 3 to 1. Typical extrusion temperatures for P/M superalloys range from 1040 to 1175 °C (1900 to 2150 °F).

The postconsolidation processing of P/M superalloys is similar to that used for ingot products, but the P/M material has a number of advantages. The uniform grain size and lack of segregation in P/M material generally improves forgeability, machinability, and ultrasonic inspectability. Most P/M superalloys exhibit superplasticity and are normally isothermally forged at low strain rates to reduce force requirements and to produce close-tolerance forgings. Conventional high-strain forging is difficult to accomplish due to the high strength and cracking tendencies of these materials. However, recent work has shown that the high-strain-rate formability of Udimet 720 can be markedly improved by HIP at a temperature slightly below the solidus of the alloy (Ref 5). The improvement is attributed to the elimination of grain boundaries, which are

coincident with prior-particle boundaries. As a result, conventional forging and ring rolling of P/M billet is deemed practical. The ultrasonic inspectability (background noise level) of P/M alloys, due to their homogeneity, is superior to most conventional cast plus wrought superalloys. As a result, smaller flaws can be detected in the P/M alloys.

Heat treatments applied to P/M materials are also similar to those used for ingot product. In general, this involves a solution treatment followed by multistep aging treatments to stabilize carbides and precipitate and stabilize γ' (generally, a precipitate of the form Ni_3Al). Maximum short-time strength is developed with a "subsolvus" solution treatment at a temperature slightly below the γ' solvus temperature. As discussed later, recent studies have shown, however, that fatigue crack growth resistance and creep strength of P/M superalloys can be significantly improved with a "supersolvus" solution treatment slightly above the γ' solvus temperature. The result is improved defect tolerance in these high-strength materials. The supersolvus treatment is being applied to a number of P/M alloys.

Composition and Mechanical Properties of P/M Superalloys

Table 3 gives the compositions of P/M superalloys. Alloys that are in commercial production include René 95, IN-100, LC Astroloy, N18, and René 88DT. A number of alloys are in earlier stages of P/M development. These include Udimet 720, Inconel 706, Inconel 718, AF115, and KM4. Other alloys, such as PA101, MERL 76, and AF2-1DA, were originally considered for P/M applications but are not currently being used commercially. The characteristics and properties of individual alloys are discussed in the following paragraphs.

René 95 is one of the highest-strength alloys available for service in the range of 425 to 650 °C (800 to 1200 °F). The alloy also provides excellent high-temperature creep resistance and low-cycle fatigue life. René 95 was originally developed as a cast and wrought material, but was soon changed to a P/M material due to forging difficulties and inconsistent mechanical properties. Initially, the P/M version was developed for use in the as-hot isostatically pressed (i.e., no hot working) plus heat treated condition (Ref 6). For maximum short-time strength, HIP René 95 is solution treated slightly below the γ' solvus temperature (subsolvus treatment) and rapidly cooled using a molten salt quench followed by two-step aging. This treatment results in a fine equiaxed structure (ASTM 11) with a fine dispersion of γ' . Solution treatment above the γ' solvus (supersolvus treatment) provides increased creep resistance and stress rupture strength through a slightly increased grain size (ASTM 7-8). Tensile and creep rupture properties for hot isostatically pressed René 95 are given in Tables 4 and 5.

Although as-hot isostatically pressed René 95 is in current use, most René 95 production involves extrusion of preconsolidated powder followed by isothermal forging and heat treatment. Tensile and creep rupture properties for

thermomechanically processed P/M René 95 are given in Tables 6 and 7. Typical low-cycle fatigue properties are given in Table 8.

IN-100. Powder metallurgy IN-100 is a modified version of what was originally a casting alloy (Ref 9). It is now widely used as a compressor and turbine disk material by Pratt & Whitney Aircraft. Powder metallurgy IN-100 hardware is produced by extrusion of preconsolidated powder followed by isothermal forging and heat treatment. Typical properties are given in Table 9 (Ref 10, 11).

LC Astroloy is a low-carbon version of cast plus wrought Astroloy. The alloy offers a unique combination of excellent ductility and high-temperature strength. As-hot isostatically pressed Astroloy is used by AlliedSignal in dual-alloy turbine disks as well as one-piece hubs with inserted blades for aircraft auxiliary power units (Ref 2, 4). Processing of the alloy usually involves powder consolidation by HIP or direct extrusion plus heat treatment. Typical properties of HIP plus heat treated LC Astroloy are given in Tables 10 and 11.

N18 is a defect tolerant modification of LC Astroloy developed by SNECMA for high-pressure turbine engine disks (Ref 13, 14). The alloy exhibits high strength as well as good creep resistance and excellent creep fatigue crack growth behavior up to 650 °C.

Alloy N18 is useful in both bore and rim locations at temperatures up to ~650 °C. The alloy is normally produced by extrusion followed by isothermal forging and a subsolvus (1165 °C) heat treatment. Under these processing conditions, the resulting grain size is 12 μm (ASTM 10). Typical tensile, creep rupture, and crack growth rate properties are compared with those of LC Astroloy and IN 100 in Fig. 2, 3, and 4. The properties of the alloy are markedly affected by grain size (Ref 15, 16). Increasing the grain size to 60 μm (ASTM 6) using a supersolvus treatment (1200 °C) increases creep (Fig. 5) and fatigue crack growth resistance (Fig. 6) without major change in low-cycle fatigue resistance. Larger grains can decrease low-cycle fatigue resistance; thus grain size control during processing is most important.

René 88DT (damage tolerant) is a nickel-base P/M superalloy that was developed by General Electric to meet the higher-temperature requirements of advanced engines (Ref 17). The specific goals relative to René 95 were a 50% reduction in cyclic fatigue crack growth rate, a 13 °C (23 °F) minimum improvement in creep and stress rupture strength, and a maximum 10% reduction in tensile strength. The alloy is currently used in production engine disk hardware (e.g., high- and low-pressure turbine disks and forward outer seals). Typical properties of René 88DT are given in Tables 12 and 13.

Udimet 720 was originally developed as a wrought turbine blade alloy for industrial turbines. In the cast and wrought form it is being used as a turbine disk alloy. More recently, the alloy has been evaluated as a P/M material (Ref 18, 19). Reportedly, P/M Udimet 720 has excellent fatigue crack growth resistance and is being strongly considered as a disk material in small to medium gas turbine engines as well as aircraft auxiliary power units. Udimet 720 can be produced by HIP or by extrusion plus isothermal forging. Figure 7 shows a fully machined P/M Udimet 720 turbine disk produced by extrusion plus isothermal forging. A comparison of the costs for P/M and cast and wrought Udimet 720 disks showed more than 20% cost reduction with the P/M process (Ref 18). Tensile properties for P/M Udimet 720 are shown in Fig. 8, and the results of fatigue crack growth rate tests of P/M and cast and wrought material are shown in Fig. 9. Low-cycle fatigue tests ($R = 0.0$, $K_t = 1.0$, $F = 20$ cpm at 425, 540, and 650 °C (800, 1000, and 1200 °F) have shown that the P/M Udimet 720 has mean lives that are higher than cast and wrought Udimet 720.

IN-706 is an iron-nickel-base superalloy that is used for very large forged turbine disks in land-based turbine engines for power generation. Cast and wrought processing for these applications includes vacuum induction melting plus electroslag remelting plus vacuum arc remelting to minimize melt-related defects and segregation. Powder metallurgy is being developed for IN-706 in an effort to further minimize segregation and to lower the cost of these large forgings (Ref 20, 21).

In the P/M work, the effects of varying process parameters (argon and nitrogen atomization, powder size, HIP temperature, forging conditions, and heat treatment) have been studied. Tables 14 and 15 give the results of room-temperature tensile and Charpy V-notch tests of P/M IN-706 in the HIP plus heat treated and HIP forged plus heat treated conditions, respectively. Typical data for cast plus wrought IN-706 are included for comparison. Table 16 gives fracture toughness and low-cycle fatigue data for forged P/M IN-706. Compared to cast and wrought material, the P/M material exhibits good fracture toughness and excellent fatigue resistance. The work conducted to date indicates that P/M IN-706 ages more rapidly than cast and wrought IN-706. As a result, some heat treatment modifications may be required for the P/M version of IN-706.

In addition to excellent mechanical properties, P/M IN-706 is highly resistant to grain growth at elevated temperatures. This is shown in Fig. 10, which compares the grain growth characteristics of IN-706 with cast and wrought IN-706. The grain growth resistance of P/M IN-706 may permit the use of higher forging temperatures and lower forging forces than that used

for cast and wrought material. Powder metallurgy would also permit larger finish cross sections and more reliable ultrasonic inspection.

Fig. 10 Grain size of HIP plus forged P/M 706 and cast and wrought (C/W) 706 after heat treating. Source: Ref 21

IN-718 is similar to IN-706, but has higher elevated-temperature strength. Powder metallurgy IN-718 is being considered as a disk material in the next generation of land-based power generation turbine engines (Ref 22). Research is currently in progress, but no mechanical property data have been reported in the literature. The potential advantages of P/M IN-718 are similar to those described above for P/M IN-706.

AF115 was developed in the 1970s as a very-high-strength P/M disk alloy for 1400-F service (Ref 23), but the alloy is not currently specified for any engine system. However, a lower-carbon version of the alloy (0.05% versus the original 0.15%) continues to be considered for disk application in the as-HIP and HIP plus forged conditions (Ref 24, 25, 26). Typical properties for the alloy in the as-HIP condition are given in Fig. 11, 12, 13, and 14. Properties in HIP plus forged condition are discussed below in the section "Dual-Alloy Turbine Disks/Wheels" in this article.

AF2-1DA-6 is one of the strongest nickel-base superalloys available for use in the temperature range of 650 to 980 °C (1200 to 1800 °F). Typical tensile rupture properties are given in Tables 17 and 18. Powder metallurgy AF2-1DA-6 has been evaluated as a turbine disk material (Ref 29). However, the alloy is not currently specified for any turbine engine application.

Table 17 Tensile properties of P/M AF2-1DA-6 produced by extrusion plus isothermal forging

PA101 is a hafnium-containing modification of the cast alloy IN-792 (Ref 30). The alloy is not currently specified for any engine system, but it has been successfully evaluated as one component of a dual-alloy turbine wheel for small turbine engines (Ref 31, 32). Tensile and stress rupture properties of as-HIP PA101 in a dual-property wheel are given in Tables 19 and 20.

Table 19 Tensile properties of as-HIP P/M PA101 produced as part of a dual-property wheel

760	1400	586	85	70	10

MERL 76 is a P/M alloy that was developed for as-HIP fabrication of turbine engine components (Ref 33). It was designed to have properties in the HIP condition similar to those of isothermally forged IN-100. There are no current applications for MERL 76. Figures 15 and 16 give tensile and stress rupture properties, respectively, for the alloy in the as-HIP plus heat treated condition.

Fig. 15 Tensile and yield strength for as-HIP MERL 76. Heat treatment: 1105 °C (2125 °F)/2 h/oil quench + 870 °C (1600 °F)/40 min/air cool + 982 °C (1800 °F)/45 min/air cool + 650 °C (1200 °F)/24 h/air cool + 760 °C (1400 °F)/16 h/air cool. Source: Ref 33

Specialized P/M Superalloy Processes

Dual-Alloy Turbine Disk/Wheels. There are significantly different operating conditions for various locations in gas turbine wheels and disks (Ref 34). The rims of these parts operate in the 650 to 750 °C (1202 to 1382 °F) temperature range where creep and rupture strength are limiting properties. The bores of these parts operate at temperatures below 550 °C (990 °F). In this temperature region, high tensile strength and low-cycle fatigue resistance are required. Conventional processing of disks and wheels uses a single alloy to meet these varied requirements. As a result, some compromise in properties in either the rim or the bore often has to be tolerated, thereby limiting the service conditions of these parts. Several P/M approaches have been developed to resolve this problem.

AlliedSignal has developed one such process and qualified it for use in auxiliary power unit engines (Ref 2). The process involves a preconsolidated P/M LC Astroloy hub that is HIP bonded to a cast IN713LC blade ring to produce an axial turbine wheel (Fig. 17). The development allowed the high-cycle fatigue requirements of the engine to be met. A similar process has been reported for manufacturing a small axial wheel by HIP bonding a P/M PA101 bore to a cast MAR-M246 blade ring (Ref 32).

Fig. 17 Section of a dual-alloy property turbine wheel produced by HIP bonding a cast IN-713C blade ring to a P/M LC Astroloy hub. Courtesy of AlliedSignal Engine Division

Kobe Steel has developed a process that uses two P/M superalloys: AF 115 for the rim and TMP-3 for the bore (Ref 35). In this process, the bore alloy is HIP consolidated. The rim is then consolidated and bonded to the bore in a second HIP cycle. The resulting assembly is isothermally forged to a turbine disk configuration. Subsequent heat treatment develops the required coarse-grained microstructure in the rim alloy and retains the fine-grained structure in the bore alloy. Figures 18, 19, and 20 give the tensile, stress rupture, and low-cycle fatigue properties of the resulting forging. The tensile properties of the bore and rim section are very similar. As desired, the rim section (AF 115) had the highest strength, whereas the bore section TMP-3 exhibited the highest resistance to low-cycle fatigue.

Fig. 19 Stress rupture strength of a TMP-3 (bore)/AF115 (rim) dual-alloy turbine disk. T , in K; t , in h. Source: Ref 35

Fig. 20 Low-cycle fatigue life of a TMP-3 (bore)/AF115 (rim) dual-alloy turbine disk. Source: Ref 35

General Electric has developed a dual-alloy disk process that utilizes two advanced high-strength P/M superalloys designated KM4 and SR3 as bore and rim alloys, respectively (Ref 36). The process involves forge bonding to join the two components. The advantages of the process are the high degree of mechanical work at the joint and the expulsion of bondline material, which are key factors in developing a high-integrity joint. Figures 21, 22, and 23 give the results of tensile and creep tests of the dual-alloy wheel. The results indicate no loss in strength in the joint region.

Fig. 21 Tensile strength of a KM4 (bore)/SR3 (rim) dual-alloy turbine disk produced by forge bonding. Source: Ref 36

Fig. 22 Yield strength of a KM4 (bore)/SR3 (rim) dual-alloy turbine disk produced by forge bonding. Source: Ref 36

Fig. 23 Time to 0.2% creep data for a KM4 (bore)/SR3 (rim) dual-alloy turbine disk produced by forge bonding. Source: Ref 36

Other dual-alloy processing scenarios are possible. For example, various combinations of alloys and various solid-state joining techniques such as friction inertia welding, hot uniaxial pressing, HIP, and extrusion (Ref 37).

Laser Assisted Rapid Prototyping and Manufacturing. Several processes are being developed that produce a part directly from a three-dimensional computer-aided design (CAD) model. The attraction for these processes is that they require no hard tooling and, as a result, considerable time and cost can be saved in prototyping or manufacturing a metal article. In these processes, a laser is used to sinter or melt input powder one layer at a time until the entire part is built up layer upon layer. Two basic techniques are used: selective laser sintering and direct metal deposition.

In selective laser sintering (Ref 38), a thin layer of powder is laid out on a substrate. A computer-guided laser then traces the first planar layer of the part and sinters only that powder that lies in that plane of the part. The part is then indexed downward the equivalent of one powder layer. A new layer of powder is then placed on the part and the laser traces the second plane of the part and sinters only the powder that lies in that plane of the part. The process is repeated until the part is complete. Figure 24 shows the major components of selective laser sintering equipment.

Fig. 24 Major hardware components of selected laser sintering equipment. Source: Ref 38

Heating the metal to sintering temperatures can adversely affect the mechanical properties of the material, and residual stresses developing upon cooling can induce distortion. An alternate approach has been developed to minimize these difficulties using polymer-coated metal powder as the raw material. The laser is then used only to soften the polymer and form necks with other coated particles that then hold the metal particles in the desired shape. The "green" parts are porous and must be further treated to remove the polymer and sinter the metal. Full density can then be attained by HIP (Ref 39).

Direct metal deposition is similar to selective laser sintering with the exception that the powder is introduced into the laser beam, melted, and deposited. The CAD-based model is used to index the laser and/or the part as the metal is laid down one layer at a time. Variations of the process are referred to as directed light fabrication (DLF) (Ref 27, 40), laser engineered net shaping (LENS) (Ref 41), laser-aided direct metal deposition (LADMD) (Ref 42), or laser aided direct deposition of metals (Ref 43). Figure 25 shows a schematic of the DLF process. Figure 26 shows an Inconel 690 hexagon shape made by the DLF process.

Fig. 25 Schematic of DLF system. Source: Ref 40

Fig. 26 Inconel 690 hexagon shape with hole array made by DLF. Courtesy of Los Alamos National Laboratories

Currently, there is considerable activity aimed at the full development of laser-assisted rapid prototyping and manufacturing. Much of the work has been conducted using stainless steels (Ref 27) and die steels (Ref 44). However, some trials have been conducted on nickel-base alloys such as Inconel 690, Inconel 625, IN-100, and IN-718. Table 21 gives the properties of Inconel 690 bar produced by the DLF process. Some cracking difficulties have been encountered with the γ' -strengthened alloys indicating that some specialized techniques may be required for precipitation-hardened alloys. For more information, see the article "Powder Metallurgy Methods for Rapid Prototyping" in this Volume.

Table 21 Tensile properties of Inconel 690 bar produced from powder by DLF

Material condition	0.2% yield strength		Tensile strength		Elongation, %
	MPa	ksi	MPa	ksi	
DLF--as deposited	448	65	668	97	49
DLF + 930 °C (1700 °F)/ 1 h	489	71	689	100	46
DLF + 980 °C (1800 °F)/ 1 h	475	69	682	99	46
DLF + 1040 °C (1900 °F)/ 1 h	448	65	668	97	47

Conventionally processed hot-rolled rod	372	54	737	107	50

Powder injection molding (PIM) is a relatively low-cost process for producing large quantities of small net-shape complex parts. The process involves mixing powder with a suitable binder, pelletizing the mixture, injection molding into a die, debinding, sintering (plus HIP if required), and heat treatment (Ref 45). The process is used to produce a wide variety of parts from steels, stainless steels, nickel alloys, and cobalt alloys, but has been only recently considered for use with superalloys for aerospace applications. This work has centered primarily on IN-718 (Ref 46, 47, 48, 49). As shown in Table 22, the tensile, stress rupture, creep and high-cycle fatigue properties of PIM IN-718 can meet the minimum requirements of aerospace materials specification AMS 5596. Based on the results of this work, PIM IN-718 is believed to be a viable process for demanding applications with an expected cost reduction of 50% (Ref 48). In another study (Ref 50), PIM was evaluated using MERL 76 and Udimet 700. After HIP, densities of nearly 100% were attained and tensile strengths were at acceptable levels. The oxygen and carbon contents were relatively high, but the distribution of nonmetallic inclusions was fine and uniform.

Table 22 Mechanical properties of PIM Inconel 718

Property	PIM Inconel 718	AMS 5596
Room-temperature tensile

Spray forming involves atomizing a stream of molten metal into droplets and collecting the droplets, an approximately 50/50 mixture of liquid and solid, on a substrate before they fully solidify. The process is capable of producing various shapes such as billet, tubes, disks, and sheet (Ref 51, 52, 53, 54, 55, 56, 57, 58). Spray-formed preforms can have a density up to about 99.8% of theoretical, but the material is normally HIP and/or hot worked to fully densify and improve properties. Compared to conventional P/M, the advantage of the process is the potential of lower cost because powder handling, canning, and the initial consolidation step are eliminated. Disadvantages of the process are a coarser structure and the inability to control inclusion size through particle sizing. The process was originally developed by Osprey Metals and is currently being commercially used to produce billet and tubular shapes of steels and corrosion-resistant alloys.

The application of spray forming to superalloys is currently being developed. The process is being considered for producing engine hardware such as disks and ring-shaped components. For superalloys, the process utilizes vacuum induction melting or electroslag melting to minimize inclusions.

In a process developed by Howmet, designated Spraycast-X, metal is vacuum induction melted, argon atomized to a spray, and deposited onto a preheated rotating mild-steel mandrel. The resulting preform is then fully densified by HIP. Further processing may involve ring rolling or forging. In conjunction with Pratt & Whitney, the process is being evaluated for use in manufacturing engine hardware. A spray plus HIP plus ring-rolled IN-718 PW4000 high-pressure turbine case has been successfully tested (Ref 58).

A process developed by General Electric (Ref 52) uses electroslag remelting of a vacuum induction electrode and a ceramic free-metal delivery system to minimize inclusion content (Fig. 27). Argon gas can be used for atomization, but gas entrapped in the structure can lead to pore formation with subsequent high-temperature exposure such as that encountered in forging, heat treatment, or welding. For this reason, nitrogen gas atomization is being explored (Ref 56, 57). Nitrogen reacts with most superalloys to form stable nitrides. As a result, pore formation does not occur during high-temperature exposure.

Fig. 27 Schematic of General Electric's clean metal spray forming concept. Source: Ref 52

A number of different alloys have been spray formed and evaluated. These include René 95 (Ref 56), 718 (Ref 53, 57, 58), René 41 (Ref 53, 55), MERL 76 (Ref 56), Astroloy (Ref 56), Waspaloy (Ref 53), AF2-IDA (Ref 56), and AF115 (Ref 56). In most instances, the properties of spray-formed plus HIP and/or hot working are equal to or improved over those of cast and wrought material. For example, Fig. 28(a) to (c) compare the properties of spray-formed IN-718 with conventional wrought material. Figure 29 compares low-cycle fatigue data of spray formed plus electron beam welded René 41 with that of conventional wrought material. The low-cycle fatigue strength of the base metal was excellent, but that of the weld material was low apparently due to argon pore formation during welding.

Mechanical alloying is a dry, high-energy ball milling process that can be used to produce composite metal alloy powders with a uniform dispersion of refractory metal particles in a complex alloy matrix. The process occurs by repeated welding, fracturing, and rewelding of powder metal particles. The resulting mechanically alloyed powder is subsequently consolidated and then thermomechanically treated to optimize grain structure and properties (Ref 59, 60, 61, 62). Several alloys have been developed using a γ' strengthened matrix with an yttrium oxide dispersion. The resulting alloys have an exceptional strength at very high temperatures. Compositions of superalloys produced by mechanical alloying are given in Table 23. Typical properties are given in Table 24 and 25 (Ref 63, 64, 65).

Powder Metallurgy Superalloys

John H. Moll and Brian J. McTiernan, Crucible Research, Crucible Materials Corporation

Technical Issues

The major technical issue for P/M superalloys, and cast and wrought superalloys as well, has been and continues to be crack initiation and growth. The useful life of heavily stressed superalloy disks in critical rotating components in aircraft engines can be reduced by the presence of even small inclusions that can act as crack initiators under low-cycle fatigue loading (Ref 66). It is important to note, however, that the low-cycle fatigue behavior of superalloys is being continually improved through inclusion control, alloy development, and heat treatment modifications. Furthermore, designers are now using probabilistic lifing strategies to more reliably predict the useful life of engine hardware. The P/M process is uniquely suited to utilize all four of these methodologies.

Inclusion Control. Figure 30 shows an example of the improvement in low-cycle fatigue behavior of a production P/M superalloy in recent years. This improvement is primarily the result of three major factors. First, the size of potential inclusions has been reduced by reducing the powder particle size. Early P/M superalloy materials were made using powder with a maximum particle size of 250 μm . Most P/M superalloys are now made using a maximum particle size of 105 μm or smaller. From an economic standpoint, this has been made possible by major improvements in fine-powder yields. A second factor is a decrease in the frequency of inclusions. Figure 31 shows an example of how the occurrence of surface-initiated failures in low-cycle fatigue tests has decreased dramatically in recent years, indicating a major reduction in inclusion frequency.

Fig. 30 Average low-cycle fatigue life for a P/M superalloy during 1980 through 1996

Fig. 31 Frequency of surface-initiated failure in 540 °C (1000 °F) strain-controlled low-cycle fatigue tests of a P/M superalloy during 1980 through 1996

The third factor in inclusion control is minimization or elimination of certain types of inclusions. In early P/M superalloys there were four types of potential defects: (1) metallic inclusions, (2) reactive nonmetallic inclusions that result in heavy prior-particle boundary outlining, (3) nonreactive nonmetallic inclusions, and (4) pores and voids. The first two of these tended to be particularly troublesome because they can grow in size with thermal exposure. However, a recent evaluation of low-cycle fatigue fracture initiation sites in P/M Udimet 720 has shown that the predominant initiation features were either grain-boundary facets or microporosity formed by entrapped argon (Ref 18). Less than 30% of the specimens failed at nonmetallic inclusions. These were identified as either discrete particles of zirconia or agglomerated particles of alumina, silica, or titanium oxide. The indication is that metallic and reactive nonmetallic inclusions have been dramatically reduced in

P/M superalloys. Other work has shown that no prior-particle-boundary outlining type defects have been observed at low-cycle fatigue fracture initiation sites in HIP René 95 in the last six years (Ref 8).

It should be noted that a general condition of prior-particle-boundary outlining can occur under conditions that are not related to inclusions. Certain alloys develop particle outlining due to their composition and physical metallurgy. For example, Astroloy can develop γ' decoration at prior-particle boundaries upon slow cooling from above the γ' solvus. The problem can be corrected by resolutioning and rapid cooling. Astroloy, IN-100, and Inconel 718 are prone to form oxycarbonitrides at prior-particle boundaries during consolidation (Ref 67). Usually the condition is minimized by reducing the carbon content of the P/M version of the alloy. The condition can also result from exposure of powder to air at an elevated temperature. The resulting oxygen at the surface apparently facilitates precipitation of oxycarbonitrides at the powder surface. Nitrogen atomization can also result in particle outlining for the same reason.

Prior-particle-boundary outlining caused by the above described compositional and metallurgical factors need not be of great concern. The condition can be avoided by alloy selection, alloy modification, or proper selection of processing parameters. In the event that the condition occurs as the result of a processing error, it is throughout the consolidated material and is readily detected by routine metallography. Furthermore, the condition may not necessarily be detrimental, particularly if the precipitate at the powder boundary forms as discrete particles and not as a continuous film. As previously described, recent work has shown that nitrogen-atomized IN-706, with prior-particle-boundary outlining, has properties that are at least equal to those of argon-atomized IN-706 (Ref 20, 21).

Alloy Development and Heat Treatment. In recent years, considerable effort has been made to improve the defect tolerance of P/M superalloys through alloy development and heat treatment modification. For example, N18 is a modification of Astroloy that exhibits improved creep behavior and fatigue crack growth resistance (Ref 13, 14). Similarly, René 88DT was developed as a more damage-tolerant material than René 95 (Ref 17). As previously discussed, the defect tolerance of nickel-base alloys can also be improved by solution treatment slightly above the γ' -solvus temperature. This "supersolvus" treatment can result in significant improvement in creep strength and fatigue crack growth resistance (Ref 15, 16). These new developments may not have been possible without the compositional uniformity afforded by the P/M process.

Probabilistic Lifting Strategies. The major advantages of P/M superalloys are that they contain less segregation and a finer grain size than conventionally produced alloys. The major benefit of these characteristics is that they deliver a higher fatigue life at elevated temperatures and high stresses. Although it is difficult to directly quantify, it is probable that P/M superalloys contain a lower frequency of large inclusions when compared with cast and wrought product. Designers must use sophisticated means to predict the inclusion size and frequency that will occur in production. Then, some degree of confidence must be calculated that any large inclusion that may occur in production can be detected by available ultrasonic or other nondestructive evaluation techniques after part fabrication. The improved ultrasonic inspectability of P/M alloys is a major benefit to the life prediction analyses of these alloys.

Probabilistic lifting strategies are being used to more accurately estimate part life. These techniques account for the probability of an inclusion being located at, or near, the part surface, and the probability of the inclusion being larger than a critical flaw size. This method of fatigue life calculation initially lowered original estimates of P/M part life when based primarily on laboratory test results. However, as process improvements have been realized that reduce inclusion size and frequency, probabilistic lifting strategies have enabled designers to rely on increased and improved fatigue life predictions for P/M superalloys (Ref 68, 69, 70, 71).

Powder Metallurgy Refractory Metals

Introduction

THE REFRACTORY METALS include niobium (also known as columbium), tantalum, molybdenum, tungsten, and rhenium. With the exception of two of the platinum-group metals, osmium and iridium, they have the highest melting temperatures and lowest vapor pressures of all metals. The refractory metals are readily degraded by oxidizing environments at moderately low temperatures, a property that has restricted the applicability of the metals in low-temperature or nonoxidizing high-temperature environments. Protective coating systems have been developed, mostly for niobium alloys, to permit their use in high-temperature oxidizing aerospace applications.

Refractory metals at one time were limited to use in lamp filaments, electron tube grids, heating elements, and electrical contacts; however, they have since found widespread application in the aerospace, electronics, nuclear and high-energy physics, and chemical process industries. Typical applications are summarized in Table 1.

Table 1 Commercial applications of refractory metals and alloys by industry

Application	Material
Aerospace and nuclear industries	
Counterweights (aircraft, inertial guidance systems)	Tungsten alloys
Solid-propellant rockets	
2650-2750 °C (4800-4980 °F) flame temperature	Molybdenum, tungsten
3425-3550 °C (6195-6420 °F) flame temperature	Silver and copper-infiltrated tungsten
Lifting and guidance structures for glide reentry vehicles	Cb-752 ^(a) , FS-85 ^(a) , C-129Y ^(a)
Leading edges and nose caps for hypersonic flight vehicles	Cb-752 ^(a) , FS-85 ^(a) , Ta-10W ^(a)
Thrust chambers	C-103 ^(a)
Radiation nozzle extensions	C-103 ^(a) , FS-85 ^(a)
Jet engine components	
Augmenter liners	C-103 ^(a)
Center body	Cb-752 ^(a)
Flame holders	Cb-752 ^(a)
Rocket nozzles	FS-85 ^(a) , Ta-10W(Ta-Hf clad)
Thermal shields	C-129Y ^(a)
Porous ionizer plates	Tungsten
Heat shields and cesium vapor inlet tubes (ion engine)	Tantalum
Fasteners	Nb-Ti
Honeycomb structures	Molybdenum, Cb-752, Ta-10W
Hot gas tubing	Ta-10W ^(a)

Hot gas bellows	C-103 ^(a)
Solid propellant expansion nozzle	C-103 ^(a)
Nuclear and high-energy physics	
Linear accelerators, microwave cavities	Niobium
Superconductors	Nb-Ti, Nb ₃ Sn
Liquid metal containers and piping	Nb-1Zr
Electronics industry	
Capacitors	Tantalum powder, foil, wire
Capacitor cases	Tantalum strip
Rectifiers, railway signals	Tantalum
Battery chargers	Tantalum
Transducers	Molybdenum, tungsten
Electron tube parts	
Heaters	Tungsten, W-Re
Supports	Molybdenum
Cathodes	Tantalum
Anodes	Molybdenum, tungsten
Superconducting wire	Nb-Ti, Nb ₃ Sn
X-ray targets	Tungsten, molybdenum, rhenium, composite W-Mo
Electrodes (mercury switches)	Molybdenum, tungsten
Thin-film substrates	Molybdenum, tungsten
Electrical contacts	Tungsten, rhenium, W-Ag, W-Cu
Heat sinks	Molybdenum, tungsten
Backing wafers, semiconductors	Molybdenum, tungsten
Filaments, ion gages, photoflash	Rhenium, W-Re
Process industries	
Heating and cooling coils	Tantalum, Ta-Nb
Shell and tube heat exchangers	Tantalum
Condensers	Tantalum
Tantalum-clad steel vessels	Tantalum
Distillation towers	Tantalum
Valves for hot sulfuric acid service	Molybdenum, tantalum, Ta-Nb
Expansion joints (bellows)	Tantalum
Glass-processing equipment	Tantalum
Crucibles, all sizes up to 1 m (3 ft) diameter × 1.3 m (4 ft) high	Tungsten, tantalum, Ta-40Nb
Spinnerettes, textile industry	Tantalum, niobium
Thermocouple protection tubes	Tantalum-coated copper or steel
Rupture discs	Tantalum
Thermowells	Tantalum-coated copper, tantalum
Spargers, funnels, jet ejectors	Tantalum
Bayonet heaters	Tantalum
Pumps for hydrogen chloride service at 200 kPa (30 psi) and 150 °C (300 °F)	Tantalum (exposed parts)
Cathodic protection electrodes	Niobium
Special equipment	
Furnace parts	
Heating elements, shields, boats, trays, platens, fixtures	Tungsten, molybdenum, tantalum
Susceptors (induction furnace)	Tantalum
Extrusion dies	Tungsten, molybdenum
Piercing points, hot punches	Tungsten, molybdenum
Cups	Tungsten, molybdenum, tantalum
Fasteners (nuts, screws, studs, rivets)	Tungsten, molybdenum, C-3009, C-129Y
Die casting molds, cores	Molybdenum, tungsten
Vacuum-metallizing coils, boats	Tungsten, molybdenum
Springs	Tungsten, molybdenum, tantalum
Boring bars	Tungsten, molybdenum
Surgical implants	Tantalum
Instruments	Tantalum
Electroplating equipment	Tantalum
Thermocouples, spot weld electrodes	W, W-Re alloys

- (a) C-3009 is in the literature as a family of alloys ranging from 9-15% W and $\leq 5\%$ Ti. The hafnium content is constant at 30%.
- (b) Various molybdenum contents; two most common alloys listed.
- (c) Various rhenium contents to $\leq 26\%$; three most common alloys listed

Molybdenum, molybdenum alloys, tungsten, and tungsten alloys require special fabrication techniques. Fabrication involving mechanical working should be performed below the recrystallization temperature. These materials have limited solubilities for carbon, nitrogen, oxygen, and hydrogen. Because the residual levels of these elements required to prevent embrittlement are impractically low, the microstructure must be controlled to ensure a sufficiently low ductile-to-brittle transition temperature (DBTT).

Hot forging or extrusion is used for breaking down ingots into rounds or rectangular sheet bar. These bars, as well as sintered products, are processed into sheet, plate, foil, tubing, and bar. Table 3 gives typical mill-processing temperatures for the refractory metals.

Table 3 Mill-processing temperatures for refractory metals

Metal alloy	Forging		Typical total reduction, %	Extrusion		Typical reduction ratio	Rolling		total reduction between anneals, %

(a) Where a range is given, the higher temperature is the typical starting temperature and the lower temperature is the minimum working temperature for that process.

Most refractory metals and alloys also are available as wire. Tungsten wire, for example, which comes in diameters as small as 0.0102 mm (0.0004 in.), is used as fiber reinforcement in composite materials in which the matrix is any one of various ductile alloys. Tantalum wire is used extensively in capacitor manufacturing and in surgical applications.

Recently, chemical equipment has been fabricated from steel plate explosively clad with tantalum. Forming and welding methods have been developed for fabrication of the clad plate into reactor vessels, tanks, and other types of chemical equipment. Explosive bonding produces a metallurgical bond at the tantalum/steel interface where bond efficiency is over 98%.

Cleaning is critical throughout the fabrication process, especially for niobium and tantalum. Cleaning should both precede and follow welding, heat treating, or any thermal process. Cleaning for these metals is accomplished in a hot alkaline solution (minimum 10 min exposure), followed by a chemical cleaning in a mixture of hydrofluoric, nitric, and sulfuric acids. A coupon of the same alloy must accompany each lot of hardware to record material removal. The coupon should have a reference point for measurement. Each cleaning operation should remove approximately 0.0025 mm (0.0001 in.) per side. The activity of the acid should be checked before the hardware is placed in the acid. If the oxide is thicker than 0.0025 mm (0.0001 in.) per side, it is likely that the entire component has been contaminated.

After cleaning, the part should be handled with clean, lint-free white gloves, and the edges to be welded should be wrapped in a clean, lint-free material such as plastic. Welding should commence as soon as possible after cleaning; the time between cleaning and welding should never exceed 4 h. All weld tooling should be thoroughly cleaned with methyl ethyl ketone (MEK) or an equivalent residue-free compound; an argon or helium cover gas should be kept flowing at 0.6 to 1.1 m³/h (20 to 40 ft³/h) during welding. If copper tooling is used, it must be chromium plated to avoid copper contamination.

Welding. All refractory metals can be joined by electron beam welding, gas tungsten arc welding, or resistance welding. Two major problems are encountered in joining: chemical changes due chiefly to atmospheric contamination and microstructural changes resulting from thermal cycling. The latter changes include grain growth and different stages of

precipitation hardening (solution, precipitation, and overaging). Preheating and postheating generally are required to minimize deleterious effects arising from precipitation hardening as well as from the residual stresses normally induced by welding.

Although recrystallization and grain growth are unavoidable in weldments of wrought tungsten and molybdenum, proper choice of welding process and procedure can localize these effects. Electron beam (EB) welding has proved effective in achieving full weld penetration with an extremely narrow heat-affected zone. As larger EB chambers become available, size limitations for electron beam welding have become less restrictive. Chambers capable of handling hardware up to 1.5 m (5 ft) in the longest dimension are in commercial use.

Rhenium welds made by inert gas or EB methods are extremely ductile and can be formed further at room temperature. Care must be taken during welding to protect the rhenium against oxidation, however. All other refractory metals suffer losses in ductility and increases in DBTT when welded, but niobium and tantalum alloys are less affected than are molybdenum and tungsten alloys. Tantalum and niobium alloys generally retain greater than 75% joint efficiency after gas tungsten arc welding. Preheating is not required, but postweld annealing can restore large amounts of ductility and toughness to commercial alloys. Table 4 summarizes recommended postweld annealing treatments for selected refractory metal alloys; Table 5 lists recommended welding conditions.

Table 4 Recommended postweld annealing treatments for selected refractory alloys

For niobium and tantalum alloys, joint design is particularly important. The surface to be melted must be twice the thickness of the thickest component; that is, if welding a 1.5 mm (0.060 in.) part to a 1.0 mm (0.040 in.) part, weld height (thickness) must be 3.0 mm (0.120 in.). Weld tooling should be of hard chromium-plated copper. No copper can contact the refractory metal. Before use, the hard chromium plate should be wire brushed to check adhesion. If the chromium flakes, the tooling must be stripped and replated.

For gas tungsten arc welding, the weld zone should be well flushed with inert cover gas before striking the arc, and the fusion zone should be allowed to cool below 205 °C (400 °F) with gas coverage. Prior to welding, all burrs should be removed by draw filing with a file used only for one particular alloy. All hand welding should be accomplished in chambers that are evacuated prior to backfilling with argon and/or helium.

Although pure niobium shows no evidence of an aging reaction, Nb-1Zr undergoes abrupt losses in strength and ductility when treated at 815 to 980 °C (1500 to 1800 °F) for up to 500 h. Welds are subject to such embrittlement but can be restored to a ductile condition by postweld vacuum annealing at 1040 to 1205 °C (1900 to 2200 °F) for 3 h. This treatment produces overaging, preventing embrittlement on subsequent heating at a lower temperature.

In contrast to welds in niobium and tantalum, which retain good ductility, welds in molybdenum and tungsten are brittle (<50% joint efficiency), and thus these metals are difficult to join. Before welding, molybdenum and tungsten must be preheated above their ductile-to-brittle transition temperatures to prevent fracture. Sections in thicknesses of 0.64 mm (0.025 in.) and less demand special attention in this respect and, at best, present serious cracking problems. Welds in these metals are always brittle, and joint efficiency depends on the reinforcing effect of the weld bead. Resistance welding is feasible, but some problems with electrode sticking can arise. Resistance Welding Manufacturers' Association (RWMA) class I copper electrodes show the least susceptibility to sticking. Projection welding can result in relatively high mechanical properties.

Tungsten is the most difficult refractory metal to join for satisfactory high-temperature service. Welding, especially the EB process, offers the best compromise for joining tungsten for service at high temperatures. Mechanical joints are unsatisfactory unless molybdenum fasteners are used. Diffusion bonding is impractical because of severe tooling problems. Brazing for relatively low-temperature applications is done using precious metals (silver, palladium, and platinum alloys) and transition metals (nickel and manganese alloys) as filler metals.

Table 6 lists typical brazing filler metals and their maximum service temperatures for all refractory metal systems. Molybdenum brazing has received much attention. Brazed molybdenum honeycomb configurations are used for structural and heat shield applications at temperatures from 1370 to 1650 °C (2500 to 3000 °F). Low-temperature brazing processes have been developed for titanium-zirconium-molybdenum (TEM) alloy. The high remelt temperatures of the filler metals listed in Table 6 permit relatively high service temperatures.

Niobium and its alloys may be silicide-coated with a chromium- and titanium-containing material before being subjected to temperature-oxidizing environments; the preferred braze alloy is Ti-33Cr because it is compatible with the coating. Foil, 0.13 mm (0.005 in.) thick, is fit metal-to-metal to ensure good filleting of the joint. The foil should be held in place with resistance spot welds. Cleanliness of the mating surfaces will ensure good flow of the alloy. A clean vacuum furnace is heated to 1315 °C (2400 °F) and held for 5 min, then increased to 1480 °C (2700 °F) and held for 8 min. The parts must be furnace cooled to 205 °C (400 °F) before exposure to air. After brazing, the hardware should be pickled and diffusion treated at 1315 °C (2400 °F) in a vacuum for a period of 16 h. When possible, the parts should be wrapped in tantalum foil to minimize contamination.

Diffusion bonding also is used to join refractory metals, primarily niobium and tantalum. The same rationale is required as for brazing. Vanadium foil, 0.05 to 0.08 mm (0.002 to 0.003 in.) thick, is placed in the joint and weighted using molybdenum or tungsten tooling. Diffusion bonding with vanadium is considered superior to brazing because a bimetallic system is not necessary, and the joint is microstructurally clean because vanadium forms a continuous solid solution with niobium and tantalum.

Explosive Bonding. Recently, chemical equipment has been fabricated from steel plate explosively clad with tantalum. Forming and welding methods have been developed for fabrication of the clad plate into reactor vessels, tanks, and other types of chemical equipment. Explosive bonding produces a metallurgical bond at the tantalum/steel interface where bond efficiency is over 98%.

Powder Metallurgy Refractory Metals

Properties and Applications

Typical physical properties for pure refractory metals are summarized in Table 7. Figures 1 and 2 compare the temperature-dependent ultimate tensile strengths and elastic moduli of the refractory metals. The values for hexagonal close-packed (hcp) rhenium are quite different from those of the other metals, which are body-centered cubic (bcc).

Tungsten- and molybdenum-base alloys must be hot worked, whereas tantalum and niobium are easily cold worked. Rhenium is used primarily as an alloy additive. Most molybdenum and niobium is used as alloy additions in steels, irons, or superalloys. Other applications are noted in the following sections.

Tungsten

Despite difficulties in fabrication, tungsten is used in more applications than any other refractory metal besides tantalum. Tungsten is consumed in four forms:

- Tungsten carbide
- Alloying additions
- Pure tungsten
- Tungsten-base chemicals

Tungsten carbide accounts for about 65% of tungsten consumption. It is combined with cobalt as a binder to form the so-called cemented carbides, which are used in cutting and wear applications (see the article "Powder Metallurgy Cermets and Cemented Carbides" in this Volume). Metallic tungsten and tungsten alloy mill products account for about 16% of consumption. Tungsten and tungsten alloys dominate the market in applications for which a high-density material is required, such as kinetic energy penetrators, counterweights, fly-wheels, and governors. Other applications include radiation shields and x-ray targets.

In wire form, tungsten is used extensively for lighting, electronic devices, and thermocouples. Tungsten chemicals make up approximately 3% of the total consumption and are used for organic dyes, pigment phosphors, catalysts, cathode-ray tubes, and x-ray screens.

The high melting point of tungsten makes it an obvious choice for structural applications exposed to very high temperatures. Tungsten is used at lower temperatures for applications that can use its high elastic modulus, density, or shielding characteristics as an advantage.

Tungsten and tungsten alloys can be pressed and sintered into bars and subsequently fabricated into wrought bar, sheet, or wire. Many tungsten products are intricate and require machining or molding and sintering to near-net shape and cannot be fabricated from standard mill products. Further information on fabrication and forming is discussed in the article "Refractory Metals and Alloys" in *Properties and Selection: Nonferrous Alloys and Special Purpose Materials*, Volume 2, ASM Handbook.

Tungsten mill products can be divided into three distinct groups on the basis of recrystallization behavior. The first group consists of EB-melted, zone-refined, or arc-melted unalloyed tungsten; other very pure forms of unalloyed tungsten; or tungsten alloyed with rhenium or molybdenum. These materials exhibit equiaxed grain structures upon primary recrystallization. The recrystallization temperature and grain size both decrease with increasing deformation.

The second group, consisting of commercial grade or undoped P/M tungsten, demonstrates the sensitivity of tungsten to purity. Like the first group, these materials exhibit equiaxed grain structures, but their recrystallization temperatures are higher than those of the first-group materials. Also, these materials do not necessarily exhibit decreases in recrystallization temperature and grain size with increasing deformation. In EB-melted tungsten wire, the recrystallization temperature can be 900 °C (1650 °F) or lower, whereas in commercially pure (undoped) tungsten it can be as high as 1205 to 1400 °C (2200 to 2550 °F).

The third group of materials consists of AKS-doped tungsten (that is, tungsten doped with aluminum-potassium-silicon), doped tungsten alloyed with rhenium, and undoped tungsten alloyed with more than 1% ThO₂. These materials are characterized by higher recrystallization temperatures (>1800 °C, or 3270 °F) and unique recrystallized grain structures. The structure of heavily drawn wire or rolled sheet consists of very long interlocking grains.

Tungsten rod or wire has many uses, including light bulb filaments, electron emitters, welding electrodes, electrical contacts, and reinforcing filaments for metal-matrix composites. The rod is fabricated by isostatic pressing of powder and sintering, usually by resistance heating, in a hydrogen atmosphere. The rod is reduced to wire or other forms by hot swaging and is cut to length with diamond saws.

Non-sag wire, prepared from tungsten powder containing about 0.1% potassium aluminum silicate, is particularly useful for hot filaments. During sintering or annealing, the aluminum and silicon volatilize, producing bubbles several angstroms in size. On subsequent working, these bubbles align and promote the formation of interlocking, elongated recrystallized grains.

Additions of thoria or zirconia stabilize the grains and strengthen tungsten rod and wire. Because these compositions can contain up to 1 to 2% oxide, they are, strictly speaking, tungsten alloys. The thoria or zirconia is added as an aqueous nitrate salt solution to tungstic oxide (blue oxide) before reduction. The material is then dried and reduced in hydrogen.

Because thoriated tungsten is stronger than pure tungsten, higher sintering temperatures and longer sintering times are necessary. Swaging and drawing is similar to that performed on pure tungsten except that the rate of work hardening is greater, requiring more intermediate anneals.

Non-swig wire is better when distortion is a problem; however, thoria or zirconia dispersion-strengthened tungsten has superior hot strength and electron emission characteristics. Consequently, thoriated tungsten is widely used for inert gas welding electrodes.

Although silicide and noble metal coatings are effective oxidation-resistant coatings, protective atmospheres such as helium or argon are used to protect tungsten heating and incandescent elements and welding electrodes. Superior heat resistance also makes tungsten an ideal candidate for trays and radiation shields in vacuum or controlled-atmosphere furnaces.

Superior electrical conductivity, combined with resistance to wear and spark erosion, makes tungsten, tungsten-copper, and tungsten-silver useful for electrical contacts. Tungsten is also used in contacts for automotive ignition systems, broadcasting equipment, light switches, and voltage-control thyatron devices.

Tungsten heavy metals contain 90 to 97% W, and the remainder is either copper and nickel or iron and nickel plus additional elements. Densities are high, ranging from 16.8 to 18.5 g/cm³. These compositions are easier to machine than pure tungsten. Tensile strength is several times higher than carbon steel and twice that of brass or cast iron, ranging from 760 to 970 MPa (110 to 140 ksi). Young's modulus for tungsten heavy metals is from 270 to 340 GPa (40 to 50 × 10³ ksi).

Tungsten heavy metals have low thermal expansion coefficients (about half that of iron). They retain dimensional stability over a wide temperature range and exhibit excellent corrosion resistance. These materials can be fabricated economically by P/M techniques, including liquid phase sintering and infiltration. In the latter process, a porous tungsten powder compact is placed in contact with a second, lower melting point metal, which is then heated to its melting point. The liquid metal infiltrates the pores of the tungsten compact. Heavy metal parts are readily machined to close tolerances. More information on processing and properties is contained in the article "Powder Metallurgy Tungsten Heavy Alloys" in this Volume.

Tantalum

Currently, the largest use of tantalum is in electrolytic capacitors. Tantalum P/M anodes are used in solid and wet electrolytic capacitors, and precision tantalum foil is used, although to a lesser extent, in foil capacitors. Tantalum is also used in chemical process equipment, such as heat exchangers, condensers, thermowells, and lined vessels; most notably, it is used for the condensing, reboiling, preheating, and cooling of nitric acid, hydrochloric acid, sulfuric acid, and combinations of these acids with many other chemicals. Because of its high melting point, tantalum is used for heating elements, heat shields, and other components in high-temperature vacuum furnaces, and it has found some use for trueing of grinding wheels. Tantalum and its alloys have been used in specialized aerospace and nuclear applications and have found increasing use in military components. Because of its corrosion resistance to body fluids, it is used in prosthetic devices and in surgical staples. Tantalum is used as an alloying element in superalloys. Tantalum carbide is an important constituent in complex cemented carbides used in cutting tools.

Tantalum Powder. Several methods for reducing tantalum compounds to tantalum metal have been developed, but sodium reduction of K₂TaF₇ to produce tantalum metal powder is the most commonly used today. The product of the sodium reduction can then be further refined by melting. The powder can also be pressed and sintered into bar or sold as capacitor-grade powder. By varying the parameters of sodium reduction (for example, time, temperature, sodium feed rate, and diluent), powders of various particle sizes can be manufactured.

A wide range of sodium-reduced capacitor powders are currently available, with unit capacitances ranging from 5000 $\mu\text{F} \cdot \text{V/g}$ to greater than 25,000 $\mu\text{F} \cdot \text{V/g}$. Capacitor powders are also manufactured from hydrided, crushed, and degassed EB-melted ingot. These melt-grade powders have higher purity than the sodium-reduced types and have better dielectric properties. However, unit capacitance is usually lower for EB-type powder.

Additions of small amounts (10 to 100 ppm) of sintering inhibitors, such as phosphorus, are frequently employed. These agents allow finer powders to be used than would be possible in the absence of an inhibitor. Alternatively, higher sintering temperatures can be used without loss of surface area, thereby aiding vaporization of undesirable impurities. Dielectric properties are thereby improved.

Sodium-reduced tantalum powders are used for 80 to 90% of capacitor applications. Electron beam melted, degassed-hydride powders account for the remainder. Sodium-reduced material is used in high-capacitance devices at lower voltage ratings (<50 V) because these powders can be produced in finer particle sizes, and the material has improved pressing characteristics. The latter permits anodes to be pressed at lower green density.

Consequently, sodium-reduced powders are more efficient, requiring less powder to achieve a given capacitance rating in a finished device. However, electron beam melting provides degassed-hydride powders with an additional purification step. Because of this higher purity, the anodic oxide film can be electrolytically formed, or stressed, to higher voltages without breakdown. Therefore, electron beam melted powders frequently are required for high-reliability capacitors rated for 50 to

125 V use. Figure 3 compares capacitance at several anode sintering temperatures for sodium-reduced and electron beam melted, degassed powders.

Fig. 3 Capacitance of sodium-reduced and electron beam melted, degassed-hydride tantalum powder. For 30 min anode sintering temperature at anode green densities commonly used for each powder

Although the dielectric properties of niobium oxide are inferior to those of tantalum oxide, niobium has been evaluated as a means of producing low-cost capacitors. Considerable niobium powder development work is still required before niobium capacitors will be offered commercially.

Pressing and Consolidation. Tantalum and its alloys are produced in semifinished metallic form by further processing of the sodium-reduced powders. The powder is isostatically pressed into bars, which can then be electron beam melted or sintered at high temperature under vacuum. Tantalum ingots up to 305 mm (12 in.) in diameter can be produced by electron beam melting.

Pressing and Sintering. Manufacturing of the tantalum pellet begins by cold pressing the powder into a low-density pellet. The capacitance rating of the device determines the powder weight required. On the average, the weight per pellet is about 0.2 g (0.007 oz). The pellet is then sintered in high vacuum (10^{-4} torr). The sintering temperature is set low enough to

retain as much of the porous structure as possible, while sintering the "necks" of adjacent particles to form a continuous path of conducting metal.

Further surface purification of the metal also occurs during sintering by volatilization of the monoxides of tramp cations, the presence of which can otherwise cause defects in the anodic oxide film. Sintering temperatures usually range from 1450 to 2000 °C (2640 to 3630 °F). Selection of temperatures is determined by the type of powder and device required; there is a trade-off between loss of surface area and improved purity as temperature increases.

The EB-melting process utilizes evaporation, volatilization of suboxides, and carbon deoxidation as purifying reactions. All of these reactions are more favorable in high vacuum (<130 MPa, or 10^{-3} torr). Because of its high melting point and very low vapor pressure, tantalum can be produced with a purity exceeding 99.95%. In addition, certain metallurgical properties can be imparted to the ingot by the addition of a vacuum arc remelt of the EB-melted ingot. One such property is grain size refinement.

Powder Metallurgy Mill Products. Unalloyed tantalum and tantalum alloy ingots can be broken down by either forging or extrusion. Arc cast ingots should be extruded only after upsetting and side forging. Powder metallurgy sintered bars can be rolled directly without any prior breakdown.

Powder metallurgy products differ from those produced from cast materials primarily because surface oxides are present in the starting powders. These oxides are present in the microstructure of the P/M material. Recrystallization is inhibited and finer grain metal is produced. The product is usually harder and has higher yield and tensile strength but somewhat less ductility.

Powder metallurgy tantalum has superior deep-drawing properties, but it should not be welded because of the porosity that forms in the heat-affected zone. However, EB-melted tantalum can be used for various welded products, including welded and drawn tubing.

Powder metallurgy mill products begin by cold isostatic pressing the powder into bars. The bars are then direct resistance sintered by clamping the ends firmly between water-cooled copper terminals in a vacuum furnace at 1.33×10^{-2} Pa (10^{-4} torr). Heating occurs by the passage of an electric current.

For tantalum, temperatures above 2300 °C (4170 °F) are required to achieve full density and adequate purification (removal of interstitial impurity elements). Sintered bars are then rolled or drawn at room temperature, with appropriate intermediate vacuum anneals.

Tantalum products can subsequently be manufactured by standard cold-working techniques, such as rolling, drawing, tube reducing, and swaging. Typical reductions between anneals are 75 to 80%, but reductions in excess of 95% are not uncommon. Rolled sheet having a controlled, predominant {111} crystallographic texture is being produced because of its superior drawing and forming characteristics. The texture control is achieved by a specific thermomechanical process history.

Microalloying. Oxide microalloying additions, such as thoria or yttria, are sometimes intentionally added to control grain size and strength after recrystallization. Small quantities of silicon are also added, particularly to bars that are subsequently drawn to capacitor wire.

Silicon aids in the retention of ductility of the wire by preventing embrittlement of the tantalum lead-wire embedded in the capacitor pellet. During anode vacuum sintering, oxygen diffuses from the surrounding powder into the embedded wire, which has lower oxygen, and collects at grain boundaries, thus causing embrittlement. Silicon acts as a getter for the excess oxygen. There is evidence that the microstructure is modified with precipitated oxides in the form of globules rather than platelets. A portion of the silicon vaporizes harmlessly as volatile silicon monoxide.

Tantalum Alloys. Selected mechanical and physical properties for commercially prepared pure EB-melted and P/M tantalum and tantalum alloys are given in Table 8.

Table 8 Typical properties of tantalum and tantalum-base alloys

Tungsten and hafnium are the alloying additions commonly added to improve the strength properties of tantalum. Although tantalum powder can be an intermediate, most tantalum alloys are melted. As examples, Ta-2.5%W is used for the fabrication of corrosion-resistant heat exchangers, valves, and other chemical equipment. Ta-10%W, although less ductile, is a harder, stronger, and more wear-resistant alloy and is particularly suited for the fabrication of furnace hardware, missile parts, nozzles, and fasteners.

A Ta-7.5%W alloy, useful for springs, bellows, and leaf springs in severe corrosion environments, such as dry chlorine, bromine, or hydrochloric acid, is made by powder metallurgy. For springs, the modulus of resilience, U_R , is an important parameter. Resilience is defined as the "ability of a material to absorb energy when deformed elastically and retain it when unloaded" (Ref 1). Because the yield strength of the P/M product is higher than ingot material of the same tungsten content, its modulus of resilience is also considerably higher, as shown in Table 9.

Table 9 Properties comparison of Ta-7.5%W sheet made by powder metallurgy and from ingot

$$U_R = \sigma_0^2 / 2E \text{ (see Ref 1)}$$

Molybdenum

More molybdenum is consumed annually than any other refractory metal. Molybdenum ingots, produced by melting of P/M electrodes, are extruded, rolled into sheet and rod, and subsequently drawn to other mill product shapes, such as wire and tubing. These materials can then be stamped into simple shapes. Molybdenum is also machined with ordinary tools and can be gas tungsten arc and electron beam welded, or brazed.

Molybdenum has outstanding electrical and heat-conducting capabilities and relatively high tensile strength (Fig. 4a and b). Thermal conductivity is approximately 50% higher than that of steel, iron, or nickel alloys. It consequently finds wide usage as heatsinks. Its electrical conductivity is the highest of all refractory metals, about one third that of copper, but higher than nickel, platinum, or mercury. The coefficient of thermal expansion of molybdenum plots almost linearly with temperature over a wide range (Fig. 4c). This characteristic, in combination with its heat-conducting capabilities, accounts for its use in bimetal thermocouples. Methods of doping molybdenum powder with potassium aluminosilicate to obtain a non-sag microstructure comparable to that of tungsten also have been developed.

(d)

Fig. 4 Physical and mechanical properties of molybdenum compared to molybdenum alloys and other refractory metals. (a) Specific resistance. (b) Specific heat. (c) Thermal expansion. (d) Strength versus temperature

Applications. The major use for molybdenum is as an alloying agent for alloy and tool steels, stainless steels, and nickel- or cobalt-base superalloys to increase hot strength, toughness, and corrosion resistance.

In the electrical and electronic industries, molybdenum is used in cathodes, cathode supports for radar devices, current leads for thorium cathodes, magnetron end hats, and mandrels for winding tungsten filaments. Molybdenum is also used as a filler

metal for brazing tungsten. Molybdenum resistance heating elements are used in electric furnaces that operate at temperatures up to 2205 °C (4000 °F).

Molybdenum is important in the missile industry, where it is used for high-temperature structural parts, such as nozzles, leading edges of control surfaces, support vanes, struts, reentry cones, heat-radiation shields, heat sinks, turbine wheels, and pumps. Molybdenum alloys are particularly well-suited for use in airframes because of their high stiffness, high recrystallization temperature, retention of mechanical properties after thermal cycling, and good creep strength. Alloy Mo-0.5Ti has been used in many aerospace applications, but TZM is preferred where higher hot strength is needed.

In the metalworking industry, molybdenum is used for die casting cores; for hot work tools such as piercer points and extrusion and isothermal forging dies; for boring bars, tool shanks, and chill plates; and for tips on resistance welding electrodes. It is also used for cladding, for equipment for trueing grinding wheels, for molds, and for thermocouples.

Molybdenum has also been useful in the nuclear, chemical, glass, and metallizing industries. Service temperatures for molybdenum alloys in structural applications are limited to a maximum of about 1650 °C (3000 °F). Pure molybdenum has good resistance to hydrochloric acid and is used for acid service in chemical process industries.

The mechanical properties of molybdenum and molybdenum alloys greatly depend on the amount of working performed below the recrystallization temperature and on the ductile-to-brittle transition temperature. The minimum recrystallization temperature for molybdenum is 900 °C (1650 °F). For optimum ductility, parts should be given at least 50% reduction in area. The metal exhibits superior strength and hardness at elevated temperatures (Fig. 4d). However, when hot strength is required, a molybdenum alloy rather than the element is the material of choice. Titanium and zirconium additions to molybdenum produce alloys with hot strength and recrystallization temperatures above those of unalloyed molybdenum.

Table 10 summarizes the chemistry and basic mechanical property data for 0.38 mm (0.015 in.) wire fabricated from unalloyed molybdenum and several of the newer molybdenum alloys. Additional property data for molybdenum alloys appear in the compilations that follow.

Table 10 Room- and elevated-temperature tensile properties of 380 μm (15 mil) molybdenum wire

Molybdenum Alloy TZM. The molybdenum alloy of greatest technological importance is the high-strength, high-temperature alloy TZM. The material is manufactured either by P/M or arc-cast processes. The composition of TZM is:

Element	%
Carbon	0.01-0.04
Titanium	0.40-0.55
Zirconium	0.06-0.12
Oxygen	<0.0025
Hydrogen	<0.0005
Nitrogen	<0.002
Iron	<0.010
Nickel	<0.002
Silicon	<0.008
Molybdenum	bal

Figure 5 shows typical strength-to-density ratios for TZM compared to other refractory materials. At about 1100 °C (2010 °F), its strength is about twice that of unalloyed molybdenum. The alloy is ideal for structural applications at 1000 °C (1830 °F) under conditions where unalloyed molybdenum normally is used.

Fig. 5 Strength-to-density ratio for TZM compared to refractory alloys

TZM has a higher recrystallization temperature and higher strength and hardness at room and at elevated temperatures than unalloyed molybdenum. It also exhibits adequate ductility. Its superior mechanical properties are due to the dispersion of complex carbides in the molybdenum matrix. TZM is well suited to hot work applications because of its combination of high hot hardness, high thermal conductivity, low thermal expansion, and high resistance to heat checking compared to hot work steels. Major uses include:

- Die inserts for casting aluminum, magnesium, zinc, and iron

- Rocket nozzles
- Die bodies and punches for hot stamping
- Tools for metalworking (due to the high abrasion and chatter resistance of TZM)
- Heat shields for furnaces, structural parts, and heating elements

In an attempt to improve the high-temperature strength of P/M TZM alloys, alloys have been developed in which titanium and zirconium carbide is replaced by hafnium carbide. Such an alloy can contain 1.0% Hf and 0.06% C. It has a tensile strength of 590 MPa (85 ksi) at 1315 °C (2400 °F), compared to 480 MPa (70 ksi) for TZM. Creep rate at 1205 °C (2200 °F) at a stress of 330 MPa (48 ksi) is 0.038%/h, compared to 0.05%/h for TZM.

Other Molybdenum Alloys. Alloys of molybdenum and rhenium are more ductile than pure molybdenum. An alloy with 35% Re can be rolled at room temperature to more than 95% reduction in thickness before cracking. For economic reasons, molybdenum-rhenium alloys are not widely used commercially. Alloys of molybdenum with 5 and 41% Re are used for thermocouple wires.

Niobium Alloys

Commercial application of niobium is dominated by its use as an alloying element in steels. Almost 75% of all niobium metal is used as minor alloying additions in low-alloy steel. Another 20 to 25% is used as alloy additions in nickel-base superalloys and heat-resisting steels. Only 1 to 2% of all niobium is used in the form of niobium-base alloys and pure niobium metal including superconducting niobium-titanium alloy, which accounts for over one-half of all niobium alloys produced (Ref 2).

Originally, niobium metal was produced by powder metallurgy methods which involved high temperature vacuum sintering and carbon reduction. In the early 1960s, however, aluminothermic reduction and electron beam purification became the standard practices (Ref 2). At present, the major process for the recovery of niobium is the aluminothermic reduction of pyrochlore concentrates to ferroniobium. Niobium metal is purified by a chlorination process wherein volatile NbCl₅ is distilled and then hydrolyzed to the oxide. The metal is then recovered by a second aluminothermic reduction:

During the exothermic reaction, oxide impurities slag from the molten niobium. Carbothermic reduction has also been practiced.

Another niobium recovery process involves the collection of niobium oxide as a by-product in the processing of tantalum ores. The ore is digested in mixed acids containing hydrofluoric acid and sulfuric acid, and solvent extraction is employed for purification. After aluminothermic reduction of the recovered oxide, the metal is further purified and consolidated by EB melting.

Powder Production. Powders are produced from ingot by hydriding, crushing, and dehydriding; in addition, some recent efforts have been directed toward producing complex metastable alloy powders, such as niobium-aluminum and niobium-silicon alloys, by liquid metal atomization and rapid quenching. The particle structure of degassed hydride niobium powder is completely analogous to that of a tantalum powder produced in a similar process for capacitors. Typical compositions of niobium and C-103 alloy powder made by this process are compared in Table 11. Niobium powders produced by the hydride-crush-degas process are not normally used for capacitors, and thus milling to a very fine particle size (that is, a high surface area) is not required. Normally, powders are crushed to pass an 80-mesh screen, and a mean particle size of 10 to 15 μm (400 to 600 μin.) is typical. Although thermal agglomeration is feasible and is commonly employed to form clusters for very fine tantalum powders, it is rarely necessary for niobium.

Table 11 Typical composition of niobium and C-103 niobium alloy powder made by the hydride-dehydride process

(a) Analysis in %.

(b) Other elements include cadmium, chromium, magnesium, manganese, lead, tin, vanadium, and zinc.

Niobium powder is frequently used as the starting material to blend with alloying agent powders. The blend is pressed to bars and melted, thereby promoting alloy homogeneity. Niobium alloy scrap, which is reduced to powder by the hydride-dehydride process, can also be incorporated into the alloy blends. One P/M dispersion-strengthened alloy containing 0.5% TiO₂ is claimed to have improved yield strength and high-temperature grain stability.

Product Forms. Most commercial niobium alloys are wrought forms. Primary (bulk) working is generally done by high-temperature extrusion or forging. Secondary working produces a variety of mill products such as sheet, foil, rod, wire, and tubing.

Powder metallurgy methods have been evaluated for common niobium alloys, such as C-103 and Nb-30Hf-9W. It has been determined that the high production cost of atomized niobium powder prevents economic production of net-shape parts. However, hydride-dehydride niobium powders are used to produce commercial quantities of hot working preforms of alloy Nb-30Hf-9W (Ref 2). More information on niobium applications is discussed in Ref 2 and "Refractory Metals and Alloys" in *Properties and Selection: Nonferrous Alloys and Special Purpose Materials*, Volume 2, *ASM Handbook*.

Rhenium

Among the elements, rhenium has the highest melting point, except for tungsten and carbon. Its density is exceeded only by osmium, iridium, and platinum. A ductile-to-brittle transition temperature does not exist in pure rhenium. Rhenium is the only refractory metal that does not form carbides.

Rhenium has a high electrical resistivity over a wide temperature range. Figure 6 compares electrical resistivity values for tungsten and rhenium. Rhenium typically exhibits higher resistivity values than tungsten. This characteristic, combined with a low vapor pressure, makes it ideally suited for filament applications; additionally, it maintains ductility and is not affected by the oxidation/reduction cycle experienced in these applications, as is tungsten.

Fig. 6 Electrical resistivity versus temperature for rhenium, its alloys, and other refractory metals

One of the largest applications for rhenium is for mass spectrometer filaments. These are available in commercial (99.99%) and zone-refined (99.995%) purities.

Rhenium is not attacked by molten copper, silver, tin, or zinc. It dissolves readily in molten iron and nickel, but is stable in the presence of aluminum. Rhenium has a significant hardening effect on platinum.

At elevated temperature, rhenium resists attack in hydrogen and inert atmospheres. It is resistant to hydrochloric acid and seawater corrosion and to the mechanical effects of electrical erosion.

Rhenium is widely used in combination with platinum in catalysts, particularly for selective hydrogenation and crude oil reforming. Rhenium catalysts display high resistance to poisons, such as nitrogen, sulfur, and phosphorus.

Rhenium Alloys. Rhenium is a beneficial alloying addition with other refractory metals. Rhenium greatly enhances the ductility and tensile strength of refractory metals and their alloys (Fig. 7). This tendency is maintained on heating above the recrystallization temperature.

Fig. 7 Effect of alloying additions of rhenium on ductility. (a) Rhenium-molybdenum alloys. (b) Rhenium-tungsten alloys

Rhenium alloys are used in nuclear reactors, semiconductors, electronic tube components, thermocouples, gyroscopes, miniature rockets, electrical contacts, thermionic converters, and other commercial and aerospace applications. Tungsten-rhenium alloys, applied by vapor deposition, are used to coat the surface of molybdenum targets in x-ray tube manufacture.

Other rhenium alloys (with tungsten or molybdenum) are used for filaments, grid heaters, cathode cups, and ignitor wires in photoflash bulbs.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Introduction

TUNGSTEN HEAVY ALLOYS (WHAs) are a category of tungsten-base materials that typically contain 90 to 98 wt% W. Most commercial WHAs are two-phase structures, the principal phase being nearly pure tungsten in association with a binder phase containing the transition metals plus dissolved tungsten (Fig. 1). As a consequence, WHAs derive their fundamental properties from those of the principal tungsten phase, which provides for both high density and high elastic stiffness. It is these two properties that give rise to most applications for this family of materials.

Fig. 1 Typical microstructure of a liquid phase sintered 93 wt% WHA showing the spheroidized tungsten phase and solid solution binder

The current uses of WHAs are quite varied, spanning a wide range of consumer, industrial, and government applications that include:

- Damping weights for computer disk drive heads
- Balancing weights for ailerons in commercial aircraft, helicopter rotors, and for guided missiles
- Kinetic energy penetrators for defeating heavy armor
- Fragmentation warheads
- Radiation shielding, radioisotope containers, and collimation apertures for cancer therapy devices
- High performance lead-free shot for waterfowl hunting
- Gyroscope components
- Weight distribution adjustment in sailboats and race cars
- Heavy casings for downbore logging of oil wells
- Weights in premium golf clubs for improving consistency in response
- Low chatter, high stiffness boring bars, and toolholders for metalworking
- Electrical contacts

When compared to other high density metals, the unique combination of characteristics WHAs offer the materials engineer can easily be seen in Table 1. While lead is generally considered a very dense material, WHAs can easily exceed its density by 60% or more. Lead has been the metal of choice for low-cost density-related applications in past years. Currently, toxicity concerns drive a slow but steady process of lead replacement in many instances. Lead, however, is excluded from many density applications on the basis of its extremely low strength at room temperature, readily recrystallizing under applied stress. Room temperature creep eliminates any use in which it must be tightly fastened or where it is needed in large, thin cross-section geometries.

Table 1 Comparison of high-density metals and alloys

Material	Density, g/cm ³	Melting temperature, °C	Young's modulus, GPa	Cost	Toxicity
Iron (for reference)	7.86	1536	207	Low	Low
Lead	11.4	328	Recrystallization at RT	Low	High
Mercury	13.5	-39	Liquid at RT	Moderate	High
Tantalum	16.6	2996	186	High	Low
WHAs (typical)	17.0-18.5	(1450)	310-380	Moderate	Moderate
DU-0.75Ti	18.6	1135	160	Moderate	High
Uranium	18.9	1132	160	Moderate	High
Tungsten	19.3	3410	410	Moderate	Low
Gold	19.3	1064	80	Very high	Very low
Platinum	21.4	1772	147	Very high	Very low
Iridium	22.5	2443	524	Very high	Very low

(a) RT, room temperature

Many applications that require high gravimetric density for balance weights, inertial masses, or kinetic energy penetrators or high radiographic density for radiation shielding and collimation necessitate rather large bulk shapes. Such a requirement eliminates all but a few candidates on the basis of prohibitive cost, typically reducing the choice of very dense alloys down to either tungsten- or uranium-base materials. Uranium alloys, like lead, are eliminated from an increasing number of potential applications based on toxicity considerations, with uranium-base materials requiring a license except for very small quantities. While the precious metals listed possess attractive densities and offer essentially no toxicity, their cost is prohibitive for all but a few density applications.

WHAs are the preferred form of tungsten for most mass/density related requirements in that large components can be easily fabricated from compacted elemental metal powders by liquid-phase sintering (LPS) in H₂ at moderate temperatures, yielding complete densification at temperatures far below the melting point of tungsten. Figure 1 shows a typical LPS microstructure for WHA. In contrast, pure tungsten must be solid-state sintered at temperatures on the order of 2000 to 3000 °C and achieve densities only slightly greater than 90% without subsequent thermomechanical processing. A number of restrictions on component size and geometric complexity, absent for LPS WHAs, correspondingly apply. Secondly, WHAs are readily machinable by common metalworking tools and techniques, whereas pure sintered tungsten has limited machinability and may require shaping via grinding. Only a very few applications that require high-temperature service would favor the pure metal.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Composition

WHAs typically consist of 90 to 98 wt% W in combination with some mix of nickel, iron, copper, and/or cobalt. The bulk of WHA production falls into the 90 to 95%W range. The choice of alloy composition is driven by several considerations. The

primary factor is the density required by the given application. Further considerations include corrosion resistance, magnetic character, mechanical properties, and postsinter heat treatment options. The first WHA developed was a W-Ni-Cu alloy. Alloys of this ternary system are still occasionally used today, primarily for applications in which ferromagnetic character and electrical properties must be minimized. W-Ni-Cu alloys otherwise offer inferior corrosion resistance and lower mechanical properties than the present industry standard W-Ni-Fe alloys.

The majority of current uses for WHAs are best satisfied with the W-Ni-Fe system. Alloys such as 93W-4.9Ni-2.1Fe and 95W-4Ni-1Fe represent common compositions. Mechanical properties of the unworked alloy vary with the nickel-to-iron ratio, as seen in Fig. 2. Yet alloy selection must take into account the necessity for postsinter heat treatment of extreme nickel-to-iron ratio alloys. Optimal mechanical properties of unworked material are obtained in the vacuum heat treated and quenched state. Due to the body-centered cubic (bcc) structure of the principal tungsten phase, WHAs are sensitive to hydrogen embrittlement. There are two common postsinter heat treatments for WHAs. Vacuum heat treatment is useful for reduction of hydrogen embrittlement and resolutionization/quench for reduction of segregation-induced embrittlement. Yet for cost-sensitive applications, one or both of these processing steps may not be desired. Further, very large components with thick cross sections present a formidable challenge for effective postsinter heat treatment.

Fig. 2 Mechanical property variation as a function of Ni/Fe ratio and heat treatment condition for LPS 93W-Ni-Fe alloy. VA, vacuum anneal; VA + Q, vacuum anneal and quench

Assuming first no postsinter thermal processing, the binder composition is limited both on the nickel-rich and iron-rich sides by the formation of embrittling intermetallics, restricting the range of common use to $1.5 \leq \text{Ni/Fe} \leq 4$. The exact compositional interval is a function of cooling rate from sintering. Alloys with $\text{Ni/Fe} \leq 1.2$ typically possess very low mechanical properties due to the formation of a μ -phase (Fe_7W_6). Once formed, it cannot be resolutionized at practical processing temperatures, being stable to above 1600 °C. W-Ni-Fe alloys with $\text{Ni/Fe} > 5$ offer superior mechanical properties, but form nickel-rich intermetallics, predominantly Ni_4W .

If postsinter vacuum heat treatment is not to be performed, alloys with nickel-to-iron ratios of 1.5 to 2 typically give as good properties as higher ratios. For components that can be vacuum heat treated, nickel-to-iron ratios in the range 2.3 to 4 should be chosen, as better mechanical properties are generated. For applications such as kinetic energy penetrators that demand the utmost in mechanical performance, W-Ni-Fe alloys should be resolutionized and quenched. This processing step reduces both the segregation of interstitial species and the presence of any nickel-rich intermetallics and thereby opens the possibility for use of alloys with nickel-to-iron ratios in the range of 6 to 15, which provide noticeably improved mechanical properties.

The addition of cobalt to a W-Ni-Fe alloy is a common approach for slight enhancement of both strength and ductility. The presence of cobalt within the alloy provides solid-solution strengthening of the binder and slightly enhanced tungsten-matrix interfacial strength. Cobalt additions of 5 to 15% of the nominal binder weight fraction are most common. Higher levels of addition risk the formation of a mixed μ -phase ($[\text{Fe,Ni}]_7\text{W}_6$), which would then require high-temperature resolution/quench of the material.

For extremely demanding applications, even higher mechanical properties are obtainable from the W-Ni-Co system with nickel-to-cobalt ratios ranging from 2 to 9. Such alloys require resolution/quench, however, due to extensive intermetallic (Co_3W and others) formation on cool down from sintering. These alloys not only provide greater quasi-static tensile strength and ductility, but substantial improvement in fracture toughness as well (Table 2). The use of W-Ni-Co alloys is generally limited to defense applications requiring state-of-the-art mechanical properties.

Table 2 Property comparison of unworked alloys

Alloy	Ultimate tensile strength, MPa	Elongation, %	Hardness, HRC	Charpy toughness, J
91W-6.3Ni-2.7Fe	940	35	29	300
91W-6Ni-3Co	960	40	31	470+

A number of specialty WHAs are known as well. An example is the W-Mo-Ni-Fe quaternary alloy, which utilizes molybdenum to restrict tungsten dissolution and spheroid growth, resulting in higher strengths (but reduced ductility) in the as-sintered state. There are also a number of alloy systems in various stages of development for kinetic energy penetrators that are intended to provide a WHA that will undergo high deformation rate failure by shear localization in a manner similar to quenched and aged U-0.75Ti for more efficient armor defeat. These alloys to date have not exhibited a property set of interest for industrial applications, however.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Consolidation

WHAs are typically formulated from elemental powders with mean particle sizes in the range 1.5 to 7 μm . Blend homogeneity is essential for microstructural uniformity and predictable sintering to full density. Blended powder is sometimes mixed with an organic binder such as 1 to 2 wt% paraffin and granulated. While this procedure is required for even die-cavity filling for some component shapes (especially flat forms), it should be employed only when necessary as the introduction of organics necessitates a debinding operation in the process sequence. It is essential that any organic binder be capable of clean thermal decomposition and that the process be carried to completion as residual carbon in the sintering environment can lead to interstitial embrittlement and in the worst case, WC formation. Unlike WC grade powder, WHA blends tend to be readily pressable without a binder using standard techniques such as uniaxial compaction and isostatic pressing at pressures of ~ 200 MPa. Even without organic binders, the green strength of WHA pressings is generally quite acceptable.

WHAs are most commonly processed to full density by solid-state sintering (SSS) or LPS in H₂. The former process is ideal for parts requiring low thermal distortion ("slumping" due to capillary action and/or gravity) and need only minimal mechanical properties. This is often required for precision net-shape parts. Where practical, sintering at a slightly higher temperature allows the formation of an entirely different microstructure capable of significantly higher mechanical properties due to the occurrence of a liquid phase. In the common W-Ni-Fe compositions, liquid-phase conditions are achieved slightly above 1440 °C. Liquid-phase sintering for 90 to 97% W alloys is generally carried out in the range 1470 to 1580 °C, whereas SSS is performed at ~1430 to 1440 °C. Linear shrinkages of ~20% are typical.

Vacuum sintering of WHAs in batch-type furnaces is used only rarely due to the inferior microstructure and mechanical properties obtained. Additionally, if liquid-phase conditions are reached, the high vapor pressure of the transition metals present may cause rapid deterioration of tungsten or molybdenum furnace components in the furnace hot zone. Vacuum sinter furnaces utilizing graphite elements and heat shielding are unsuitable due to excessive carbon transport to the WHA parts, resulting in embrittlement or superficial WC formation.

It is essential that the rate of temperature rise experienced by a pressing be gradual, so as to avoid thermal shock or premature surface pore closure. Below ~1000 °C, there is significant reduction of metal oxides on transition metal particles and general desorption of O₂ and other species. At ~1000 °C and slightly higher, tungsten oxides are readily reduced by the hot H₂ and significant interdiffusion of metallic species occurs, initially by surface diffusion. As the furnace temperature exceeds ~1200 °C, surface closure of interconnected porosity is underway. It is essential that the heating rate is sufficiently slow so as to permit internal deoxidation of the pressing prior to this point. While hydrogen at these temperatures possesses high mobility through the bcc tungsten structure, the H₂O formed by reaction relies on interconnected porosity for escape. If surface porosity is closed prematurely, this molecular species will be trapped, giving rise to residual porosity. In more extreme cases of high oxygen powders, larger voids may form, a process that can be greatly minimized by the use of higher dew point H₂.

Commercial production of WHA components most commonly utilizes continuous pusher-type furnaces in that such designs offer high throughput rates and good temperature uniformity. Pressings are transported through the furnace on ceramic slabs or partially buried in molybdenum boats containing alumina sand. Stoker furnaces in general produce parts with slightly higher mechanical properties than what is obtainable for batch furnace sintering due to better internal material cleanup by the action of the hot flowing H₂, effectively sweeping evolved species from the vicinity of the parts.

While hot isostatic pressing (HIP) and rapid consolidation techniques are also available densification options, their use is very rare because the short processing times generally result in microstructures that yield inferior mechanical properties, often at a substantially higher cost as well. Problems with porosity, common in many P/M materials, is virtually nonexistent in WHAs provided LPS is correctly executed using high quality raw materials.

Liquid-phase sintering provides a superior means of densifying pressings in which a microstructure consisting of spheroids (~40 to 60 μm in size) of nearly pure tungsten in an austenitic binder phase of transition metals plus dissolved tungsten forms via Ostwald ripening. Such a structure provides better mechanical properties than SSS structures due to less angular grains, lower tungsten-tungsten contiguity for a given tungsten content, and a greater percentage of metastable tungsten in the austenitic solid-solution binder. The amount of tungsten retained for common cooling rates from sintering is substantially greater than equilibrium values and varies with the binder composition as seen in Table 3. The slower the cooling rate from sintering temperature, the lower the percentage of retained metastable tungsten in the binder phase.

Table 3 Metastable tungsten retained in solution

Alloy	% W in solid solution
91W-6.3Ni-2.7Fe (SSS)	~18
91W-6.3Ni-2.7Fe (LPS)	~23
91W-6Ni-3Co (LPS)	~40

Postsinter Heat Treatment

A postsinter heat treatment is generally required for any WHA component that has significant mechanical requirements. The most common is a H₂ outgassing treatment employed to virtually eliminate hydrogen embrittlement. During sintering, especially if a liquid phase was allowed to form, WHA parts absorb sufficient hydrogen so as to significantly limit ductility. By subjecting the sintered components to an isothermal treatment in a low pH environment, absorbed hydrogen is given sufficient thermal activation to diffuse to a free surface, recombine into dimer form (H₂), and migrate from the furnace environment. This heat treatment is generally performed at 1000 to 1100 °C for several hours, depending on section thickness. While this operation could be performed in flowing N₂, vacuum heat treatment is usually the most convenient means of protecting the parts from oxidation during processing and is therefore commonly referred to as vacuum annealing. This procedure typically increases the ultimate tensile strength of an alloy by 5% and the elongation up to 40% as compared to the as-sintered property set. While greatly reducing hydrogen embrittlement, the additional time at moderate temperature increases both the segregation of interstitial species to grain boundaries and the amount of intermetallic precipitation in susceptible alloy systems.

While vacuum annealing provides a method of improving low strain rate properties over those of the as-sintered state, dynamic properties such as fracture toughness may in fact be lowered. Resolutionization and quench can be used for dynamic property recovery. This second postsinter step addresses two separate but related embrittlement mechanisms. First, this procedure minimizes segregation-induced embrittlement caused by sulfur, phosphorus, and carbon by providing thermal activation for redistribution of these species into the bulk and preventing reconcentration in the boundary region by imposition of rapid cooling to a temperature at which diffusion is ineffective. This mechanism is operative for all WHAs. Resolution is performed in the vicinity of 1100 °C for 1 to 2 h, followed immediately by a water quench. Secondly, in alloy systems containing intermetallic precipitates, resolution and quench also provides a means of property recovery. The treatment temperature must be increased to ~1200 °C for effective resolution of nickel-base compounds. Quenched WHAs typically exhibit another 5% gain in ultimate tensile strength, 10 to 30% gain in elongation, and ~300% gain in fracture toughness (as evaluated with unnotched Charpy impact) over vacuum annealed material. Resolution and quench make possible the use of high ductility/toughness alloys such as high nickel-to-iron ratio W-Ni-Fe alloys and all W-Ni-Co alloys. All WHAs benefit from such treatment, though not all part geometries may be suitable for such postsinter processing, however. All applications requiring high dynamic properties should specify quenched WHA. While uncommon in commercial practice, it is possible in modern cold-wall sintering furnaces to combine H₂ sintering, vacuum annealing, and quenching into a single energy and time efficient cycle.

Mechanical Processing

For nearly all density- and mass-driven applications, the mechanical properties of unworked WHAs are more than adequate. Yet for many other applications, the strength and hardness of unworked material may be insufficient. Through a combination of mechanical and thermal processing, a wide range of property sets are available. WHAs can be processed for maximum ductility with tensile elongations exceeding 40% or for strength levels exceeding 1650 MPa with a hardness of 50 HRC. As can be seen in Fig. 3, there is a continuous set of mechanical properties available via the trade-off in ductility and toughness for strength and hardness. The greater the initial unworked property set, the greater the range of processing options. The most commonly used means of increasing the strength and hardness of WHAs is by rotary swaging, in which the diameter of a bar is reduced by rapid short-stroke hammering, generally in a four-die configuration. This cold (or occasionally warm) working

results in an increase in bar length and imparts an axial orientation to the microstructure. The extent of swaging possible for a given alloy is a function of its ductility. Table 4 provides a guideline for maximum percentages of reduction in area (RA) via swaging for selected 90 to 93% W alloys, valid for initial bar diameters of 5 cm and smaller.

Table 4 Swaging limitations for various WHAs

Alloy family	Maximum % RA swage
W-Ni-Fe ($2.3 \leq \text{Ni/Fe} \leq 4$)	25
W-Ni-Fe-Co (typical)	30
W-Ni-Co	40

Fig. 3 Strength and ductility can be varied over a substantial range by postsinter processing. The higher the initial mechanical properties, the greater the practical range of processing options

Exceeding the listed %RA values often results in microcracking of the material. Such induced microstructural damage results in diminished returns for greater degrees of working. A more successful approach to achieving higher levels of strength and hardness involves taking material worked from 15% RA to the values shown in Table 4 and subjecting the material to an isothermal treatment—typically 1 to 2 h at 350 to 550 °C. This gives rise to significant strain aging of both the binder phase and the tungsten phase. Attempts at aging in the range 700 to 1000 °C may cause embrittlement in some alloys due to intermetallic precipitation. Aging at ~1200 °C recovers essentially all of the induced strain hardening and essentially returns the material to its original condition, though some microstructural orientation remains. The original mechanical property set will not be recovered, however. The binder no longer contains the same extent of tungsten supersaturation. As tungsten content of the WHA and/or starting bar diameter increases, the limiting value of %RA must be decreased. There are a number of subtle variations that can only be described generically. These include die geometry and feed rate into the swage as they determine the profile of induced deformation and the extent of work. The effectiveness of such processing is seen in Table 5.

Table 5 Typical properties for 93W-4.9Ni-2.1Fe

Condition	Ultimate tensile strength, MPa	Elongation, %	Hardness, HRC	Charpy toughness, J
As-sintered	860	15	29	...
Vacuum annealed	910	25	29	...
Quenched	930	32	29	230
Swaged 15% RA	1115	16	39	150
Swaged 25% RA	1200	14	40	110
Swaged 25% + aged 500 °C/1 h	1400	7	44	80

Although swaging is the most commonly used deformation processing technique for WHAs, alternative methods of working include extrusion (conventional or hydrostatic), forging, rolling, or upsetting for strength and hardness enhancement. Hydrostatic extrusion is capable of successfully achieving very high reduction ratios, producing a fibrous microstructure. Upsetting, a commonly used practice for introducing work into short rods (such as preforms), differs from other techniques in terms of direction of material flow. This difference must be noted for applications in which the Bauschinger effect may prove important.

Microstructure Considerations

In LPS WHAs, the microstructure of most commercial alloys is dual phase and takes the form of spheroids of nearly pure tungsten in an austenitic (face-centered cubic) matrix of the selected transition metals plus dissolved tungsten. In a mature LPS structure of W-Ni-Fe, spheroids are typically 40 to 60 μm in size with a degree of connectedness, termed contiguity. For a given composition, mature spheroid size is a function of sintering temperature, higher temperature favoring larger size. Below approximately 91% W, the binder phase is a continuous structure within the solid. Such alloys display noticeably higher ductility and toughness and also are capable of more rapid work hardening. Tungsten spheroids typically contain less than 0.2 wt% Ni and 0.1 wt% Fe in common alloys. In such alloys, three types of interfaces exist: tungsten-tungsten boundaries, binder grain boundaries, and tungsten-matrix interfaces. Of these three structures, the tungsten-tungsten contact regions are the weakest and therefore serve as a principal limiting factor in the overall strength of the alloy. Thus, any microstructural characteristics that affect these features strongly influence mechanical behavior. Segregation of impurities to this interface serves to weaken its strength. Likewise, an increase in contiguity, resulting in a greater fraction of tungsten-tungsten boundary area, also lowers mechanical properties. It has been demonstrated that the critical flaw size is comparable to the mean spheroid diameter for common alloys.

Contiguity is determined by the weight percent of tungsten, the sintering temperature, and the thermochemistry of the binder phase as to tungsten solubility and wetting behavior. High tungsten content alloys exhibit high contiguity due to the shape accommodation that occurred during LPS as tungsten spheroids grew to impingement (Fig. 4). As the microstructure becomes more brittle, the alloy can undergo less strain hardening prior to fracture. Thus, contiguity and interfacial embrittlement serve to limit both the ductility and strength of WHAs.

Fig. 4 High tungsten content WHAs display substantial amounts of tungsten-tungsten contiguity and shape accommodation during Ostwald ripening, as seen in this example of 98% W

Some applications for WHAs demand densities below 17 g/cm^3 . Such uses, which may often require high bend ductility as well, are best met with SSS material with tungsten contents in the range of 60 to 90%. Solid state sintering provides minimal sintering distortion and near full densification with a more refined microstructure than that available from LPS. A typical SSS microstructure is shown in Fig. 5. The tungsten phase exhibits a mean size of ~ 10 to $15 \mu\text{m}$ in a continuous austenitic binder solid solution. The high volume fraction of ductile binder and the low tungsten-tungsten contiguity of this type result in high deformability. Such material can be easily rolled into thin sheet providing high mechanical properties.

Fig. 5 Typical microstructure of a SSS 70W-Ni-Fe alloy exhibiting fine, polyhedral tungsten grains in a continuous

matrix phase

Whether SSS or LPS, the sintered structure of WHAs can be described as a metal-matrix composite, as each phase presents a distinctly different set of mechanical properties. This structure gives rise to notch sensitivity, and therefore all components requiring high mechanical integrity should avoid grooves, threads, or corners with radii smaller than ~ 0.5 mm. Otherwise, stress concentration will result in reduced mechanical strength. This becomes important also in mechanical property measurement, as specimen preparation, finishing, and marking techniques appropriate for steel specimens may not be suitable for WHA samples.

Notch sensitivity is also the reason why WHA toughness is most commonly evaluated using unnotched Charpy specimens per ASTM E 23, as a much higher level of discrimination is possible. Low-toughness WHA typically tests at ~ 8 J notched and ~ 55 J unnotched. The same alloy in a higher toughness condition would test at ~ 10 J notched and ~ 215 J unnotched. In the notched testing mode, statistical noise would mask any difference, whereas unnotched test results are clearly separated. The use of subscale Charpy bars are sometimes used, but results cannot be compared to full-scale values by ratio of areas as the span of the Charpy anvil remains fixed and hence provides a larger relative span for subscale specimens, leading to artificially high values of absorbed energy to failure.

WHAs also display strain-rate sensitivity. When tested at medium to high strain rates, WHAs provide a significantly higher dynamic yield strength than suggested by quasi-static values. A 90% WHA exhibits a strain-rate sensitivity exponent, m , of ~ 0.012 .

During tensile testing, unworked WHAs generate a load-displacement curve with a high-slope linear elastic region, a rather gentle transition into plasticity and work hardening, and minimal rise in engineering strength to failure. The 0.2% offset yield stress is approximately 67% of the ultimate tensile strength. A Poisson ratio of ~ 0.29 is commonly encountered. Work hardening follows power-law behavior with an exponent of $n \approx 0.51$ for 90% WHA. The rate of work hardening increases slightly with tungsten content. Load-displacement curves of heavily worked WHA exhibit sharp knees with a virtual equivalence of ultimate tensile strength and 0.2% offset yield stress.

Toughness of WHA is readily revealed by both the absorbed energy to failure numbers from Charpy testing as well as the resultant fracture morphology when tested in unnotched mode. Optimal mechanical properties are associated with alloy conditions in which the fracture surface will mainly consist of cleaved tungsten spheroids surrounded by binder that has undergone significant elongation, failing in distinct knife edges between the tungsten grains. Embrittled material typically exhibits distinct tungsten-tungsten spheroid contact zones and matrix decohesion. Highly embrittled conditions, such as from intermetallics forming a peritectic reaction layer on the tungsten phase, typically exhibit an almost glassy fracture of the binder phase (Fig. 6).

Fig. 6 Fracture morphology resulting from mechanical testing clearly reveals substantial differences in alloy properties: (A) high toughness material displaying predominant tungsten cleavage and ductile matrix failure, (B) alloy with tungsten-matrix interfacial embrittlement but good matrix ductility, and (C) extremely brittle failure due

to presence of intermetallic precipitates

In addition to the mechanical difference between the two phases, there are significant electrochemical differences as well. While WHAs are generally considered corrosion resistant, corrosion can nevertheless occur due to local galvanic activity between the tungsten phase, and the electrochemically dissimilar austenitic binder phase if a suitable electrolyte is present. Highly alkaline solutions readily attack the tungsten phase whereas the binder is more readily attacked by acidic solutions. Corrosion can occur under ambient conditions in the presence of very high humidity, especially condensing moisture, and in the presence of ionic salt solutions.

Physical Properties

In that the principal phase in WHAs is nearly pure tungsten, it follows that the physical properties of WHAs should be very close to that of elemental tungsten. A comparison of density and elastic stiffness for various W-(3Ni/Fe) alloys and pure tungsten is provided in Table 6. The (longitudinal) sonic velocity of 90 to 95% WHAs is approximately 5150 m/s, slightly lower than that of pure tungsten. In as-sintered material with a bulk hardness of 29 HRC, the microhardness of the tungsten phase is ~500 HV (25 gf)--approximately that of pure tungsten. The matrix, however, possesses a hardness of only ~300 HV (25 gf).

Table 6 Variation of density and Young's modulus with tungsten content

Wt % W	Density, g/cm ³	Young's modulus, GPa
90	17.2	345
91	17.4	350
93	17.8	360
95	18.2	370
97	18.6	385
98	18.8	390
100	19.3	410

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Thermal Properties

While primarily comprised of the highest melting point metal, WHAs are limited in service temperature by nature of the transition metal binder phase and the formation of intermetallics. There are other factors as well that serve to limit useful service temperature. Under ambient conditions, oxidation alone may impose a temperature ceiling of ~300 to 400 °C. If a WHA bar is in a mechanically worked condition, a temperature as low as ~300 °C will result in noticeable strain aging in as short a time as a few hours, resulting in altered properties. Even if a protective atmosphere is employed, service temperatures ~600 °C and higher are to be avoided as these composite materials exhibit "hot-short" behavior. The ultimate limit on service temperature is imposed by the threshold of formation of a liquid phase, which can occur in some W-Ni-Fe alloys as low as ~1450 °C.

While the coefficient of thermal expansion of pure tungsten is very low at 4.4 ppm/ °C (for 20 to 200 °C), the coefficient of thermal expansion for common WHAs is only slightly higher at ~ 5.0 ppm/ °C. Thermal conductivity for a typical commercial WHA is approximately 120 W/m · K, with a corresponding electrical conductivity of $\sim 14\%$ IACS. Specific heat decreases slightly with increasing tungsten content, ranging from approximately 0.037 cal/g · °C for 90 W to 0.032 cal/g · °C for 97% W. While thermal properties are principally determined by the tungsten phase, service temperature limitations are determined by the binder.

Applications

Virtually all of the applications for WHAs depend upon its high density. WHAs are used in an increasingly wide array of industrial, defense, and consumer products. In addition to impressive gravimetric density, WHAs offer a very useful radiographic density that generally exceeds that of lead, but is slightly lower than that of depleted uranium (DU), depending on the type of radiation and its energy. For 1 MeV γ -radiation, linear absorption by 95W-Ni-Fe is approximately 50% higher than by lead. Additionally, WHAs prove superior for most shielding and collimation applications over lead in that they provide excellent mechanical strength, are readily machined, resist routine handling damage, and pose no toxicity considerations. Consequently, WHAs are widely used as injection syringe shields, bulk radioisotope storage containers, collimator components in cancer therapy devices, and precision shielding for radiation detector assemblies. Some typical configurations are pictured in Fig. 7.

Fig. 7 WHAs can be easily machined into a variety of high density, high tolerance components such as radiation collimators and precision balance weights

A rapidly growing area of use is consumer sporting goods. While WHAs have been employed as high-density dart bodies for decades, large volume consumption is now being realized as these materials are being used for golf club weights and waterfowl shot. In the course of development for premium irons and drivers, club heads are being designed with WHA inserts that provide intelligently concentrated mass so as to increase the "sweet spot" and hence club performance. The remainder of the club head is fashioned from a low density titanium alloy, so as to keep overall club head weight comparable to former all-

steel designs. Some putter designs utilize WHA masses on the extreme ends of the head, thereby increasing the rotational moment of inertia and adding greater directional stability for slightly off-center strikes of the ball. Also of large volume usage is the application of lead-free shot for hunters of wetland birds. A WHA of sintered tungsten-iron provides an excellent density match to lead alloy shot. The tungsten-iron shot does not deform as it passes through the choke of the gun, permitting improved down-range patterning. Currently, shotshells are designed with a special provision for protecting the bore of the gun, thereby overcoming a serious problem present with early tungsten-base shotshells.

For several decades WHA has been used in various designs of kinetic energy penetrators for the defeat of armor on account of its high density and favorable mechanical properties. Designs have ranged from small- and medium-caliber (5.56 to 35 mm bore) fin-stabilized short-rod penetrators to high length-to-diameter ($L/D \sim 20+$) fin-stabilized medium- and large-caliber (35 to 120+ mm bore) rods. These massive projectiles are typically launched at velocities of 1200 to 1650 m/s, with larger designs delivering many megajoules of kinetic energy to the target. Currently, other ordnance concepts require lengths exceeding 1 m and masses greater than 500 kg. Smaller munitions devices in current use employ prescored cases of WHA loaded with high explosive. Upon detonation, the case disintegrates into a controlled dispersion of very high velocity fragments of prescribed size and flight characteristics for both antimateriel and antipersonnel effects. WHA has largely supplanted WC-Co as the material of choice for non-DU penetrators.

While political pressure is mounting against the continued use of DU for ordnance applications, its use persists in large caliber due to the 5 to 10% penetration performance advantage commonly observed over WHA. This slight difference is viewed as critical in that it determines the maximum effective engagement distance to enemy tanks. While much development work has been devoted to developing a WHA with a shearable matrix that could simulate the penetration and erosion behavior of DU-0.75Ti rods, satisfactory results to date have not been obtained. All current penetrator designs employ W-Ni-Fe(-Co) alloys with the exception of the highest performance large-caliber rods that are W-Ni-Co. While higher mechanical properties do not necessarily imply better terminal ballistic performance, high properties are nevertheless desirable for WHA penetrator materials. The higher the property set, the less support required for long rods during launch. The reduced parasitic weight of the launch package means a greater percentage of the energy of a given gun system deliverable to the target.

In addition to making the strongest possible alloys, controlled embrittlement is useful for addressing another class of ordnance requirements. By carefully controlling the degree of embrittlement of a WHA, a penetrator can be fabricated that dependably withstands chambering and launch stresses, but fragments into a controlled dispersion of fragments on impact with metal or composite sheets, depositing a large amount of energy in a localized volume. Termed frangible rounds, these penetrators are useful in damaging large areas of airframes in anti-aircraft warfare. Such rounds suffer minimal velocity fall-off to target and provide a cost-effective means for defeat of spaced light armor and aerostructures.

In answer to an opposite concern, WHA sheet by virtue of its high areal density provides a very effective ballistic shielding material against high-velocity particles even when reasonably thin. WHA has an advantage over DU in that it is not pyrophoric, a consideration that is always present when using DU, whether in machining of parts or for the end use.

WHA is widely used for high stiffness boring bars, long extension toolholders, and chatter-free tooling. When compared to more standard iron-base toolholder materials, WHA offers a 70% gain in stiffness and WC-10Co a 295% gain, as seen in Table 7. While carbide provides superior stiffness, WHA is much easier to machine to form and offers better vibration damping. The elastic mismatch of the two phases, a problem in other contexts, proves advantageous for increased damping. Additionally, the higher density of the WHA provides better inertial damping than that available from the less dense carbide.

Table 7 Comparison of various toolholder materials

Material	Modulus, GPa	Damping	Density, g/cm ³
4xxx steel	210	Low	8
92WHA	360	Moderate	17.5
WC-10Co	620	Low	14.5

One of the most common applications for WHAs is logically balancing weights and inertial masses. The strength and hardness levels of WHAs permit secure mechanical fastening of components, a prime consideration for such applications as aileron balance weights in commercial aircraft. Sizes and configurations of current WHA balancing weights span the spectrum from fractional gram masses for balancing hard disk drive heads to large keel masses for ships weighing up to a metric ton or more. Race cars, commercial aircraft, and guided missiles all benefit from the combination of high density, good mechanical properties, and low toxicity provided by these materials. WHAs are used for gyroscope rotors and flywheels, as the density of these materials allows much greater mechanical energy storage than from materials such as steel. For applications in which WHA weights are exposed to weather, cleaning fluids, or other harsh environments, corrosion can be effectively prevented by epoxy paint or plating with nickel or chromium, all of which are supplanting cadmium plating as more environmentally acceptable alternatives.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Machinability

A prime advantage of WHAs over pure tungsten is their ability to be machined to complex geometries using common metalworking tools and techniques. WHAs in general machine in a manner similar somewhat to gray cast iron. WHAs tend to form short chips on machining. The exceptions are highly ductile, lower tungsten content alloys that may tend to form continuous chips and require more attention to chip breaking. The machining characteristics of such WHAs resemble those of superalloys. As all WHAs possess high elastic stiffness, cutting forces are higher than for most metalcutting operations, thus requiring carbide tooling, rigid support, and adequate spindle torque.

Turning operations are best performed with ISO K10 type inserts. Sharp insert edges are vital for minimizing cutting force. Very rough cuts should be made with negative rake angle inserts though tooling forces will be high. Roughing passes typically utilize depths of cut of 0.7 to 3 mm, feed rates of 0.13 to 0.25 mm/rev, with surface speeds of 60 to 90 m/min. For turning and milling operations, the use of a coolant/lubricant is optional. Finishing cuts are typically made using 0.13 to 0.38 mm depths of cut and feed rates of 0.08 to 0.25 mm/rev. Large nose radius inserts, high spindle speed, and light feed rates contribute to the finest surface finish. Tightest tolerance finishing passes are made with positive rake inserts. WHAs can easily be machined dry. If a cutting fluid is to be used, it should be a water-based, nonalkaline formulation.

Multi-insert cutter heads should be employed for milling WHAs. ISO K10 inserts with a positive rake generally prove most useful. Roughing can be performed at surface speeds of 60 to 120 m/min and feed rates of 0.13 to 0.25 mm per insert. Finishing passes are often conducted at 90 to 150 m/min and reduced feeds of 0.08 to 0.25 mm per insert.

Grinding is best performed with vitrified-bond alumina or silicon carbide wheels of medium hardness. The ductile binder phase present in WHAs prevents the use of diamond wheels due to loading.

Tapping is the most challenging of machining operations for WHAs. Tapping of threads finer than 6-32 may prove impractical. The use of coated cobalt steel taps with two (at most three) heavy flutes and positive rake for increased clearance is highly recommended. Sulfonated oils are effective tapping lubricants. Approaches to minimizing tap/work contact area include the use of large pilot hole sizes and 60% thread area engagement should be considered. Holes $\frac{1}{4}$ -20 and finer may require dropping to 50% engagement due to the high stiffness of the alloy and the correspondingly high torsional stress induced in the flutes and shank. Holes should be tapped to completion without back threading. For larger holes, single-point threading may prove the best option. Designs should always utilize the coarsest thread possible.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Joining

Mechanical fastening techniques should be employed where possible so as to minimize the uncertainties associated with thermal bonding techniques, most of which relate to the formation of embrittling intermetallics. Additionally, thermal bonding of worked WHA is not feasible due to property alteration that will result as a loss of strain hardening or at lower temperatures, overaging.

Due to differences in both chemistry and melting point of the tungsten phase and the binder, WHAs are not readily weldable. Brazing of WHA to dissimilar metals is possible using copper or commercial brazing alloys based on copper, nickel, or silver. In virtually every case, the mechanical properties of the joint are lower due to the formation of intermetallics. Diffusion bonding is also readily performed, but is subject to the same limitations as brazed joints.

When it becomes necessary to join sintered WHA bodies together to form larger components, this is readily accomplished by sinter bonding, in which the pieces are placed in contact and heated sufficiently to permit liquid-phase formation. If done properly, this technique yields an imperceptible joint with no local degradation in properties.

Powder Metallurgy Tungsten Heavy Alloys

S.G. Caldwell, Teledyne Metalworking Products

Environmental Considerations

As environmental and safety considerations become evermore important drivers in the design of new products and selection of appropriate materials, the fact that WHAs have only a slight percentage of their total weight in slightly toxic metals such as nickel and cobalt provides an incentive for their selection over other common high density materials such as lead and DU. Whereas the latter two materials pose definite toxicity concerns, less than 7% of the total weight of a typical WHA is comprised of metals such as nickel and cobalt.

Life cycle considerations are also favorable for WHAs as these materials are readily recyclable by both chemical and oxidation/reduction means. Both WHA machining scrap and spent components serve as raw materials for future alloy production instead of posing a disposal problem. WHAs are therefore an ideal materials choice for applications requiring a combination of high density, good machinability, moderate cost, minimal toxicity, high stiffness, and reasonable thermal stability.

Powder Metallurgy Cermets and Cemented Carbides

Introduction

METAL AND CERAMIC composites include two types of materials known as cermets and cemented carbides. The most outstanding example of the desirable properties obtained from combining metal and ceramic materials involves the hard-metal types made from cemented carbides. Cemented carbides have enjoyed a steady expansion over the past six decades. Over that time, the development of metal-ceramic tool materials has moved away from the early tungsten-base carbides to carbide- and nitride-base compositions of increasing complexity (Table 1). This includes several types of cermet materials.

Table 1 History of cermet product development and marketing

Year	Composition	Trademark	Manufacturer
1930-1931	WC-Co	G1	Krupp-Widia
1930	TiC-Mo ₂ C-(Ni, Mo, Cr)	Titanit S	Metallwerk Plansee
1930	TaC-Ni	Ramet	Fansteel Corporation
1933	TiC-TaC-Ni	...	Siemens AG
1938-1945	TiC-VC-(Fe, Ni, Co)	...	Metallwerk Plansee
1949-1955	TiC-(NbC)-(Ni, Co, Cr, Mo, Al)	WZ	Metallwerk Plansee
	TiC-(Nb, Ta, Ti)C-(Ni, Mo, Co)	Kentanium	Kennametal
1952-1954	TiC-(steel, Mo)	Ferro-TiC	Sintercast (Chromalloy)
1960	TiC-(Ni, Mo)	...	Ford Motor Company
1970	Ti(C, N)-(Ni, Mo)	Experimental alloys	Technical University Vienna
1974	(Ti, Mo) (C, N)-(Ni, Mo)	Spinodal Alloy	Teledyne Firth Sterling
1975	TiC-TiN-WC-Mo ₂ C-VC-(Ni, Co)	KC-3	Kyocera
1977-1980	TiC-Mo ₂ C-(Ni, Mo, Al)	...	Ford Motor Company, Mitsubishi
1980-1983	(Ti, Mo, W) (C, N)-(Ni, Mo, Al)	...	Mitsubishi
1988	(Ti, Ta, Nb, V, Mo, W) (C, N)-(Ni, Co)-Ti ₂ AlN	TTI, TTI 15	Krupp-Widia

Powder Metallurgy Cermets and Cemented Carbides

Cermets

Cermet is an acronym that is used world wide to designate "a heterogeneous combination of metal(s) or alloy(s) with one or more ceramic phases in which the latter constitutes approximately 15 to 85% by volume and in which there is relatively little solubility between metallic and ceramic phases at the preparation temperature" (Ref 1, 2). A good definition of the term ceramic can be found in the *Ceramic Glossary* (Ref 3): "Any of a class of inorganic, nonmetallic products which are subject to a high temperature during manufacture or use. Typically, but not exclusively, a ceramic is a metallic oxide, boride, carbide, or a mixture or compound of such materials; that is, they include anions that play important roles in atomic structures and properties." With particular reference to cermets, this definition of the ceramic component could be broadened to include nitrides, carbonitrides, and silicides.

Cermets originally were used for cutting tool applications. Some 45 years ago (Ref 2, 4), they began to be considered for use in more taxing applications, such as propulsion systems. The expectations were that the refractory behavior, strength, and corrosion resistance of the ceramic phase could be mated advantageously on a proportional basis with the high ductility and thermal conductivity of the metallic phase, and that some superior new materials would become available for a multitude of high-temperature applications.

A significant application of cermets involves cutting tool materials that utilize titanium carbide or titanium carbonitrides as the hard refractory phase. Frequently, molybdenum carbide (Mo_2C) and other carbides are also built into these cermet formulations. The cratering and flank wear resistance properties of the titanium carbide and titanium carbonitride cermet tool materials are better than those of the conventional cemented-carbide (that is, cobalt-bond tungsten carbide) tool. In comparison to ceramic cutting tools, these cermets permit heavier cuts, which, at high speed, results in greater amount of metal removal at a comparable level of tool life. Cermets clearly possess characteristics of a cutting tool material that is capable of filling the gap between conventional cemented carbides and ceramics (see *Machining*, Volume 16 of the *ASM Handbook*).

Classification of Cermets

Cermets can be classified according to their hard refractory component. In this system, the principal categories of cermets are determined by the presence of six components: carbides, carbonitrides, nitrides, oxides, borides, and miscellaneous carbonaceous substances.

The metallic binder phase can consist of a variety of elements, alone or in combination, such as nickel, cobalt, iron, chromium, molybdenum, and tungsten; it can also contain other metals, such as stainless steel, superalloys, titanium, zirconium, or some of the lower-melting copper or aluminum alloys. The volume fraction of the binder phase depends entirely upon the intended properties and end use of the material. It can range anywhere from 15 to 85%, but for cutting tool applications it is generally kept at the lower half of the scale (for example, 10 to 15 wt%) (Ref 5).

The metallic bond for each cermet is selected in order to produce the desired structure and properties for the specific application. The iron group metals and their alloys dominate as in the cemented tungsten carbide class of hard metals; nickel and, to a lesser extent, cobalt and iron possess a desirable combination of relatively high hardness and good ductility. However, the binder for a cermet can also be chosen from the group of more reactive metals, such as titanium or zirconium, or it can be selected from series of refractory metals that includes chromium, niobium, molybdenum, and tungsten. Lower-melting metals and alloys, primarily those based on copper and aluminum, round out the list of binders at the bottom of the temperature scale. Aluminum, however, is more commonly associated with metal-matrix composites.

Carbide-base cermets are by far the largest category of cermets, even if the term is used in its narrower sense and excludes the broad field of cemented-carbide cutting tools and wear parts based on tungsten carbide (WC). Since the inception of cermet technology, the dominant concept has been that of a material based on TiC as the primary hard and refractory constituent, with the bonding provided by any of a variety of lower-melting ductile metals or alloys (much the same as those used for cemented tungsten carbides). The TiC cermets have found use in tool and wear resistance applications; in selected high-stress, high-temperature systems; and in corrosive environments. Cermets based on SiC and B₄C, which generally are classified as metal-matrix composites, have gained considerable industrial significance in wear and corrosion resistance, or antifriction, applications; they are also used in nuclear reactor applications. Cermets with a chromium carbide (Cr₃C₂) base have been used for a variety of corrosion resistance applications and as gage blocks; however, they have apparently lost much of their industrial usage.

Carbonitride-base cermets can be produced with or without additions of various other carbides (of which Mo₂C is the most important); they are bonded with the common cemented-carbide binders. At present, these materials are the primary cermets for tool applications. Their enhanced strength, which makes them suitable for high-speed cutting tools, is based on a greatly improved bond between the hard carbide grains and the binder metal. The improved bond is a consequence of a miscibility gap in the quaternary TiC, TiN, MoC, and MoN system that results in a so-called spinodal decomposition into two isostructural phases (Ref 6) with inherently better wettability to the binder (Ref 5).

Nitride-base cermets constitute a special class of tool materials. Titanium nitride (TiN) and especially cubic boron nitride (CBN) produce excellent cutting materials if they are combined with a hard binder metal. Titanium nitride and zirconium nitride (ZrN) bonded with their respective metallic elements have been developed for special heat- and corrosion-resistant purposes.

Oxide-base cermets constitute a category that includes UO₂ or thorium dioxide (ThO₂), which are used for a major fissions component in nuclear reactor fuel elements; Al₂O₃ or other highly refractory oxides, used for components in liquid-metal manipulation (for example, pouring spouts) and general furnace parts; and SiO₂, used for a minor constituent in friction elements. Combinations of Al₂O₃ with TiC are suitable for hot-machining tools.

Boride-base cermets have a boride of one of the transition metals as the dominant phase. These cermets provide excellent high-temperature corrosion resistance to attack by active metals, such as aluminum, in the molten or vapor state. A combination of ZrB₂ and SiC is resistant to erosion from the propulsion gases of chemical rockets.

Carbon-containing cermets are materials that contain graphite in varying proportions. They are used for electrical brushes and contacts or as minor constituents to provide some lubrication in friction elements. Also included in this category are diamond particles within metal matrices that are used in special tools.

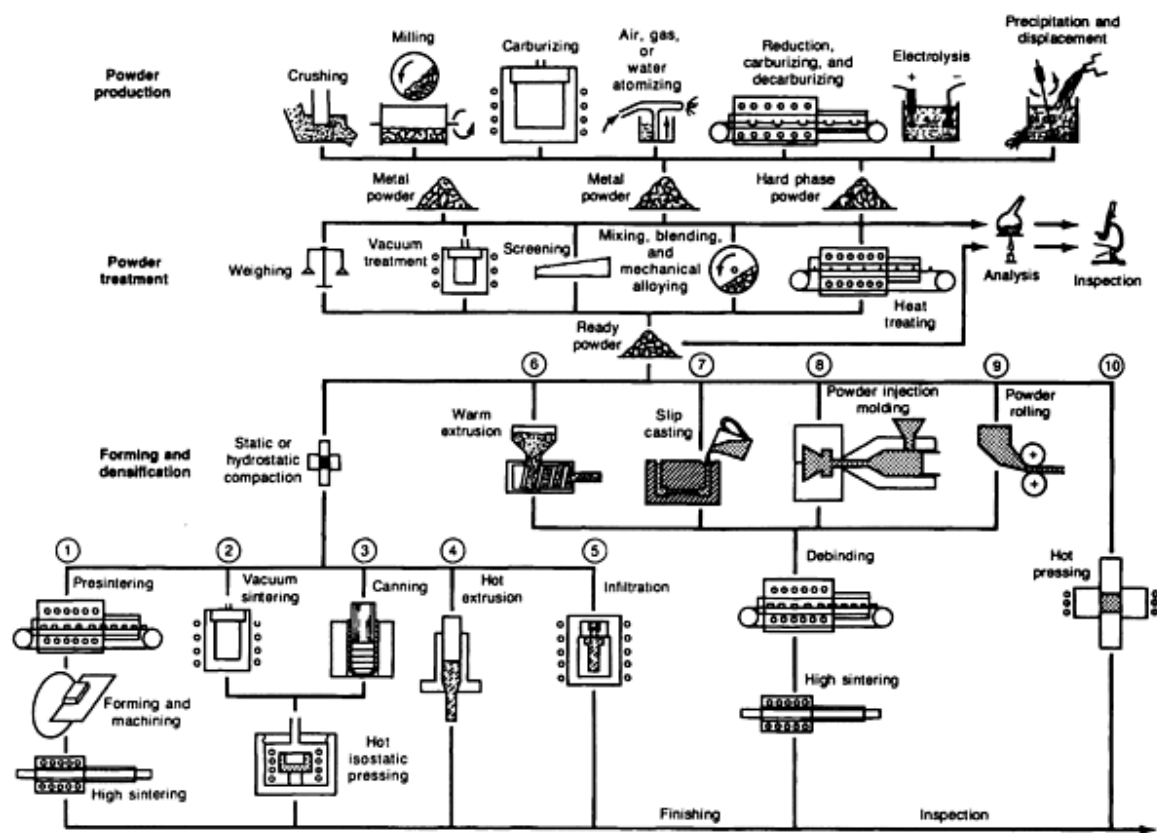

Cermet Fabrication

The methods used for powder preparation, forming, firing or sintering, and post-treatments of cermets generally are similar to conventional ceramic and powder metallurgy (P/M) processing techniques. Figure 1 is a flow chart of the various P/M

techniques applicable to cermets. Table 2 summarizes the relative characteristics of the major forming methods that are practiced in producing carbide-base and most other types of cermets. The principal processes are cold forming and sintering, pressure sintering, and infiltration.

Table 2 Cermet forming techniques

Technique	Size capability	Shape capability	Mold or die requirements	Production	
				Rate	Labor
Static cold pressing	Limited by press capacity	Prismatic shapes without undercuts	Hardened steel or carbide dies	High	Low to moderate
Hydrostatic cold pressing	Limited by capacity of pressure vessel	Simple or complex shapes	Rubber molds	Low	High
Powder rolling	Limited width, long length	Flat and thin	...	High	Low
Warm extrusion	Limited by equipment size	Long pieces with uniform cross section	Hardened steel or carbide dies	High	Low
Powder injection molding	Small pieces	Complex shapes with undercuts	Hardened steel or carbide dies	High	Low
Static hot pressing	Limited by press capacity	Prismatic shapes without undercuts	Graphite or ceramic molds	Low	High
Hot isostatic pressing	Limited by capacity of pressure vessel	Simple or complex shapes	...	Medium	Low to high
Hot extrusion	Depending on press capacity	Long pieces with uniform cross sections	Alloy steel dies	High	Low
Infiltration	Depending on equipment	Intricate shapes feasible	Graphite and ceramic molds	Low	High

Production method	Products
1. Presintering	Cemented-carbide parts and cermets
2. Vacuum sintering	Steel-bonded carbides (standard pieces) and cermets
3. Canning	Steel-bonded carbides (special pieces)
4. Hot extrusion	Aluminum cermets with moderate amounts of hard-phase additions
5. Infiltration	TiC parts with nickel- or cobalt-base infiltrants and other cermets with about 55-85 vol% hard phase
6. Warm extrusion	Cemented-carbide rods or other slender cermet parts
7. Slip casting	Cermets with high proportions of hard phase
8. Powder injection molding	A wide variety of cermet compositions
9. Powder rolling	Aluminum, copper, and other nonferrous metals with moderate additions of hard-phase components
10. Hot pressing	A wide variety of cermet compositions

Fig. 1 Powder metallurgy production methods for cermet and cemented-carbide products

The cold-pressing process includes static uniaxial and isostatic multiaxial compaction. The powder mixtures are compacted at pressures of 35 to 100 MPa (5 to 14.5 ksi). The predominant method involves pressing dry wax-lubricated powder in hardened steel dies with double-action opposing punches. For long rods or tubes of uniform cross section, these dies are used for the extrusion of a paste in which the powder particles are embedded in suitable organic binder or wax. To form complex or large shapes, the dry powder is placed in a pliable mold and compacted from all sides by hydrostatic pressure inside a sealed, reinforced steel cylinder.

Powder Preparation. The first step in the cermet production process is the mixing and milling of the ingredient powders. The mixtures, consisting of the hard-phase substance in powder form and the pure metal or metals in the proper proportions required for the composition of the binder alloy, are milled in ball mills. The balls are made of tungsten carbide or, more frequently, of a highly sintered cermet. The mill can be lined with the same type of cermet material to reduce the possibility of mixture contamination. In addition to conventional ball mills, high-energy vibratory ball mills and attrition mills are used. With the later type of mills, substantial savings in milling time, energy, and floor space can be achieved. During the milling process, the hard phase particles are comminuted and thoroughly coated with binder metal. Organic liquids such as hexane are used in the process to minimize the rise in temperature and prevent oxidation. After the powders have been milled to a particle size of 325 mesh or finer, the mixtures are dried before further processing and use. A lubricant is then added, and those powder mixtures destined for compaction in automatic presses are agglomerated so that they can flow freely from the hopper to the compacting die.

Static Cold Pressing. Cold-pressing methods for cermet powder mixtures generally follow the well-known powder-compacting techniques used in conventional powder metallurgy. Small cermet parts needed in reasonably large quantities are compacted in special hard-metal dies by automatic presses with double-action opposing punches (Fig. 2). Whether solid or segmented, the dies are shrunk into a strong, tough, heat-treated steel retainer.

Fig. 2 Static cold pressing with (a) a conventional press and (b) an anvil press. The anvil press has no upper punches; therefore, the misalignment, breakage, and wear problems associated with those punches are eliminated. Courtesy of PTX-Pentronix, Inc.

The automatic compaction cycle consists of filling powder in the die, compacting the powder, ejecting the compact, and removing it. Two methods are used for ejecting the compact from the die. In the first method, the lower punch moves upward and pushes the bottom of the pressed piece to the level of the die table. In the second method, the die is forced down (withdrawn) over the lower punch until the bottom of the compact is on level with the top of the die (Fig. 3). The second method is gaining favor with many specialists because it allows building shorter, less expensive tools, and because it provides better support for the fragile compact during ejection.

Fig. 3 Withdrawal press cycle with controlled die motion (top and bottom pressure). Courtesy of Dorst America

Another interesting variation, particularly for the compaction of fragile cermets, is provided by the so-called anvil press (Fig. 2b). In this method, the powder is pressed against the anvil by the upward motion of a single lower punch. The anvil is then laterally removed to allow ejection of the compact by the continued upward motion of the punch. Because this cold-pressing technique is a single-action pressing method, an anvil press is acceptable only for relatively thin single-level pieces. Yet, where applicable, the anvil press saves tool costs; in addition, it reduces the ejection path to a minimum, which is an important factor for fragile cermets.

Medium-to-large rectangular pieces are compacted on hydraulic presses in multiple-section dies held together by powerful steel frames. These frames are capable of counteracting the large internal forces that are exerted on the powder mass and transmitted radially to the die sections. Often, at the completion of the cycle, the dies are opened for the careful removal of the fragile cermet compact.

For round pieces it is preferable to use double-action hydraulic presses with a built-in ejection action. These presses can use either one of the two ejection methods:

- If the die is mounted on a hydraulically activated floating platen, a single-action press will adequately provide the effect of a double-action press; in this case, ejection is accomplished by the withdrawal method.
- When a full-power double-action hydraulic press is available (obviously a heavier and more expensive machine than the single-action press), the die can be mounted on the stationary platen. The compact is ejected by raising the lower punch to the level of the die table at the completion of the pressing cycle.

Cold compaction of simple cermet shapes gives generally good results when using adequately lubricated powder mixtures, well-designed tooling, and sturdy presses. Even though the compacts are fragile, they should nevertheless be firm, have adequate green strength and well-formed edges, and be free of laminations or other internal defects. Depending on the composition of the cermet, compaction problems can arise that require modifications in the equipment or the process. Generally, the higher the proportion of the hard phase, the greater the difficulties that arise in compaction; these difficulties may not be evident until after sintering. Also, more problems can be expected with iron-, nickel-, or cobalt-base cermets than with the softer, more malleable aluminum-base compositions. Larger pieces, as measured both in diameter and height, intensify the problems associated with composition. Air entrapment, bridging, laminations, intermittent voids, and variable density throughout the compact are just a few of the problems encountered in the cold compaction of cermets (Ref 7).

Some of these problems can be overcome by adding more lubricant to the mixture, by increasing the taper of the compacting die, or by slowing down the compaction process. Die wall lubrication between pressings often helps to eliminate compaction or ejection problems. Adequate preloading of the die and die lapping in the pressing direction are other precautions that help to overcome problems.

Even for the simplest forms, such as cylindrical or rectangular single-level blanks, not all problems encountered can be solved by the conventional static cold-pressing technique. This is one reason why P/M specialists depend heavily on other, more sophisticated forming processes for the fabrication of a wide variety of products.

Cold Hydrostatic Pressing. High-quality cermet compacts require uniform densification throughout. This can be ideally accomplished by cold hydrostatic pressing. In this method, pressure is applied simultaneously and uniformly from all sides toward the center of gravity of the powder mass while all friction of powders against the die wall is completely eliminated. In order to compact simple or even relatively complex shapes by this method, dry powders are filled into a pliable mold. The powders are settled, and air is removed on a vibrating table; the mold is then sealed and placed into a reinforced steel cylindrical vessel filled with a fluid. After the vessel is closed, hydraulic pressure is built up, thereby compressing the powder contained in the mold. The two hydrostatic pressing methods frequently used for pressing cermets are the wet-bag method and the dry-bag method.

The wet-bag method involves placing one or more powder-filled molds inside a hydrostatic pressing vessel (Fig. 4). The powder-filled mold is pliable and is placed within a perforated container for support. Inside the vessel, the powder-containing mold is completely surrounded by hydraulic fluid. Depending on the size of the vessel and the individual mold, often a number of molds can be placed in the vessels and compacted simultaneously. The entire process--loading the vessel with one or several molds, building up and holding the pressure, releasing the pressure, and reopening and unloading the vessel--is relatively slow. Moreover, filling the mold, assembling the mold, loading the molds into the pressure vessel, and unloading and removing the pressed piece after completion are slow, manual processes that require meticulous attention to detail.

Fig. 4 Schematic of a cold hydrostatic vessel with a wet-bag powder mold. Source: Ref 7

Dry-bag pressing uses a flexible mold that is permanently sealed in the pressure vessel (Fig. 5). After the mold cavity has been filled with a controlled quantity of powder, the cover plate is closed, and hydraulic pressure is applied. After the pressure is released, the molded piece is removed, and a new cycle commences. Dry-bag pressing is a much faster production process than the wet-bag method and lends itself to automation. Much of this technology has been developed for producing near-net shape ceramic pieces, for example, automotive spark plug bodies. Each dry-mold setup requires special engineering and development (Ref 8).

Fig. 5 Schematic of dry-bag hydrostatic pressing equipment. Courtesy of Olin Energy Systems

Advantages and Disadvantages. Hydrostatic pressing offers the following advantages (Ref 7):

- Pressed cermet pieces have a uniform density regardless of size and shape.
- Wet-bag method is well suited for large pieces and often is the only practical method for pressing such pieces.
- Slender pieces with high ratios of length to cross section are feasible.
- Mold cost is low compared to that of rigid compacting dies. Low production quantities can thus be economically produced, especially by the wet-bag method.
- Undercuts and varying cross sections are feasible with either the dry-bag or wet-bag method.
- Little or no lubricant is required.
- The process is well suited for research and development work.

The disadvantages of hydrostatic pressing are:

- Dimensional control of compacts is limited. Mold design must accommodate the radial and axial shrinkage caused by hydrostatic pressing as well as the shrinkage that occurs during subsequent sintering.
- Surfaces of compacts are less smooth than those of die-pressed pieces.
- A high liquid-phase sintering step or encapsulation is necessary before hydrostatically pressed cermet pieces can be densified by hot isostatic pressing.
- Equipment cost is high, and equipment utilization can be low.
- Labor cost is relatively high.

For difficult-to-press cermet compositions with high loading of the hard phase and/or relatively hard metal and alloy binders, cold hydrostatic pressing often is a convenient production method; sometimes it is the only reliable method for working with certain compositions.

Warm Extrusion of Cermet Powder Mixtures. The process of warm extruding cemented ultrafine carbide powder with an admixture of plasticizers has been known for many years. It is successfully used for cermets as well as for forming simple prismatic shapes that have a high ratio of length to cross sections. Cylindrical and triangular shapes and other cross sections can be readily extruded; even tubes are feasible (Ref 9).

Depending on the plasticizer used (for example, polystyrene with an admixture of diphenyl and diphenyl-ether), extrusion requires a temperature somewhere between 160 and 175 °C (320 and 350 °F). Slow and complete debinding under vacuum prior to high sintering is critical in order to avoid distortion, cracking, or microporosity. Screw extruders similar to those used in the plastics industry are adapted to this process (Fig. 6). For the production of a high-quality product, hot isostatic pressing is recommended.

Fig. 6 Warm extrusion of cermet powder mixtures. Courtesy of Dorst America

Power rolling (roll compacting) is a well-known forming process in conventional powder metallurgy that may find application in cermet production. In this process, cermet powder mixtures are fed from a hopper into the gap of a rolling mill and emerge as a continuous strip or sheet. While the horizontal arrangement of the rolls is most convenient for feeding the powder from the hopper into the roll gap (Fig. 7), the vertical arrangement is preferable for feeding the emerging fragile strip horizontally into a series of subsequent operations. The vertical arrangement requires more carefully engineered devices for feeding the powder uniformly into the roll gap (Ref 7).

Fig. 7 Schematic of powder rolling with saturated feed and horizontal roll arrangement. Compression ratio, h_0/h_g . Source: Ref 7

In contrast to the starting material in slab rolling, the loose powder used in powder rolling has no strength before entering the roll gap and must flow freely or be forced into the gap. During the roll compacting process, the density and physical properties of the powder mixture change. For cermet powder compositions, the feasibility of roll forming a strip of sufficient density and strength depends upon a number of factors, including, but not limited to, the roll diameter and speed, the degree of loading of the cermet mixture with hard-phase substances, the ductility of the metallic phase, and the amount of plasticizer added to the mixture. The presence of the hard component adds to the friction of the powders against the roll and to the internal friction of the powder mixture during the compacting step. This is a favorable characteristic of cermet powders for roll forming; however, it is offset to some extent by the inherently low green strength of the resultant sheet or strip.

The sheet thickness that can be compacted with a given diameter roll is quite limited. A ratio of roll diameter to strip thickness between 600 to 1 and 100 to 1 seems to be the range for various metal powders (Ref 7). It is reasonable to assume that the middle-to-lower range applies to cermets. Special devices are required to prevent the powders from flowing laterally out of the roll gap. A uniform flow of powders over the entire width of the roll is essential for obtaining uniform density in the roll-formed strip. Edge cracking can occur, particularly with heavier strips. An optimum strip thickness has to be established experimentally. Thicker strips are too stiff to be coiled, and thinner ones are too fragile.

Rolling speed is another variable that can only be optimized through experimentation with a given cermet powder composition. Pure metal powders without hard phase have been roll compacted at speeds of 30 m/h (100 ft/h). It remains to be seen whether an output anywhere near this order of magnitude can be obtained with cermets.

A complete powder-rolling line for continuous operation includes debinding and sintering furnaces, rerolling stands, and, if necessary, one or more reannealing furnaces. Up-coiling equipment is needed at the end of the line. This equipment constitutes a major capital investment that is warranted only by a large and continuous demand for the product. Although labor costs for such an operation are low, it may be some time before this line production method finds applications in cermets. A simpler arrangement (Fig. 8) is feasible if, after a debinding step (not shown) and continuous atmosphere

sintering, a product emerges of sufficient strength and ductility to permit upcoiling. Roll-compacting arrangements have been proposed for producing a sandwich-type strip consisting of two layers of different compositions.

Fig. 8 Powder rolling process with strip reeled into individual rolls after first sintering treatment. Source: Ref 7

Slip casting, a method for forming metal powders into a desired shape, follows a technique that has been used for ceramics for a long time. This method uses an aqueous suspension of cermet powders (the slip) that is poured into a porous plastic mold. The liquid is absorbed by the mold, and the powder is deposited on the mold wall. In the case of hollow shapes, the excess slip is drained off after the deposit reaches the required wall thickness; for solid parts the slip must remain and slowly dry.

The water-base slip has low viscosity in order to facilitate pouring, yet it should be stable during standing in order to avoid demixing. Demixing can be a serious problem with cermet powders, particularly those having a substantial difference of specific weight between the hard phase and the binder metal; it can lead to differences in composition and properties from one end of a cermet part to another. Variations in composition can lead to cracks during drying or subsequent sintering. In order to control the viscosity of the slip at the optimum level, it is generally necessary to use a deflocculant and to control the pH. After slow drying, the slip cast part needs a debinding step followed by high sintering. The resultant part has a higher density than the tap density of its original powder mixture. The fine powders that frequently are used to facilitate slip casting can lead to superior properties in the sintered part (Ref 7).

Slip casting and mold making together are more art than technology. They require knowledge of parameters such as slip viscosity and suspension stability, wetting agents and deflocculants, and slip-mold interaction and mold release. Other important parameters are wall-building rate and casting crack formation. Slip casting requires only a small investment; however, it is labor intensive and is not well suited for mass production. At the present state of technology, cermet parts of a certain complexity are more likely to be suitable for injection metal molding than for slip casting. The former process is more capital intensive, but it is better suited for a medium-to-large production volume.

The P/M injection molding (MIM) process has evoked a great deal of interest since it was first developed in the early 1970s. Commercialization has been slow, mostly because of the long cycle that is required from concept to the point of shipping acceptable parts to a customer. Intensive research and application engineering continues in many laboratories, and more rapid growth is expected in the future (Ref 10, 11).

On a laboratory basis, cermet parts have been made by this process, and its commercialization is underway, particularly in the field of cemented carbides. However, the bulk of current MIM experience is in the area of structural ferrous and nonferrous parts.

The powder injection molding process for cermets (Fig. 9) involves mixing and blending the ingredient metal and hard-phase powders with a suitable polymer binder and then granulating the mixture. The granulated product is heated and injection molded under pressure. The polymer imparts viscous flow characteristics to the mixture to aid in forming, mold filling, and uniform packing. After demolding, the binder is removed, and the remaining cermet structure is densified by sintering and, perhaps, by hot isostatic pressing (Ref 10).

Fig. 9 Mold and injection mechanism for the MIM process. Source: Ref 10

Binder compositions and debinding techniques are the main differences among the various MIM processes. There is no universal binder. A primary requirement of the binder is that it allow flow and packing into the mold cavity. It must wet the powder, and it should be designed to minimize debinding time and defects. A multiple-component binder that is not chemically intersoluble allows for progressive extraction in debinding. As one compound is removed and the pores partially opened, the remaining binder holds the particles in place and maintains the shape of the compact. The remainder then vaporizes through the open pores without generating an internal vapor pressure that might cause compact failure. Waxes with additives are most frequently used as binders. The phases of the molding operation are:

- Clamping and filling of the mold
- Maintaining pressure while the compact becomes solid
- Retraction of filling mechanism
- Opening of the mold and ejection of the compact

Mold filling depends on the viscous flow of the feedstock into the mold cavity. The viscosity depends on temperature, shear rate, binder chemistry, powder interfacial chemistry, and loading (Ref 10).

Thermal debinding is the most frequently used technique, but capillary wicking and solvent extraction can also be considered as an alternative method. Complete debinding is required before commencing the sintering cycle. Most cermets require a liquid-phase sintering cycle to achieve complete densification of the compact. A modern furnace that combines debinding, high-vacuum sintering, and a final pressure-sintering cycle can accomplish all of these steps economically.

Applications and Advantages of the MIM Process for Cermets. In recent years, major progress has been made in using the MIM process for the production of heat engine components, military hardware, computers, and aerospace and automotive components. The powder injection molding process offers new opportunities in advanced materials manufacturing (Ref 11), and it offers potential advantages for use in cermet manufacturing technology. General aspects of applying the MIM process in cermet manufacturing include:

- In principle, the MIM process is applicable to cermets without modification of the injection molding machines or the typical mold designs (Fig. 9).
- The production of small- to medium-size complex shapes by the MIM process is feasible, provided that the geometry of the shapes allows for demolding. When this requirement is met, multiple levels, reentrant angles, and undercuts can be accommodated.
- On small parts, tolerances of $\pm 3 \mu\text{m/mm}$ (0.003 in./in.) after sintering can be obtained on conventional P/M parts with the MIM process. Larger tolerances would be needed on cermets to allow for shrinkage when liquid-phase sintering is needed for complete densification.
- Small runs (of as few as 2000 parts) are feasible for conventional P/M parts. Because of the higher price level of cermets and the relatively high cost of competitive forming techniques, runs of similar or even smaller size could be economically attractive for cermet parts produced by the MIM process.
- With proper debinding techniques and a liquid-phase sintering cycle (perhaps followed by hot isostatic pressing), high-quality parts with good physical properties could be produced by the MIM process.
- Excessive mold wear caused by the hard phase during the injection molding of a cermet composition, particularly one with high loading, does not seem to be a serious problem in the MIM process. Future experience will demonstrate if such a mold wear problem exists and to what extent it affects the economics of using the MIM process for cermets.

Cermet Sintering and Consolidation

Sintering. Not all cermets require liquid-phase sintering, but the majority use this process to convert the green compacts into solid, strong, and dense products. Sintering temperatures depend entirely on the ceramic-metal system involved and on the choice between solid- and liquid-phase sintering. Typical temperatures range from 850 to 1050 °C (1560 to 1920 °F) for products that contain a bronze, silver, or copper metal matrix; 1300 to 1500 °C (2370 to 2730 °F) for cemented carbides and borides; and 1700 to 2200 °C (3100 to 4000 °F), or even higher, for certain ceramic oxide-base cermets.

For applications requiring fine machining and grinding, as in many cemented-carbide parts and tools, presintering is performed at 1000 to 1100 °C (1830 to 2010 °F) to bond the metallic contact points and give enough green strength to the body so that it can withstand rough machining. Allowance is made for the substantial shrinkage that occurs during subsequent sintering.

Depending on the green density, cermet compacts can shrink during liquid-phase sintering by as much as 18 to 26% linear (45 to 60% by volume). In systems with good sinterability, virtually all porosity is eliminated (Ref 12).

During all sintering processes, particularly during the liquid-phase process, many complicated metallurgical phenomena take place that depend on temperature, furnace atmosphere (hydrogen, inert gas, or vacuum), and the dynamics of the particular ceramic-metal system. For example, metals change into alloys; the hard phase partially dissolves in the liquid phase and changes the composition of the latter phase; portions of the liquid phase can diffuse into the hard phase; and reprecipitation of some elements dissolved in the liquid phase can take place during the cooling portion of the cycle. Also, if carbon is present in the furnace atmosphere (perhaps from the furnace furniture), it will react with oxygen or other elements. The phenomena that occur during the sintering of WC-cobalt systems have been investigated very thoroughly over a long period of time. Ample literature on the basic system and many of its alloy variations is available (Ref 12).

Mechanism of Liquid-Phase Sintering. While not strictly a cermet, the liquid-phase sintering of heavy alloys consisting of tungsten-nickel-copper has interesting ramifications that are applicable to the cermet field (Ref 7). This liquid-phase sintering process includes these principal features:

- The hard phase is partially soluble in the liquid phase during sintering. At temperature, the liquid phase is limited so that the compacts keep their shape.
- The sintering temperature must be high enough so that an appreciable amount of liquid phase is present. When these conditions are met, densification takes place.
- The finer the particle size of the hard phase is, the more rapid and complete the densification of the compact is.
- Final density is independent of the compacting pressure. To reach theoretical density, compacts pressed at low pressure will shrink correspondingly more than those pressed at high pressure.
- The microstructure will show grain growth when compared to the particle size of the original hard-phase powder. This grain growth can be appreciable and is dependent on the sintering time and temperature.

When the original hard-phase particles are angular (for example, titanium carbide), they can become rounded during the sintering process. However, this is not always the case because some angular hard substances (for example, tungsten carbide) seem to possess shape memory. During the reprecipitation of dissolved elements from the liquid phase during cooling, angular contours reappear on the hard-phase particles of these substances.

Furnaces. Continuous high-temperature sintering furnaces have been used in the cemented-carbide and refractory metal industries for many years. They are equipped with a hydrogen or protective atmosphere with a low dew point to reduce residual oxygen in the compacts and to prevent oxidation. Continuous pusher-type furnaces equipped with silicon carbide or molybdenum heating elements have been particularly successful and are used for sintering a large volume of small parts. Batch-type vacuum furnaces have become very popular in the last 30 to 40 years. When there is a choice between pusher-type continuous furnaces and batch-type furnaces, the equipment and operating costs favor the former.

In a typical operation, the parts are laid out without packing on graphite plates that are stacked with spacers within the furnace. When direct contact between the graphite and the compacts is undesirable, the plates are lined with an inert ceramic. It is essential to use vacuum equipment when highly reactive powder mixtures are sintered. The optimum level of vacuum to be reached during liquid-phase sintering varies greatly depending on the hard-phase binder system being treated. Several advanced furnace designs provide for initial operation using a hydrogen atmosphere, with a switch to vacuum at a later stage in the sintering cycle. Others provide a pulsating cycle of hydrogen pressure alternating with vacuum.

Static Hot Pressing. Hot pressing is a cermet production method in which the pressure and temperature are applied simultaneously. The powder mixtures are either compacted directly in the hot press mold or prepressed cold in dies and then transferred to the hot press tools of the pressure-sintering furnace. Pressures are considerably lower than for the cold press method. They can range from deadweight loads up to 3 MPa (500 psi) for pressure sintering (of friction elements, for example), or from 10 to 35 MPa (1500 to 5000 psi) for hot pressing; the lower end of the hot-pressing range applies to liquid-phase systems.

Sintering temperatures are reached by induction or resistance heating of the mold, or by direct induction or resistance heating of the powder compact. In the former case, the mold material consists of graphite. This is the more practical process because usually no controlled atmosphere supply is required. The latter method requires ceramic molds, which are sensitive to thermal shock, break easily on product removal, and are costly to produce accurately to the dimensions of the mold opening. The advantage of direct compact heating--that the tooling and surrounding area can remain cool--can be offset by a temperature gradient and the resulting microstructure segregation effects in the product. For most systems with readily oxidizing metal matrices, a controlled atmosphere is required.

The densification effect of conventional static hot pressing is more pronounced than the effect that can be achieved by cold pressing and subsequent sintering. Heating the cermet powder mixture increases its plasticity and produces larger areas of inter-particle contact. The surface shearing action that occurs during the process mechanically disrupts surface oxide films and generates clean bonding surfaces (Ref 13). Shape limitations are similar to those for static cold pressure. Prismatic single-level pieces that have no undercuts or re-entrant angles are preferred; however, shallow details in the punch faces are acceptable. Very large pieces are well suited for this process.

A typical graphite induction-heated vacuum furnace (Fig. 10) with graphite tooling is capable of double-action hot compacting or repressing of a 125 mm (5 in.) diam billet at pressures up to 90 Mg (100 tons) and temperatures up to 2300 °C (4200 °F) in a high-vacuum or controlled atmosphere. The fully pressed compact is ejected from the die while still hot to reduce cooling time, minimize sticking, and prolong mold life. Items produced in this type of furnace include WC-Co draw dies and friction elements, Al-B₄C billets, stable oxide components, and some boride-base cermets.

Fig. 10 Production-scale 225 Mg (250 tons) vacuum hot press. Courtesy of Vacuum Industries, Inc.

Among the various cermet production processes, static hot pressing in such a furnace is the only reliable single-step method for producing a fully dense, high-quality, near-net shape compact from a cermet mixture. However, graphite die life is limited, and cermet compositions that do not react with graphite are preferred. In order to avoid a cermet-graphite reaction, ceramic molds can be used for hot pressing, although they are more fragile and costly than cermet molds. The complete hot press setup (including a vacuum system or atmosphere generator power system, hydraulic system, controls, and instrumentation) is expensive. In addition, static hot pressing is labor intensive because products are pressed one at a time. Therefore, hot isostatic pressing may be more appropriate for many sensitive high-temperature consolidation tasks involving small- and medium-size pieces. For large and very large pieces, vacuum hot pressing is often used because large equipment is readily available (Ref 14). For example, Fig. 10 shows a 225 Mg (250 ton) vacuum hot press with double-action bottom rams and a 1070 mm (42 in.) square platen; the press has a maximum operating temperature of 1315 °C (2400 °F).

Hot isostatic pressing (HIP) has become increasingly popular as a means for producing carbide-base and other cermets of very high and uniform density. Internal flaws and micro- or macroporosity are virtually eliminated in the resultant product. Isostatic pressing is a batch process accomplished in water-cooled pressure vessels capable of withstanding internal pressures of up to 210 MPa (30 ksi). Heating up to a temperature of 1600 °C (3000 °F) is achieved with a high-frequency or resistance furnace mounted inside the pressure vessel. The pressure medium is an inert gas, usually argon. The pressure medium can also be helium (Ref 8), which at the pressure employed (100 to 150 MPa, or 15 to 20 ksi) has a density close to that of water.

Hot isostatic pressing was originally developed for use in gas pressure-assisted diffusion bonding processes such as the encapsulation of nuclear fuel elements (uranium oxide, for example) in a zircaloy sheath. This was soon followed by applications such as powder consolidation and densification of difficult-to-sinter substances and cermet composition (Ref 13). Hot isostatic pressing is most successfully applied in the cemented-carbide industry and in the manufacture of steel-bonded titanium carbide. Notwithstanding the ease with which these cermets sinter to high density, they often have slight localized porosity in the range up to 50 μm; on occasion they have voids in the range from 0.25 to 2.5 mm (0.01 to 0.1 in.) caused by random or accidental contamination.

Hot isostatic pressing is an improvement over static hot pressing in that it eliminates the need for costly and highly perishable molds. However, before compacts are submitted to isostatic pressing, they need to have a sufficiently dense structure (at least at the skin) to inhibit gas penetration. Compacts with lower density and interconnecting pores require a gas-tight encapsulation of some sort before being treated. Three methods are in common use to accomplish this encapsulation (Ref 13). In the first method, compacts are formed and sintered to 95% or more of theoretical density, and the resultant continuous, dense surface structure acts as an impenetrable envelope to the high-pressure gas. Alternatively, the density is raised to a sufficiently high level that no interconnecting porosity remains within the compact. This method is used primarily for small- and medium-size pieces.

The second method involves a steel can that is prepared in accordance with the desired form of the compact. The can is filled with a powder mixture that is densely packed by vibration or pressing. (A cold-compacted or hydrostatically pressed piece could be encapsulated in the steel can instead of the powder mixture.) After loading, the can is closed tightly by welding and then evacuated. This method is most commonly used for medium- and large-size pieces, in situations where the additional cost of a perishable can is economically bearable.

The third method is the Ugine-Sejournet process, in which vitrified glass is used to encapsulate the compact. This method may be more economical than the steel can method.

None of the methods for preventing the high-pressure gas from penetrating the compact are inexpensive. Fortunately, the HIP process is flexible enough to allow for the simultaneous hot isostatic pressing of a number of freestanding or encapsulated compacts. The process cost can be apportioned according to the volume occupied by each piece in the available furnace space.

The cemented-carbide and P/M products that undergo HIP processing are of substantially higher quality than those produced by any other process. The higher quality is a result of the near theoretical densities produced by HIP processing. Pieces with near theoretical densities have high strength levels and reliable physical properties. Hot isostatic pressing is a capital-intensive batch process; when the encapsulation method is used, it is labor intensive as well.

Hot extrusion of cermet billets is unique among the various cermet processes because it is essentially a solid-state process. All of the other previously discussed densification processes involve a liquid phase. During hot extrusion of powdered material, large hydrostatic compression forces occur. A unidirectional force component first compresses the powder material to full density and then forces the material through the die. Depending on the configuration of the front surface of the extrusion die, a large shear component can absorb as much as one-half of the total energy needed for extrusion. The total amount of one-step deformation (ratio of the cross section of the billet to the cross section of the die opening) is much larger than in any other cermet hot-working process.

Hot extrusion is an attractive forming and densification process for cermets. Unfortunately, its application in this broad field has serious limitations caused by the loading of the nonmetallic material, the choice of the metallic component, and the degree of interaction between the two substances. Precise limitations on the volumetric amount of nonmetallic substance have not been established, but when this substance exceeds about 18 to 25 vol%, the composite material exhibits hot shortness to such an extent that the problems of edge cracking, internal lamination, and distortion of the extruded product become intolerable. When the nonmetallic phase occurs in the form of very fine powders, the hot shortness problems are aggravated; they are also aggravated when the nonmetallic substance interacts with the metallic component at the extrusion temperature to form new phases or eutectoids. How to deal with these complex problems for each particular pairing of cermet components is beyond the scope of this review. A careful study of the constitution diagram of the binder metal and the hard phase before undertaking any serious work is recommended.

Like metal alloy billets, cermet billets are much easier to extrude when aluminum or aluminum alloys are used for the metallic components. Billet densification and extrusion occur at lower temperatures and pressures. The expensive canning and decanning process can generally be avoided, as can the use of a protective atmosphere. Moreover, straightening and finishing of the extruded product often can be performed at room temperatures. Defects due to hot shortness in extruded aluminum-base products occur only at higher levels of loading with hard-phase substances.

Compared with cermets containing aluminum or aluminum alloys, cermets with iron, nickel, cobalt, or alloys of these metals as the metallic phase are more technically demanding and more costly to extrude. For example, billet heating and hot

compacting require a controlled atmosphere, billet canning is practically unavoidable, and a glass process is required for lubrication and reduction of die wear. Postextrusion finishing, such as the removal of can material, straightening, finish rolling, and so on, also requires more costly processes. The extruded cermet product can be expected to be harder, stiffer, less malleable, and more brittle than the metal binder component. Because of the higher extrusion temperature, metallurgical interaction between the matrix metal or alloy and the hard-phase cermet component is far more likely to occur, particularly if the hard phase cermet component is a nonmetallic compound of the carbide or boride group. Oxide-base hard-phase components are less likely to interact with the metallic component.

The undesirable interaction between the hard substance and the metallic component of the cermet is easier to control with the solid-state extrusion process than with any densification process involving a liquid phase. Also, in spite of the aforementioned limitations and problems, hot extrusion continues to attract the attention of product development engineers as a possible production method for certain cermets, particularly those with an aluminum base. It has the potential to be a relatively low labor cost, yet capital-intensive, mass-production process for high-technology rod or strip material.

Combination Sintering-Compacting. Combination debinding, sintering, and pressure consolidation furnaces have been developed in an attempt to simplify the manufacturing process for cermets and similar products. As stated before, a debinding step is essential before sintering green products that contain admixed lubricants, organic binders, or plasticizers. These additives are needed in varying proportions for static cold pressing, warm extrusion, powder roll compacting, slip casting, and injection metal molding of cermets. After debinding and during liquid-phase sintering, the green compacts shrink to nearly complete density. When densification progresses to the point that pressurized gas can no longer penetrate into the compact, hot isostatic compacting occurs. Gas compacting the already-sintered dense cermet at high gas pressures and at a temperature near that of liquid-phase formation improves the product quality by eliminating all residual porosity, internal flaws, and defects.

Recent experience with WC-Co compacts has shown that using a lower isostatic pressure of only 2.7 MPa (390 psig) can produce compacts with strength and densification nearly equal to those of compacts produced by the high-pressure HIP process (Table 3). Based on these findings, multimode single-chamber pressure furnaces have been developed that are capable of operating in vacuum, with partial pressure, and with positive gas pressure up to 10 MPa (1500 psig); the furnaces operate at temperatures between 1450 and 2200 °C (2640 and 3390 °F) (Ref 15).

Table 3 Comparison of transverse rupture strength for various cemented carbides after hot isostatic pressing and pressure sintering

Processing method	Density		Hardness, HRA	Transverse rupture strength	
	g/cm ³	lb./in. ³		Mpa	ksi
6% cobalt					
Vacuum sintering	14.87	0.537	91.6	2180	316
Vacuum sintering and HIP	14.90	0.538	91.9	2645	384

Pressure sintering	14.11	0.510	90.8	2565	372

This new furnace concept of combining three operations in one cycle offers several advantages over separate sintering and hot isostatic pressing operations:

- Debinding, sintering, and densification under pressure take place in one cycle and in a single vessel.

- During the various stages of the process, the compacts do not come in contact with air.
- Controlling the cycle with an electronic microprocessor ensures automatic operation and a high degree of program reproducibility (Fig. 11).
- Transfer of parts from one process step to another is avoided, saving labor cost and process time.
- Combining processes saves energy.

Infiltration is a process that is similar to liquid-phase sintering, except that the solid phase is first formed into a porous skeleton body, and the liquid-metal phase is introduced during sintering from the outside and allowed to penetrate the pore system. Excessive shrinkage associated with in situ liquid-phase sintering is avoided, and dimensional stability of the product is obtained, except for about 1% growth that is due to a thin surface film formed by the liquid metal.

This technique is used for systems of two or more components that have widely differing melting temperatures. Aside from hot pressing, infiltration is the only powder processing method that can obtain essentially full density of a near-net shape. All of the other densification processes involve substantial shrinkage and thus destroy shape and dimensional accuracy. By machining, hydrostatic pressing, or powder injection molding the skeletal preforms prior to infiltration, complexities in part design, such as undercuts, re-entrant angles, and multiple levels, can be realized to an extent not possible in parts of comparable high density that are made by extrusion or hot pressing. The other unique feature of infiltration is that--under suitable conditions of low contact angles and limited solubilities between the high- and low-melting phases-- systems of completely intertwined continuous networks can be obtained. This is of considerable importance for making products that must combine high thermal or electrical conductivity with acceptable levels of strength and abrasion or erosion resistance.

The procedure used for TiC cermets involves two steps (Ref 17). First, an approximately 60% dense carbide skeleton body of near-net shape is formed by mixing the TiC powder with a small percentage of nickel binder and wax, cold pressing the mixture at about 35 MPa (5000 psi) into a slab, vacuum sintering the slab at about 1300 °C (2370 °F), and then machining the contour (for example, a turbine blade). The second step consists of inserting the skeleton shape into a mold assembly that contains the metal in a ceramic tundish on top and provides for the gravity feeding of the liquid to the skeleton at the preferred contact faces (Ref 18).

The mold assembly is made of graphite, and its cavity is lined with a refractory ceramic in powder form that interfaces with the TiC skeleton. The ceramic liner is chosen so that it does not react with the titanium carbide up to infiltration temperature and also so that it shrinks at a controlled rate, permitting the formation of a uniform gap all around. The mold assembly is heated in a vacuum furnace to about 1400 to 1500 °C (2550 to 2730 °F), well above the melting temperature of infiltrating alloys, such as 80Ni-20Cr and 70Co-24Cr-6Mo. During infiltration, the liquid metal first fills the gap between the liner and the skeleton exterior by capillary forces and then penetrates the interior of the porous TiC part. After furnace cooling, the fully infiltrated product can be readily extracted by fragmenting the sintered ceramic liner without degrading the graphite mold assembly, which can be reused.

Graded cermet parts can be produced by varying the density of the TiC skeleton through the use of a special die filling and multiple-step pressing. For example, a turbine blade can be made that has a high concentration of titanium carbide and, therefore, high strength at the center of the foil and in the transition to the root. The turbine blade also has a metal-rich jacket around the foil and especially at the mechanical shock-sensitive blade edges, as well as around the serrated root needed for blade attachment to the turbine disk.

The infiltration process has been successfully applied to other cermet systems; it has been especially successful when used with interfacial reactions. An example of such an application is the production of complex ceramics that are reinforced by microscopic-size platelets of another compound and bonded by a third species (Ref 19). The preformed ceramic is a metalloid carbide, the binder is a relatively high-melting reactive metal, and the platelets are the reaction product of the carbide and binder. The unique composite microstructure of such a platelet-reinforced ceramic is obtained by gravity infiltration of the molten metal into a porous preform or bed of the carbide. In the case of a B₄C ceramic and a zirconium metal infiltrant, controlled oxidation at the contact faces produces a new phase, ZrB₂, that precipitates abundantly in the form of platelets that reinforce the ceramic. A similar result is achieved with SiC preforms or fillers that are infiltrated with molten aluminum metal under oxidizing conditions; the reaction product in this case is Al₂O₃ (Ref 19).

The container or mold used in the infiltration process is made from graphite, and it is shaped in accordance with the configurations of the desired product; the process is conducted in an argon atmosphere. The infiltration and reaction temperature depends on the melting point and liquidity of the metal. It can be as high as 2000 °C (3630 °F) in the system involving zirconium. The time to complete penetration and reaction is in the 1 to 2 h range, and the end product typically contains 5 to 15% residual binder metal. The platelet-reinforced infiltrated ceramic system of the type ZrB₂/ZrC_x/Zr exhibits a good combination of high strength, high fracture toughness, and high thermal conductivity. This combination makes it an interesting candidate material for rocket engine components and wear parts (Ref 20). Other systems that have been successfully produced or are potentially workable by the infiltration process include TiB₂ ceramics combined with nickel as second phase (Ref 21), TiC with steel (Ref 22), WC with cobalt (Ref 23), AlN with aluminum (Ref 24), and Al₂O₃ with aluminum (Ref 25).

Infiltration processing of boron carbide and boride-reactive metal cermets has also been used successfully in the development of high-strength, hard, and lightweight products that offer an interesting combination of toughness with high thermal and electrical conductivity (Ref 26). The process involves the infiltration of molten reactive metals, particularly aluminum, into chemically treated boron carbide, or it can use metal-boride starting constituents, such as powders or low aspect ratio fibers, that have been consolidated into a porous ceramic precursor sponge. This process is an alternative to the infiltration of the molten aluminum into thermally modified precursor sponges. Conventional or colloidal chemistry is used in the chemical reaction-controlled casting and infiltration procedures. The potential also exists for consolidating the precursor sponges by injection molding in either a single-step or a two-step process. The key to the process lies in controlling the surface chemistry of the starting constituents. In the two-step process, the first step is the production of highly configured geometries that can be molded by using chemically pretreated binders. In the second step, the binder is volatilized from the precursor, leaving it as a skeleton ready for infiltration.

Cemented Carbides

Cemented carbides belong to a class of hard, wear-resistant, refractory materials in which the hard carbide particles are bound together, or cemented, by a soft and ductile metal binder. These materials were first developed in Germany in the early 1920s in response to demands for a die material having sufficient wear resistance for drawing tungsten incandescent filament wires to replace the expensive diamond dies then in use. The first cemented carbide to be produced was tungsten carbide (WC) with a cobalt binder. Although the term cemented carbide is widely used in the United States, these materials are better known internationally as hard metals.

Tungsten carbide was first synthesized by the French chemist Henri Moissan in the 1890s. There are two types of tungsten carbide: WC, which directly decomposes at 2800 °C (5070 °F), and W₂C, which melts at 2750 °C (4980 °F). Early attempts to produce drawing dies from a eutectic alloy WC and W₂C were unsuccessful, because the material had many flaws and fractured easily. The use of powder metallurgy techniques by Schroeter in 1923 paved the way for obtaining a fully consolidated product. Schroeter blended fine WC powders with a small amount of iron, nickel, or cobalt powders and pressed the powders into compacts, which were then sintered at approximately 1300 °C (2400 °F). Cobalt was soon found to be the best bonding material. Over the years, the basic WC-Co material has been modified to produce a variety of cemented carbides, which are used in a wide range of applications, including metal cutting, mining, construction, rock drilling, metal forming, structural components, and wear parts. Approximately 50% of all carbide production is used for metal cutting applications.

This section discusses the manufacture and composition of cemented carbides and their microstructure, classifications, physical and mechanical properties, and applications. The current status of cemented carbides in nonmetal cutting applications will also be covered.

Manufacture

Cemented carbides are manufactured by a powder metallurgy process consisting of a sequence of steps in which each step must be carefully controlled to obtain a final product with the desired properties, microstructure, and performance. The steps include:

- Processing of the ore and the preparation of the tungsten carbide powder
- Preparation of the other carbide powders
- Production of the grade powders
- Compacting or powder consolidation
- Sintering
- Postsinter forming

The sintered product can be directly used or can be ground, polished, and coated to suit a given application.

Preparation of Tungsten Carbide Powder. There are two methods by which tungsten carbide powders are produced from the tungsten-bearing ores. Traditionally, tungsten ore is chemically processed to ammonium paratungstate and tungsten oxides. These compounds are then hydrogen-reduced to tungsten metal powder. The fine tungsten powders are blended with carbon and heated in a hydrogen atmosphere between 1400 and 1500 °C (2500 and 2700 °F) to produce tungsten carbide particles with sizes varying from 0.5 to 30 μm. Each particle is composed of numerous tungsten carbide crystals. Small amounts of vanadium, chromium, or tantalum are sometimes added to tungsten and carbon powders before carburization to produce very fine (<1 μm) WC powders.

In a more recently developed and patented process, tungsten carbide is produced in the form of single crystals through the direct reduction of tungsten ore (sheelite) (Ref 27). The ore is mixed with iron oxide, aluminum, carbon, and calcium carbide. A high-temperature exothermic reaction ($2\text{Al} + 3\text{FeO} \leftrightarrow \text{Al}_2\text{O}_3 + 3\text{Fe}$) at about 2500 °C (4500 °F) produces a molten mass that, when cooled, consists of tungsten carbide crystals dispersed in iron, and a slag containing impurities. The crystalline WC (Fig. 2) is then chemically separated from the iron matrix.

Tungsten-titanium-tantalum (niobium) carbides are used in steel-cutting grades to resist cratering or chemical wear and are produced from metal oxides of titanium, tantalum, and niobium. These oxides are mixed with metallic tungsten powder and carbon. The mixture is heated under a hydrogen atmosphere or vacuum to reduce the oxides and form solid-solution carbides such as WC-TiC, WC-TiC-TaC, or WC-TiC-(Ta, Nb)C. The menstruum method can be used to produce WC-TiC solid solution. In this method, the individual carbides are dissolved in liquid nickel. Solid-solution carbides are then precipitated during cooling.

Production of Grade Powders. Cemented carbide grade powders may consist of WC mixed with a finely divided metallic binder (cobalt, nickel, or iron) or with additions of other cubic carbides, such as TiC, TaC, and NbC, depending on the required properties and application of the tool. Intensive milling is necessary to break up the initial carbide crystallites and to blend the various components such that every carbide particle is coated with binder material. This is accomplished in ball mills, vibratory mills, or attritors that use carbide balls. The mills are usually lined with carbide sleeves, although mills lined with low-carbon steel or stainless steel are also used.

Milling is performed under an organic liquid such as heptane or acetone to minimize heating of the powder and to prevent its oxidation. The liquid is distilled off after the milling operation. A solid lubricant such as paraffin wax is added to the powder blend in the final stages of the milling process or later in a blender. The lubricant provides a protective coating to the carbide particles and prevents or greatly reduces the oxidation of the powder. The lubricant also imparts strength to the pressed or consolidated powder mix.

After milling, the organic liquid is removed by drying. In a spray-drying process commonly used in the cemented carbide industry, a hot inert gas such as nitrogen impinges on a stream of carbide particles. This produces free-flowing spherical powder aggregates.

Powder Consolidation. A wide variety of techniques is used to compact the cemented carbide grade powders to the desired shape. Carbide tools for mining and construction applications are pill pressed (pressure applied in one direction) in semiautomatic or automatic presses. Metal cutting inserts are also pill pressed, but may require additional shaping after sintering. Cold isostatic pressing, in which the powder is subjected to equal pressure from all directions, followed by green forming, is also a common practice for wear and metal forming tools. Rods and wires are formed by the extrusion process.

Unlike most other metal powders, cemented carbide powders do not deform during the compacting process. Generally, they cannot be compressed to much above 65% of the theoretical upper limit for density. Despite this low green density, carbide manufacturers have developed the technology for achieving good dimensional tolerances in the sintered product.

Sintering and Postsintering Operations. The first step in the sintering process is the removal of the lubricant (dewaxing) from the powder compact. The pressed compacts are normally set on graphite trays coated with a graphite paint. The compacts are first heated to about 500 °C (900 °F) in a hydrogen atmosphere or vacuum using either semicontinuous or batch-type graphite furnaces.

After lubricant removal, the compacts are heated in a vacuum (0.1 Pa, or 10^{-3} torr) to a final sintering temperature ranging from 1350 to 1600 °C (2460 to 2900 °F), depending on the amount of the cobalt binder and the desired microstructure. The dewaxing and sintering operations can also be performed in a single vacuum cycle using furnaces equipped to condense the lubricant and remove it from the heating chamber.

During the final sintering operation, the cobalt melts and draws the carbide particles together. Shrinkage of the compact ranges from 17 to 25% on a linear scale, producing a virtually pore-free, fully dense product.

In the 1970s, the cemented carbide industry took advantage of hot isostatic pressing (HIP) technology, in which vacuum-sintered material is heated again under a gaseous (argon or helium) pressure of 100 to 150 MPa (15 to 20 ksi). The temperatures of this additional process are 25 to 50 °C (45 to 90 °F) below the sintering temperature. The high temperatures and pressures employed in the HIP furnace remove any residual internal porosity, pits, or flaws and produce a nearly perfect cemented carbide.

The latest advancement in sintering technology is the sinter-HIP process, which was developed in the early 1980s (Ref 28). In this process, low-pressure hot isostatic pressing (up to about 7 MPa, or 1 ksi) is combined with vacuum sintering, and the pressure is applied at the sintering temperature when the metallic binder is still molten. With this process, void-free products can be produced at costs only slightly higher than those of vacuum sintering. More information on sintering cemented carbides is in the article "Production Sintering Practices" in this Volume.

Postsinter Forming. A large number of cemented carbide products are shaped after sintering because of surface finish, tolerance, and geometry requirements. This forming operation is both time consuming and expensive. The sintered material is formed with metal-bonded diamond or silicon carbide wheels, turned with a single-point diamond tool, or lapped with diamond-containing slurries.

Machining Applications

The performance of cemented carbide as a cutting tool lies between that of tool steel and cermets. Compared to tool steels, cemented carbides are harder and more wear resistant, but also exhibit lower fracture resistance and thermal conductivities than tool steel. Cermets, on the other hand, are more wear resistant than cemented carbides, but may not be as tough. Any comparison of cermets and cemented carbides, however, depends on the percent of binder material and the type and size of carbide grains. Cermets and cemented carbide cutting tools are described in more detail in Volume 16, *Machining*, of the *ASM Handbook*.

The performance of carbide cutting tools is strongly dependent on composition and microstructure, and the properties of cemented carbide tools depend not only on the type and amount of carbide but also on the carbide grain size and the amount of binder metal. The basic physical and mechanical properties of refractory metal carbides used in the production of cemented carbide tools are given in Table 4. Tungsten carbide and molybdenum carbide have hexagonal crystal structures, whereas the carbides of titanium, tantalum, niobium, vanadium, hafnium, and zirconium are cubic. They undergo no structural changes up to their melting points.

Table 4 Properties of refractory metal carbides

Carbide	Hardness, HV (50 kg)	Crystal structure	Melting point		Theoretical density, g/cm ³	Modulus of elasticity		Coefficient of thermal expansion, μm/m · K
			°C	°F		GPa	10 ⁶ psi	
TiC	3000	Cubic	3100	5600	4.94	451	65.4	7.7
VC	2900	Cubic	2700	4900	5.71	422	61.2	7.2
